Dr. E. N. Brush said that the history of the young woman brings to mind a case which had gone, as Dr. Kerlin says they may do, a little further. The girl not only became a public prostitute, but had passed into a condition of marked insanity. The mental disturbance was as much in the line of moral obliquity as anything else. She was very active in causing mischief among the attendants and other patients at the asylum. At one of the visits of a committee of inspection she trumped up a story that the engineer, the apothecary, and one of the physicians, had come to her room at night and violated her person. She got one old gentleman very much interested in her case, but before he got through with his investigation disgusted him by making a similar charge against him.

Dr. Charles K. Mills believed that the term moral imbecility is a good one to apply to a certain line of cases, as it has a distinctive meaning. From his experience outside of institutions he could give at least a score of cases similar to those described by Dr. Kerlin. In the case of a boy recently seen, there was a distinct history of neurotic conditions and of insanity in other members of the family. Almost all the cases of this kind show a marked element of heredity. The question is not whether or not these subjects have any intellectual aberration at all, but whether or not the moral aberration vastly predominates. If so, we have a right to class these cases with those of moral imbecility and moral insanity.

Dr. James Hendrie Lloyd thought that there is a decided distinction between depravity and insanity. Practically, we never find a case of pure moral lesion. There is always an intellectual defect, and frequently a marked congenital defect of the whole brain organization.

Dr. Kerlin asked if we shall be more grateful to Dr. Lloyd if for the terms moral insanity and moral imbecility he will give us expressions defining any better the conditions which we find in a large percentage of so-called feeble-minded persons, in many of the commitments to Houses of Refuge, and in a larger proportion still of those found in such institutions as the Reformatory at Elmira, New York.

The difference between those who argue for and against moral insanity, is a disagreement about the name, rather than about the existence of a condition accepted by most Germans and many English writers on psychiatry, and supported by Ray, Spitzka, Bannister, and many others in America. During the past few years there seemed to be a growing advance in sentiment among our profession, and in the public mind, with reference to this subject. Dr. Brockway, of the Elmira Reformatory, states that he discovers among his prisoners only six per cent. in whom the moral sense is normal. He prefers to speak of many of his cases as moral imbeciles. It is true that we are using this term for the want of something better; but it certainly defines to the common understanding a class of individuals in whom there is a lack of self-control, a weak volition, and failure in, if not an absence of, the higher elements of a full cerebral development, for which we know no more suitable appellation than moral imbecility.

Adopting these views, their practical application soon comes in a sequestration of many whose liberty now is only a vicious license. The tendency of the Elwyn Institution is toward life detention of all such cases. There they refuse for them the ordinary routine of education because they believe that in educating moral imbecility after the current notions of education, they are training experts who may afterward figure in the *rôle* of so-called moral insanity; that by giving such subjects any considerable school education they are only arming them for more serious exhibitions of evil. It is a radical, often inherited condition, just as incurable as inherited forms of idiocy or intellectual imbecility. When we shall arrive at this definite conclusion about cranks, habitual drunkards, and the like, and fully apply it, and when we introduce the indeterminate sentence for crime, such sequestration of the morally and socially unfit will be brought about that our human stock will be improved by keeping out of the national blood some terribly bad strains.

It is a noteworthy fact that in most, if not all, the cases which have been determined to be moral imbeciles, there is a neurotic history in the family antecedents; epilepsy, monomanias, inebriety, crime, are frequently the correlative exhibitions in families from which proceed these children of keen intellectual precocities, but inveterate tendencies to vagrancy, prostitution, and lawlessness.

Dr. A. W. Wildmarth then read a paper on

THE PATHOLOGY OF IDIOCY.

largely based on the post-mortem records of forty cases observed at the Pennsylvania Institution for Feeble-minded Children.

Dr. Francis X. Dercum then reported the following

CASE OF TIC DOULOUREUX OF TWELVE YEARS' STANDING SUCCESSFULLY TREATED BY LARGE DOSES OF THE SALICYLATES.

The patient, Mrs. K., aged fifty-two, was first seen November 30, 1886. She stated that she suffered from tic douloureux, and as she spoke she was constantly interrupted by frightful paroxysms of pain. Twelve years ago, when apparently in good health, she had been attacked with pains in the right side of the face. This she attributed to a cold. The pain gradually increased in intensity. The suffering had practically been continuous, the paroxysms sometimes occurring many times a minute, again only four or five times an hour. She was always worse in cold and damp weather. The distribution most affected was that of the superior maxillary nerve. The inferior maxillary was also decidedly affected, but the ophthalmic division did not appear to be at all involved. During the entire period there had been but one remission. This had occurred two years ago, when she suffered from a severe attack of rheumatism, affecting mainly the lower extremities. The attack lasted eight weeks, and during this time she was free from the tic douloureux, which, however, reappeared as the rheumatism subsided. The operation of nerve-stretching was suggested to her.

The previous history suggested a possible connection with rheumatism, and it was decided to treat the case on this basis before resorting to operation. Oil of gaultheria, in fifteen drop doses, every three or four hours, was ordered. Within four days there was decided improvement. The remedy was continued up to December 20th, when, as a result of indiscretion in diet, she

suffered from diarrhœa. The oil of gaultheria was now stopped. December 24th she ventured out of the house, the day being cold. This was followed by a mild recurrence of the tic. She again resumed the oil of gaultheria, which, two days later, was replaced by salicylate of sodium, in twenty grain doses. Every trace of the tic douloureux now disappeared. The use of the salicylate was continued until January 12th, when it was finally abandoned. Since then she has been exposed on numerous occasions, and once caught a severe cold, giving rise to bronchitis, but with no return of the tic. At the present writing (February 28th) she is entirely well.

Dr. Charles K. Mills stated, in regard to the use of salicylate of sodium in rheumatic neuritis, he had found it one of the most valuable of remedies, and he recalled two cases in which it had been especially beneficial. One was a case of brachial neuritis, involving the entire arm, in a person suffering with diabetes. He got well after some weeks treatment under salicylate of sodium, in twenty grain doses, and hypodermatic injections of atropia and morphia, with blistering. The second case was that of a physician with rheumatic brachial neuritis, involving one arm, with great pain and stiffness, and also some paresis. He recovered under the same treatment. He has used salicylate of sodium with success in a number of instances.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, February 23, 1887.

The President, Charles McBurney, M.D., in the Chair.

Dr. John A. Wyeth read a paper on

LIGATION OF THE EXTERNAL CAROTID ARTERY; A SYNOPSIS OF FIVE SUCCESSFUL CASES.

(See page 312.)

Dr. Markoe asked regarding the cause of the aneurism of the internal carotid artery, mentioned in the last case. The reader replied that it was due to atheromatous degeneration of the artery.

Dr. Sands remarked that Dr. Guyon, a French surgeon, was one of the first to prove that the arguments against the safety of the operation of tying the external carotid were unsound. He showed, in a paper written by him in 1863, that there was very slight danger to be apprehended from secondary hemorrhage. The cases then on record, as well as some additional ones, were tabulated by the late Dr. Longworth, of Cincinnati (a former pupil of Dr. Sands), in a paper published in 1873. In this paper the operation referred to was strongly advocated. The speaker added that he had tied the external carotid three times, the first case being that of a man who had extensive epithelioma of the face; chloride of zinc paste was applied, and caused such deep sloughing that a large vessel was opened behind the jaw, and such profuse hemorrhage resulted that it was necessary to ligate the external carotid; no anæsthetic was employed, as the patient was extremely weak.

In the second case he removed a tumor of the lower jaw, and had to contend with a very severe hemorrhage, which was found to be due to an accidental wound of the internal jugular vein, and an excision of a piece of the external carotid artery. In the third case the artery was tied on account of an aneurism about half as large as a hen's egg, which was supposed to involve the posterior auricular artery. The operation was performed five years ago, and though the patient recovered he was not completely cured—the tumor became smaller, but continued to pulsate.

The practice of tying the external carotid as a preliminary step before removing a tumor of the tongue, was certainly different from that usually followed, which is to tie the lingual *in loco*. The latter seems to serve the purpose equally well, while the surgeon can usually avoid placing a ligature on the vessel close to its point of origin. Removal of the parotid gland would seem to be a formidable operation as regards hemorrhage, but he was aware of no death from this cause; it is better, he believed, in this operation to tie the external carotid artery, when necessary, as near to the tumor as possible; that is, at a distance from its origin. In general, the speaker would always prefer to ligate the external, rather than the common carotid.

Dr. Stimson said that he had tied the external carotid once for epithelioma involving the side of the face; the operation was successful, but the patient succumbed to the disease. In regard to ligature of the artery as a preliminary measure before removing tumors of the parotid, the speaker thought, with Dr. Sands, that it is practicable to secure the vessel higher up, behind the angle of the jaw. In one case he had been able to remove nearly the entire gland without cutting the artery. Dr. Wyeth's last case suggested the interesting and important question whether it might not be proper to place a catgut ligature on an atheromatous artery, meaning by the latter term a vessel, the walls of which were softened, but not calcified; could it not safely be tied with catgut? There would, of course, be a greater chance of the subsequent formation of an aneurism near the ligature, but might it not be reasonably expected that secondary hemorrhage would not occur? When we remember how much more rapidly and perfectly tissues heal under our present antiseptic methods, why could we not venture, the speaker asked, to tie even an atheromatous artery in continuity?

Dr. Sands said that he had once assisted Dr. Lange in the amputation of a thigh in an old man. Dr. Lange thought that he would apply the dressings before removing the tourniquet, but he determined not to do so, and, on loosening the latter, profuse hemorrhage occurred, which was found to be due to the fact that the ligature placed on the main artery of the limb had cut through, in consequence of the vessel being atheromatous. The speaker himself had amputated a leg for senile gangrene, the arteries of which were so rigid from calcareous degeneration that they did not pulsate, but, on removing the tourniquet, there was free hemorrhage. The vessels were tied with catgut, and the patient did perfectly well. Dr. Sands agreed with Dr. Stimson that the danger of tying atheromatous vessels was much lessened since the healing of wounds had become more perfect. He would say that it was not unsafe to apply a ligature to such an artery, unless the latter was so soft and friable that it would cut through. In Dr. Wyeth's case there would have been no use in tying the internal carotid, as it was so extensively dis-

eased. Simultaneous ligation of the external carotid and the common carotid for aneurism of the internal carotid produces practically the same effect as the application of a distal ligature.

DR. MARKOE said that he recalled a unique case, which had become historical, which threw light upon the subject under discussion. In October, 1845, Dr. J. K. Rodgers tied the left subclavian artery in the first part of its course, about one inch from its point of origin from the aorta; the patient lived fifteen days, and died from secondary hemorrhage from the distal part of the artery. The autopsy showed that the ligature had passed directly through an atheromatous plate, yet the artery on its proximal side was firmly plugged, and the usual changes which take place after ligature, had occurred normally, and effectively closed the artery. Shortly before this operation, Dr. Hoffmann had exposed the innominate artery in a case of aneurism, with the intention of tying it, but he refrained from applying the ligature, because the vessel was atheromatous. The patient subsequently died of hemorrhage from the aneurism; probably, if the artery had been tied, no bad result would have followed, even though it was diseased.

DR. WEIR said that he had applied catgut ligatures to calcified arteries in the cases of amputation for senile gangrene. It has been shown by English authorities that there is no danger in ligating such vessels, provided that the ligature is not tied too tight.

THE PRESIDENT thought that Dr. Wyeth had acted wisely in tying the external carotid first, because, if the ligature had been applied first to the atheromatous internal carotid, it would have cut off the possible chance of obtaining a good result after subsequent ligature of the external carotid.

DR. MARKOE asked the reader if he found the point of origin of the internal carotid.

DR. WYETH replied in the affirmative, adding, in response to a question from Dr. Sands, that the diseased vessel was of larger calibre than normal, having undergone a sort of general fusiform dilatation.

THE PRESIDENT asked if it was easy to identify the external carotid. The reader answered that he had experienced no difficulty after finding the bifurcation at the upper border of the ala of the thyroid.

DR. MARKOE said that he had tied the internal carotid with the common three times, and had found it without difficulty.

DR. WYETH remarked, in closing, that the cases which Dr. Sands had said were published by Guyon, had nearly all been reported by Maisonneuve. Several papers on the same subject had appeared previous to the one published by Longworth. The reader did not wish to be understood as recommending ligature of the external carotid as a preliminary measure in all cases of excision of the tongue for cancer. He, himself, generally tied the lingual artery, but in the case described, the muscles and floor of the mouth were so much involved, that it was necessary to remove them extensively, and the hemorrhage could only be controlled by placing a ligature on the main artery. Neither would he tie the external carotid before removing an ordinary parotid tumor. The two growths to which he had referred in his paper were unusually large; on one side the artery was tied first, but on the other the tumor was dissected out rapidly, the vessel being ligated as soon as it was reached. He had ligated an atheromatous artery in a case of amputation of the thigh, and had no hemorrhage. In the case described he would not have tied the atheromatous internal carotid, even if he had believed that there was no danger in the procedure, because he could accomplish the object desired by placing the ligatures on sound arteries.

OPERATION FOR THE CURE OF PROLAPSUS ANI.

DR. LANGE presented a patient upon whom he had performed the operation which he had described at the previous meeting. He desired to modify the statement which he had made with regard to the condition of the patient, as the latter had become worse during the past few weeks. There was no return of the prolapse, but the patient did not have perfect retention, so that fecal matter was discharged while he was walking. The action of the sphincter and the levator ani was pretty good, but it was not perfect. The present case had been a very obstinate one. Future developments will show if the operation possesses any lasting value. The speaker called attention to the fact that the anal ridge was situated more deeply (nearer to the middle of the body) than normally, and that the posterior anal commissure was carried forward—a change probably due to contraction of the levator ani.

In reply to a question from Dr. Sands, as to whether the cure might not be made more complete by contracting still further the anal aperture, the speaker said that the prolapse was already cured, but that the patient had not acquired sufficient control over his bowels. The orifice might be narrowed, as suggested, since the muscular action alone was not enough to cause perfect closure. He feared that an attempt to contract the aperture by excising the mucous membrane alone would not produce lasting results; this had been tried several times before. He intended to use cold water injections and electricity with a view to stimulating the parts to contract.

SARCOMA OF THE PHARYNX, REMOVED BY PARTIAL EXSECTION AND DISLOCATION OF THE INFERIOR MAXILLA.

DR. LANGE showed a patient from whom he had removed a tumor that occupied the left half of the pharynx, extending upward behind the soft palate, and down the throat so far as to dislocate the larynx. Following Mikulicz, he performed preliminary tracheotomy, and then made an incision along the inner border of the sterno-mastoid muscle, and a horizontal incision along the border of the zygomatic arch, so as to expose the angle of the jaw, which was removed subperiosteally, so as to give access to the tumor. The operation was a long and tedious one. The patient had intense iodoform-poisoning, being at first greatly excited, and then speechless for fourteen days. He was fed by a stomach-tube, which he swallowed one day, through the carelessness of a nurse. After being retained for five weeks, the tube (which was eighteen and a half inches long) was passed per rectum. The patient finally recovered, with paralysis of the lip on the side of the wound, but there was no displacement of the teeth, his power of mastication being as good as ever. The operation was performed on the 28th of September.

In reply to a question from the President, Dr. Lange said that all of that portion of the angle of the jaw which corresponded to the insertion of the masseter muscle had been removed, and that the jaw had then been dislocated, so as to afford a view of the interior of the pharynx; but, in spite of this, he did not obtain a clear idea of the connections of the tumor, and was obliged to scrape it out piecemeal, so that the operation was not as thorough as he could have desired. The growth was about the size of a goose-egg, so that it interfered with deglutition, and was beginning to cause dyspnœa. It had no bony attachments, and was encapsulated, but broke down readily, so that it was impossible to remove it entire; it was also quite vascular. Microscopically it presented the appearances of a mixed round- and spindle-celled sarcoma.

Dr. Weir asked whether it would not have been possible to reach the tumor by Kocher's method—that is, through the nose.

Dr. Lange replied that there would not have been sufficient room.

Dr. Sands said that Busch had described a variety of fibro-sarcoma of the pharynx that was neither very vascular, nor was it firmly attached. He had had a similar case several years before; supposing that he would have a profuse hemorrhage on removing it, he introduced a Trendelenburg's tube, but it was not needed, as there was but little bleeding. As soon as the capsule of the tumor was divided, it could be shelled out easily; it seemed to spring from the connective tissue.

Dr. Lange said that the tumor which he had described extended high up behind the soft palate, and was very vascular.

RENAL CALCULUS REMOVED POST-MORTEM FROM A PYONEPHROTIC KIDNEY.

Dr. Lange said that he had exhibited at the previous meeting a renal calculus removed by nephrotomy from a woman, who was reported as doing well five days after the operation. Her condition changed suddenly for the worse. An examination of the other kidney showed that it was enlarged. Fourteen days after the operation the patient had a chill, followed by septic symptoms. The kidney was punctured with a needle, and pus was found, while a calculus could be felt. After refusing for five days to allow an operation to be performed, she finally consented. The pelvis of the kidney was found to be dilated and filled with extremely offensive pus, and the specimen shown was also found in it. The patient had complete suppression before her death, which occurred six days later from septicæmia.

Within the pelvis of the kidney which was first incised (the specimen was shown) were found numerous fragments of calculi, some of which resembled the processes in the original stone. The septic poison was due to the numerous abscesses in the opposite kidney. The patient would have been seriously ill, even if she had survived the second operation, although if it had been done at the proper time the result would have been different.

Dr. Lange showed some

CURVED NEEDLES FOR SEWING THE ABDOMINAL WOUND

which he had devised. They were of a fusiform shape near the point, the eye being situated behind the largest part of the needle. There was a small indentation in the beak, so that if caught by the needle-holder the point would not be spoiled.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

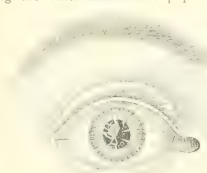
Stated Meeting, February [illegible], 1887.

The President, J. Solis-Cohen, M.D., in the Chair.

Dr. Charles S. Turnbull exhibited a patient presenting a

PERSISTENT PUPILLARY MEMBRANE.

The patient has in his right eye what is known as a "persistent pupillary membrane." This is a remnant of fœtal life, but its exact structure has not been ascertained. Some consider it to be made up of atrophied bloodvessels, which have served their purpose. Other authorities hold that it consists of the remains of connective tissue through which bloodvessels pass. In this man's right eye there is a network of hair-like fibres occupying the outer half of the pupil (see Figure).



These fibres originate from the anterior surface of the iris, and interfere in no way with the constrictor muscle of the pupil. This form of congenital anomaly was first observed about 1735, and on an average about one case has been reported every five years since that time.

Dr. E. Jackson said that this case is notable for the clearness with which it shows the relation between the membrane and the iris. In all the cases he had seen, heretofore, as in this, the pupillary membrane has seemed to arise from the anterior surface of the iris; but in no other instance has the connection been so obvious, the membrane here appearing to be simply an extension of the anterior layer of the iris; and similar to it in structure.

Dr. Turnbull said that the point referred to by Dr. Jackson is well illustrated in this case, and it settles the disputed question as regards the origin of these fibres. It is distinctly seen that the sphincter muscle is in no way involved. The membrane has no connection with the muscle nor with the inner pupillary margin.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, March 1, 1887.

The President, Charles L. Dana, M.D., in the Chair.

Dr. H. M. Biggs presented the

CORD AND NERVES IN A CASE OF ALCOHOL PARALYSIS—MULTIPLE NEURITIS.

Bertha S., aged thirty-five, married, admitted to the hospital, September 20, 1886. History imperfect. Noth-

ing of importance in the history up to the beginning of her present illness, about five weeks before admission, when she began to have sharp shooting pains in both legs, but more severe in the right. She began to lose power in her limbs, and one week later was unable to walk because her limbs were "too weak." The loss of power seemed to begin in her feet. She complained of pain in her back and weakness when she tried to stand. Later she began to have pain and lose power in her arms. She says she has been a moderate drinker, and denies syphilis.

On admission the patient was almost completely paralyzed in her lower extremities; could barely raise her limbs from the bed. The muscles of the upper extremities, especially the extensors, were also somewhat affected. There were some spots of hyperæsthesia and partial anæsthesia irregularly distributed over the lower extremities, and also considerable numbness. Sensation in the upper extremities seemed to be normal. The reflexes were lost. There was marked atrophy in the legs and thighs on both sides, particularly of the extensors of the foot, and a moderate amount in the arms. The extensors here were also most affected. She complained of very severe pain in the arms and legs which kept her awake at night, and there was marked tenderness on pressure. Temperature at 9 A. M., 100°; at 5 P. M., 101.2°. Pulse, 9 A. M., 104; at 5 P. M., 112. Urine, 1.018; albumen one-eighth in bulk, no casts.

Two days after admission the patient was found to have a moderate amount of fluid in the right pleural cavity. Twenty-four ounces of serum were withdrawn. She gradually failed, lost strength, emaciated. The pleurisy developed into an empyema, for which a free opening was made in the chest. Before death, which occurred in February, 1887, she had lost all power over both lower extremities, and the arms were partially paralyzed. Atrophy was very marked in both lower extremities and forearms. Pain was constant and paroxysmal, and very severe. Tenderness on pressure and pain on movement of muscles marked. Contraction of the muscles had gradually developed until the thighs were sharply flexed on the trunk, and the legs on the thighs; attempts to straighten the limbs caused the most severe pains. The bladder and rectum, the muscles of phonation, deglutition, and respiration, and the nerves of special sense were entirely unaffected. The reactions of degeneration were present. The patient died of exhaustion resulting from the empyema.

Autopsy.—Patient greatly emaciated. Legs and thighs markedly flexed. Muscles of the leg of a yellow color, and apparently converted almost entirely into fat; muscles of thigh much less affected. Spinal cord nerve roots and trunks normal in appearance.

Microscopical Appearances.—Spinal cord apparently normal, with the exception of slight sclerosis in the columns of Goll in cervical region. Nerve roots normal. In one of the sacral nerves before its exit from the spinal canal was found a marked increase in the endoneurium with diminution in the number of the nerve fibres, and an irregularity and indistinctness in these appearances. The right sciatic nerve showed the same changes more marked. In the posterior tibial the process was even more advanced, and in this only an occasional nerve fibre could be detected. Microscopically the gastrocnemius was composed almost entirely of adipose tissue; only here and there atrophied muscle fibres were found. The small nerve trunks in the muscle showed advanced degenerative neuritis, with comparatively little new growth of connective tissue in the nerves.

THE PRESIDENT thought that in this case it had been fully demonstrated that the alcohol paralysis was due to a neuritis and not to a myelitis.

DR. M. A. STARR had seen the specimens, and said there was no question with regard to the existence of neuritis in this case, and the normal condition of the anterior cells of the spinal cord. There was slight sclerosis in the columns of Goll which he was unable to explain. The same condition had been observed in a case of Hamilton recorded by Grainger Stewart. He referred to a well-prepared specimen by Dr. Van Gieson in a case of Dr. Ball's, not yet published; also to the manner of preparing specimens.

DR. BIGGS said that, contrary to the ordinary condition found, the process seemed to be more a degeneration of nerve fibre than an interstitial neuritis, especially in the smaller nerves.

DR. NOYES spoke of the frequent occurrence of amblyopia with alcoholism, and said that it was due to a partial neuritis of the optic nerve, referred, as had been shown, to the centre field, and not to the field at large. He suggested that in cases like the one reported by Dr. Biggs, the neurologist should make careful examination of the optic nerves. In reply to Dr. Starr, whether scotoma is due as frequently to tobacco as alcohol, he said it might be due to either, but the patients frequently combine the two habits.

THE PRESIDENT said that the name alcohol paralysis was rather begging the question; this patient, it seemed, had been only a moderate drinker. The same fact had been noticed in other cases.

DR. STEVENS then made some remarks on

IRRITATIONS ARISING FROM THE VISUAL APPARATUS CONSIDERED AS ELEMENTS IN THE GENESIS OF NEUROSES.

Two classes of influences were recognized as causes of functional nervous disorders; the remote and the immediate. The remote causes may be sufficient to perpetuate a neurosis when once a nervous irritation has been instituted. While immediate causes rarely induce long-continued disorders, preëxisting influence may serve to continue it indefinitely. It is of little practical importance that some exciting circumstance has given rise to a nervous trouble. The event has passed and cannot be recalled. If there is an underlying cause, it is of much more importance.

Persons in whom underlying causes of neurosis exist are said to possess a neuropathic predisposition, and those subject to it are liable, from trifling immediate causes, to suffer from various neuroses. In a considerable proportion of cases the neuropathic tendency is hereditary, but the result is not always manifested in the same form in different generations.

A third class of cases which should be recognized, may be designated as *modifying tendencies*, among which may be mentioned vitiated atmosphere, the period of life, and the performance of certain physiological functions.

Often as a result of the predisposing influence, when one form of complaint is supposed to be cured,

the subject of it is simply suffering from some other form.

Must the predisposing cause of neurosis be general, pervading the whole organism, or must it of necessity be located in the great nerve centres, or may it be entirely local and outside those great centres? Undoubtedly it may be local, and confined to any portion of the nervous system.

Inasmuch as the tendency is often hereditary, may not the evil consist of some peculiarity of anatomical structure or of physiological adaptations which are inconsistent with the most regular and easy performance of the function of a part or parts; and may not certain classes of mechanical peculiarities be unusually liable to become factors of physiological disturbance?

If we answer in the affirmative we assume a hypothesis which must be maintained by long observations conducted in a spirit of judicial independence and free from the bias which might result from occasional and exceptional experiences. The conclusions announced are based upon observations in more than five thousand cases in private practice and of a considerable number in public institutions, all of which have been made with as much precision as the exacting demands of an active professional life would permit. The central truth as arrived at by these observations may be stated, as it has already been done, in a memoir to the Royal Academy of Medicine, Belgium, in 1883, as follows:

Difficulties attending the functions of accommodating and of adjusting the eyes in the act of vision, or irritations arising from the nerves involved in these processes, are among the most prolific sources of nervous disturbances, and more frequently than other conditions constitute a neuropathic tendency.

In the proposition all causes of nervous irritation are recognized. It is held that the influences indicated are preëminent, but not exclusively permanent causes. Let it be remembered that it has been universally conceded that the nature of the neuropathic tendency is unknown. If one preëminently important element is demonstrated, it is not to be rejected because it may not include the whole.

He proposed only to illustrate the result of his experience by exhibiting some photographs of cases of notable neuroses which showed very remarkable changes of physiognomy, such as habitually occurred when certain hurtful tensions of the ocular muscles were relieved. If he had designed to present only the most remarkable cases of the class to which these belonged he would have chosen only a few of these. The design was, however, only to show by these contrasting photographs the very notable improvement which, in obstinate, and even, by ordinary means, hopeless cases of the most important neuroses, might be expected from relief from certain hurtful tensions of the eye muscles.

The portraits were in pairs, the first having been taken at the commencement of treatment, the second at a later period, the interval being, on an average, about one month. The first series represented cases in his private practice; the second series, cases which were under his care for a short time at the Willard Asylum for the Insane, last summer. The first series had been made by various photographers, the second by Dr. P. M. Wise, Superintendent of the Willard Asylum. Thirteen pairs of photographs were exhibited, nine of the first, and four of the second series. In all these very striking contrasts existed between the first and second portraits.

In No. 1, a weary and listless young girl, a sufferer from headache, and who had never been able to attend school, is seen to be transformed in twelve days into a vivacious and thoroughly awake child, following relaxation of each of the inner eye muscles. The change in health was marvellous. In No. 2, an epileptic girl whose vacant gaze and half-open mouth indicated a profound degree of dementia, within a single month put on an appearance of robust health and of lively intelligence. In another case a boy, choreic from infancy, and imbecile, whose constant movements were too rapid even for the modern photographer, showed in the second photograph from which the distortions of the face and wrinkles in the skin had disappeared, a clever mental state.

He related in brief some of the results of a short season among the most hopeless cases of the Willard Asylum for the Insane. Two of these hopeless cases, who had, during the month preceding treatment directed to the eye muscles, been subjected to about one hundred and seventy convulsions, suffered only about forty convulsions in the month succeeding that treatment, notwithstanding the withdrawal of all bromides. Fifty per cent. of epileptics so treated had remained well for a length of time varying from many years to only a single year, but sufficiently long to indicate that a great change had been wrought. Thirty-two per cent. had received very marked relief but short of absolute cessation of the complaint. They were all better without drugs than they had formerly been with. In seventeen per cent. no good results had been obtained.

He thought that with a better understanding on his own part of the extremely complicated condition of the ocular muscles often found in epilepsy this record could be improved.

The method of procedure in examining for muscular defects was given. It differed radically from that proposed by Gräfe and generally adopted, and from other methods which had been suggested. His method of performing tenotomy was also described.

In conclusion, Dr. Stevens said he thought it was not unreasonable to look for the future advance in medical practice along the great lines; the one related to micro-organisms, the other to irregular phenomena resulting from well-defined causes of irritation, which causes must be sought for principally in the direction of difficulties in the performance of necessary functions. With the removal of such difficulties we might look with confident expectation to the cessation of the peculiar irregularity which constituted the special form of nervous disease.

DR. E. C. SEGUIN said with regard to the etiology of neuroses and serious mental disorders that he thought we ought to look a great deal deeper than the exciting and superficial causes which occurred in many cases of that kind. In epilepsy and chorea, for instance, he thought we had to look for the efficient cause not in disturbed external apparatus, but to hereditary predispositions and faulty tendencies. That faulty external apparatus would cause more attacks, or possibly aggravate the mental disorder, he thought no one would

deny, consequently the optic apparatus, the genital apparatus, etc., should be put in perfect order. As to the great improvement after tenotomy in epilepsy, the records of surgery and medicine are filled with cases in which trauma of various kinds have interfered with epileptic manifestations for months or even years. It seemed to him the report of a case within six months after tenotomy was rather premature. He referred to one of his cases of epilepsy recently submitted to division of the ocular muscles, the bromides at the same time being withdrawn, and three days later she commenced to have from six to twelve convulsions in the twenty-four hours—more than she had ever had before the operation. He had had patients go three years without an epileptic attack, and then have a relapse.

DR. H. D. NOYES thought the precise ocular conditions in the cases reported should have been recorded; perhaps they were in that part of the paper not read. He had with him the exact records of a number of cases of ocular trouble with the result of treatment. It had not fallen within his experience to meet with the class of cases referred to by Dr. Stevens. He dwelt upon the importance of making a thorough ocular examination, including that of the muscles of the eye, in every case. He had come to realize more and more the importance of insufficiency of the external recti. He had obtained benefit in many cases from prisms. He spoke of the method of examination and of performing tenotomy. The paper deserved the most careful consideration.

DR. D. B. ST. JOHN ROOSA said that that part of the paper which especially concerned the ophthalmologist was as old as ophthalmology itself, and it did not call for discussion to-night. The real point in the paper was, he thought, that the correction of errors of refraction, improper relations between the ciliary and internal recti muscles, and other deviations of the ocular muscles was capable of curing constutional disease. He took it that epilepsy is a constitutional disease and not merely a functional disturbance. The same is true of chorea. The question was, Did these operations cure epilepsy and chorea? But it had been shown that people with chorea got well without ever having error of refraction corrected. It had also been shown that the vast majority of people who are not myopes are hypermetropes, yet suffer no inconvenience from it. In this, the author's second paper, another step had been taken, namely, that these constitutional diseases, epilepsy and chorea, were due not solely to errors of refraction, but to want of coördination between the recti and ciliary muscles. Then the prism test came upon the field, and we had to exercise the ocular muscles by prisms. Then in the order of advance came the doctrines taught in the paper of to-night. Granting the claims of the paper, that the patients had for a time after correction of an ocular difficulty been greatly relieved, possibly cured, yet that was a long way from assuming that the ocular disturbance, whatever it was, was the cause of the epilepsy. Many great men having strabismus had not become choreic, epileptic or insane.

DR. A. L. RANNEY thought that following the exhibition of the photographs little need be said in confirmation of the views advanced by Dr. Stevens. The photographs were so startling that they would be accepted in any court of justice by an unprejudiced jury as proof that unmistakable benefits had been derived from the treatment. He had personally seen and examined several of the cases, and he considered the published histories as decidedly under-estimated. Dr. Ranney had performed the operation for the relief of ocular insufficiency nearly two hundred times, and had carefully examined the condition of refraction and accommodation as well as that of the ocular muscles in several hundred subjects afflicted with various forms of nervous disease. He did not pretend to pose as an oculist, but as a neurologist. Originally he was a sceptic, but his scepticism became no longer tenable when he saw a choreic and epileptic imbecile in Dr. Stevens's office who was perfectly restored in a short time to health and mental sanity by the method he had described. He thought the paper would tend to establish a new era in neurology. Regarding the operation, in no case had he had bad effects from it, but the treatment required careful regard to detail.

Respecting the view that the eye is an important factor in creating and prolonging the so-called "neuropathic predisposition," the following facts were pertinent: 1. No one has yet shown in what this predisposition lies; hence, if Dr. Stevens has shown that eye defect is an important element in these conditions a great advance has been made; 2. There is no recognized pathology in the functional nervous diseases; 3. Heredity is very common in these affections; 4. Dr. Ranney's records in common with those of Dr. Stevens's go to show that eye-defect is found in a very large proportion of such subjects; 5. Many of the eye-defects found can be shown to be congenital—being inherited like features; 6. The manifestations of the neuropathic predisposition vary with each case, and are called forth often by trivial circumstances which are too frequently regarded as of great clinical interest.

In the treatment of the severer forms of functional nervous disease, for example, in chronic epilepsy, one radical cure without the aid of drugs offsets a thousand failures as a proof of the scientific value of a discovery. Dr. Stevens had seven cases free from epileptic seizures for more than five years after tenotomy of the eye-muscles, and without the aid of drugs. This could not be explained by chance. Then the records of the Willard Asylum were hard to contradict.

During the past year and a half he had seen sixteen epileptics in private practice; in only one was no defect in the eye muscles found. He had an opportunity to operate on the eyes in eight of the cases; three of these were cured; two had had no fits for over one year. In the five cases still under observation the attacks had been lessened in all, drugs having been withdrawn. One had been reported by Dr. Stevens. In headache and neuralgia he had had some very remarkable results from tenotomy of the eye muscles; also satisfactory results in hysteria and hystero-epilepsy.

DR. HERMAN KNAPP said his practice had not brought him much in contact with people who had neurotic conditions, and most of those whom he had seen had passed into other hands. He was very much surprised to learn that there was so high a percentage of ocular difficulties in the patients Dr. Stevens had examined in the asylum. He thought nervous people generally showed not only one complaint. Many people, especially young ladies, who suffer from headache, etc., cease to complain after correction of a deviation of the

eye muscles, etc. He had listened with the greatest attention to Dr. Stevens, and he felt quite sure that his work was not only legitimate, but that it was highly promising. He was only afraid we would not be spared disappointments in that line of treatment.

Dr. Gruening said his experience had been very much like that of Dr. Knapp. He always examined for muscular defect, and said that when one placed a prism before the eye it disturbed binocular vision. For the correction of this apparent muscular defect an operation was performed, but the muscle was sewed to its original place, or the lateral attachment was not divided; and this was only the simulation of an operation. He had benefited many patients by cylinders.

Dr. Stevens, in closing the discussion, said there was no suggestion in the paper regarding cures. He did not believe in cures; take away the cause of the trouble and they get well. If the patients could not be said to be cured, it was still a very fortunate thing that they had got rid of their chorea, epilepsy, etc.

CORRESPONDENCE.

AGARIC IN THE SWEATING OF PHTHISIS.

To the Editor of The Medical News,

Sir: I notice that some correspondence has lately taken place in The Medical News with reference to "Agaric in the Sweating of Phthisis." The introduction of the drug has been attributed to Siefert, and others. Will you allow me to state that I believe that I was the first to reintroduce this drug into practice, and my note on this subject was published in the *Medical Times and Gazette* in 1881. In a short paper, I there stated that I had used agaricus in a number of cases with complete success, and I claimed for it that, being harmless, it was to be preferred to atropine and other like drugs.

My note attracted the attention of Dr. Young, of Glasgow, who then tried agaric in Dr. Gairdner's wards in the Glasgow Infirmary, and confirmed the opinion I had formed of it. The dispenser at the infirmary then extracted what Dr. Young called an alkaloid, viz., agaricin, but which is really agaricic acid, and Dr. Young administered this successfully. Murrell, of London, next spoke of it. Continental physicians, Siefert, Probsting, Pribriam, and others, reported favorably of it.

Agaricus had formerly been extensively used at the beginning of this century, but had, undeservedly, fallen into disuse. It was my note in the *Medical Times* of 1881, "On Agaricus in the Treatment of Night-sweating," which again attracted attention to it, and rescued a deservedly useful drug from oblivion. Others have only confirmed what I originally wrote of it.

I may say that I have used it extensively since 1881 with the best results. Besides checking night-sweating, agaricus has a decided influence in retarding the tendency to hæmoptysis. My object is to show that it was not due to Seifert, or other physicians, that the drug now retains a place in medical practice, but to myself.

I am, sir, yours faithfully,

R. Norris Wolfenden, M.D. Cantab.,
Senior Physician to Throat Hospital,
Golden Square, London.

DEATH-RATE OF THE BOSTON LYING-IN HOSPITAL.

To the Editor of The Medical News,

Sir: In the article on "The Death-rate of Lying-in Hospitals," by Dr. B. C. Hirst, which appeared in The Medical News of March 5, 1887, appears the following sentence:

"The sudden decrease in the mortality of the Boston Lying-in Hospital, in 1884, was the result of a letter calling the attention of the managers to the really murderous death-rate of former years in that institution."

I do not know the authority Dr. Hirst has for making such a statement. No such letter has ever been received by the managers or any member of the medical staff. It seems to me a matter of justice that you should give this denial as prominent a place in your journal as the original statement.

Yours very truly,

William L. Richardson,
Visiting Physician of the Boston Lying-in Hospital.

Boston, March 9, 1887.

Sir: The assertion to which Dr. Richardson refers was made on what I supposed good authority, before I had read his paper on "The Use of Antiseptics in Obstetric Practice." I am now convinced that it is entirely incorrect, and while much regretting having made such a mis-statement, I am glad to have an opportunity to acknowledge and correct it.

Yours, etc.,

B. C. Hirst.

Philadelphia, March 14, 1887

ANTIPYRIN IN HEMICRANIA.

To the Editor of The Medical News,

Sir: An abstract of an article on the use of antipyrin in hemicrania, which appeared in your journal of March 5, 1887, leads me to relate my experience with this drug in neuralgia, especially of the cranial nerves.

The most striking case is that of a lady, who, for the last ten years, at least, has suffered from neuralgia of all the branches of the facial nerve and certain ones of the cervical plexus. She has tried various remedies and methods of treatment, but from none has she obtained so much relief as from antipyrin, which in two out of three trials completely relieved the paroxysm; in the third trial it diminished the severity, but did not completely arrest the attack.

I have tried this drug in three other cases of neuralgia, two of the facial nerve and one of the supraorbital. In all of these cases it relieved the paroxysm, but did not prevent a recurrence. It has been my habit to administer it in fifteen grain doses repeated in one hour, and if necessary a third dose is given at the same interval.

Yours truly,

C. B. Lyman, M.D.

Denver, Colorado, March 13, 1887.

NEWS ITEMS.

The Philadelphia County Medical Society has memorialized the Legislature in opposition to the passage of Section 10 of the proposed Pharmacy Law, now pending. This Section so far repeals the Registration Act

as to permit druggists to engage in the practice of medicine, provided that they conduct only an office practice. The Society urges that this proposition is unworthy of approval and support, for many reasons, but above all, because of the danger to which it exposes the lives of individuals and the health of the community. The Druggists' Association of Philadelphia has also taken similar action.

FRENCH SURGICAL CONGRESS.—The third meeting of the French Surgical Congress will take place in Paris in April, 1888, at a date which will be announced shortly, under the presidency of Professor Verneuil. The following questions are arranged for debate at the Congress: 1. On the Treatment of Gunshot Wounds of the Visceral Cavities; 2. On the Value of the Radical Treatment of Hernia as a Permanent Cure; 3. Chronic Suppuration of the Pleura and its Operative Treatment; 4. Recurrence of Tumors after Operation (Causes and Prevention). The object of the French Surgical Congress is to establish scientific relations amongst surgeons and practitioners of France and foreign countries. All qualified men become members of the Congress on duly entering their names and on payment of the subscription of 20 francs.

THE FUNERALS OF THOSE DYING FROM CONTAGIOUS DISEASES.—A clergyman who conducted the funeral service of children who died from diphtheria, contrary to the regulations of the Board of Health of Des Moines, Iowa, has been arrested and quarantined. He appealed to the State Board of Health, and the local board's action was confirmed.

FOREIGN UNIVERSITY INTELLIGENCE.—*Berlin.* The temporary charge of the University Clinic for Women in Artillerie-strasse, vacant by Professor Schröder's death, has been given to Dr. Hofmeier, the chief assistant physician.

Leipsic. After having met with two refusals, the invitation of the University to fill the Chair of Midwifery has been accepted by Professor Zweifel, of Erlangen.—*Lancet*, February 26, 1887.

CHEAP VENTILATION.—According to Professor V. C. Vaughn, for every room heated by a stove, there should be two flues, one for the smoke and other gaseous products of combustion, the other for ventilation. The latter should extend to the floor, just above which there should be a register. The smoke flue should be of iron pipe placed in a large flue, and the space all around the pipe will serve as a ventilating flue. With this arrangement, the air in the ventilating flue will be heated whenever there is a fire in the stove, and the removal of the foul air will be so far insured. It should be seen to in building the chimney that the inside of the ventilating flue is finished quite smoothly, and not clogged with mortar or pieces of brick.

For the supply of fresh air, a simple and efficient plan is to bring a pipe of about six inches in diameter through or under the floor, to the stove, where it terminates in a sheet-iron jacket placed around the stove, leaving a space of one or two inches, and having escapes only at the top. The heat of the stove will produce a current through the pipe of fresh, warmed air.—*Sanitary Era*, March 1, 1887.

INSECTS CARRIERS OF DISEASE.—The views of Dr. Grassi, that insects, especially flies, may be considered as veritable authors of epidemics, and agents in infectious maladies, are strengthened by the investigations of Dr. R. L. Maddox, as explained in a paper read by him to the Royal Microscopical Society.

He believes that the comma-bacillus from cultures can pass, in a living state, through the digestive tube of some insects, and, from this cause, insects feeding upon bacilli are likely to become the media of distributing diseases. Instances have been heretofore published of the discovery of living infinitesimal worms carried from one locality to another in the proboscis of the fly, caught after feeding upon substances containing such worms, and examined with the microscope. Such records open up an immense field of possibilities to the imagination of speculative individuals.—*Popular Science News*, March, 1887.

TOO FREQUENT LAPAROTOMIES.—At the annual meeting of the Governors of the Liverpool Hospital for Women, the case of Dr. Imlach was made the subject of lively discussion, he having been accused of too frequent indulgence in spaying, and of varying from the consultation custom of the hospital. The controversy seems to have been based mainly on personal grounds, there being great jealousy and antagonism among the staff. On the question of reëlecting the staff arising, first, Dr. Briggs, a new member, was elected unanimously; secondly, Dr. Burton, who had been on the staff since the formation of the hospital, and who was pointedly accused by Mr. S. B. Bacon of being "the originator" of the quarrels, was elected, by thirteen votes to nine; thirdly, when the case of Dr. Imlach's reëlection came up, it was negatived by seventeen to sixteen votes.—*New York Med. Record*, March 5, 1887.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 8 TO MARCH 14, 1887.

[illegible], *Assistant Surgeon*, [illegible] to duty at U. S. Military Academy, West Point, N. Y., August 28, 1887, relieving Lieut.-Col. Andrew K. Smith, surgeon, who will then report by letter to the Surgeon General.—*S. O. 52, A. G. O.*, March 5, 1887.

CARTER, WM. F., *Captain and Assistant Surgeon.*—Leave of absence extended four months on surgeon's certificate of disability. —*S. O. [illegible], A. G. O.*, March 11, 1887.

[illegible], *Captain and Assistant Surgeon.*—Leave of absence extended one month. —*S. O. 52, A. G. O.*, March 5, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 12, 1887.

[illegible], *Assistant Surgeon.*—Detached from Naval Hospital, Philadelphia, Pa., and granted six months leave.

STEELE, JOHN W., *Second Passed Assistant Surgeon.*—Ordered to Naval Hospital, Philadelphia, Pa., without delay.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING MARCH 12, 1887.

BANKS, C. E., *Passed Assistant Surgeon.*—To proceed to Chicago, Ill., and assume temporary charge of the Service, March 10, 1887.

VOL. L. SATURDAY, MARCH 26, 1887. No. 13.

ORIGINAL ARTICLES.

CONTRIBUTIONS TO THE DIAGNOSIS OF YELLOW FEVER.[1]

BY AUGUSTIN M. FERNANDEZ, M.D.,

CORRESPONDING MEMBER OF THE MEDICO-CHIRURGICAL ACADEMY OF MADRID, SPAIN.

IT seems at first sight incredible that after three hundred years of study of yellow fever, a dozen physicians can not be found in any city holding the same opinion in regard to its true nature and treatment. Even in places where this disease is endemic, and has been known for over a hundred years in uninterrupted succession, there also exists a variety of opinion among practitioners. Probably there is no medical society that has paid more attention to the subject than the Academy of Medical, Physical, and Natural Sciences of Havana, Cuba,—an unpretentious scientific body, full of good faith and disinterested love of science—yet, I believe it would be difficult to find among its members half a dozen sustaining exactly the same opinion in regard to all the phases of yellow fever.

The maxim of Dutroulau—that in this disease it is necessary to see a great deal in order to see correctly, ought to be supplemented by adding that it is necessary at the same time to take very minute clinical notes in order to see intelligently, for all epidemics do not bear the same characteristics, and even all the cases of the same epidemic do not present the same symptoms; there are epidemics so malignant that for a person to fall sick is equivalent to die, in spite of all kinds of treatment, while there are others so benign that even expert diagnosticians confound many cases with other diseases possessing very analogous symptoms. In fact, a typical case of yellow fever, as it is described in the text-books, is very rare; hence the difficulty of the diagnosis.

It suffices to see but a few yellow fever patients to become convinced that this formidable malady constantly presents two distinct stages. The first is a short one, lasting no more than three days, generally called "the stage of reaction;" the second is that of defervescence and decomposition of the blood, known as "the stage of calm," and lasting from a few hours to two weeks, according to the form and character of the epidemic. When the case terminates happily during the first stage, the second is marked only by the beginning of its evolution in convalescence. The more rapidly the two stages succeed one another the more dangerous the case, and *vice versâ*.

In places where yellow fever is endemic, the character of each summer's appearance depends on the telluric, climatological, and hygienic conditions of those places, especially the velocity and direction of the prevailing winds at that time. It is worthy of attention in this regard, the explanation given by Hippocrates of "medical constellations," or atmospheric conflicts, as the pathogeny of epidemic diseases,—a *quid occultum* developed in the atmosphere of certain foci of infection as the sum total of a series of coefficients.

The epidemic forms of uncomplicated yellow fever may with advantage be divided into *ephemeral*, *adynamic*, and *ataxic*. In the ephemeral form the patients suffer the general prodromata of the disease—fever, headache, pain in the back and lower limbs, nausea, epigastric discomfort and tenderness on pressure, etc.—but the fever does not exceed 103°, and lasts only two or three days; vomiting is rare, and if it occurs, it is of a bilious character; the mind is perfectly clear, with no other disturbance of the nervous system than the anxious expression of the face. In this form we have the nearest approach to bilious remittent fever, and in places where yellow fever is endemic it constitutes the so called "acclimatization fever." The patients usually get well in about seven days. In the adynamic form predominate all the symptoms of decomposition of the blood. It always breaks in suddenly with a chill from the hours of six o'clock in the evening to six in the morning, followed by high fever (over 103°), a sense of weight in the head, besides the cephalalgia; the pain in the lumbar region extends around the waist as if having a tied belt, gurgling in the right iliac fossa distinctly perceptible; there is a mahogany coloration of the face and chest; tongue slightly coated, red at the tip and edges; bowels constipated; lessened quantity of urine, highly colored and albuminous; the sclerotic has an icteric tint under the inferior eyelid after the first day of the attack; without much retching altered blood or "black vomit" is ejected, although this symptom has not, in this form of the disease, the great pathognomonic importance generally attributed to it. The febrile signs increase toward evening and lessen toward morning, but do not distinctly remit until the third day. This form is always grave, and when death occurs in the second stage it generally takes place from the seventh to the fourteenth day. In the ataxic form predominates the nervous depression. It is always very grave and rapid in its course, the second stage almost immediately following the first, giving rise to those fulminant cases lasting only forty eight hours, so common in Vera Cruz, and known to the French physicians as "*coup de barre*," or stroke of the bar, on account of the suddenness and intensity of the pain across the loins. In this

[1] Read before the Orleans Parish Medical Society, New Orleans.

form the "black vomit" is always present, and sometimes also hemorrhage from other situations; there are disquietude, delirium, hiccough, photophobia, and once in a while amaurosis, ischuria, and finally collapse or convulsions. Death generally takes place on the fourth or fifth day. It is of good omen if the patient outlive the seventh day.

Yellow fever, however, does not at every appearance and in all localities present exactly the same group of symptoms; for not only the constitution and the peculiar variations in the state of the individual exert a modifying influence, but also the meteorological conditions and the diseases prevailing at the time. The recognition of this dreadful disease, nevertheless, speaking in general terms, is easy. Whenever, during the summer, we are called to see a patient suddenly taken sick with one paroxysm of cold, which occurred when the sun had disappeared from the horizon, followed by rapidly rising fever (102°, 103°, 104°), and accompanied by headache, pain in the back and lower limbs; the face flushed with an anxious expression, and the eyes brilliantly injected and watery; hurried breathing; the stomach very irritable, with great epigastric discomfort and tenderness on pressure, nausea, and anorexia; the tongue moist, slightly coated, sometimes red at the tip and edges, yet otherwise natural; bowels constipated, gurgling in the right iliac fossa; lessened quantity of urine, darker in color and albuminous; general muscular debility; pulse rapid, strong, tense, sometimes dicrotic, with from 90 to 120 pulsations to the minute; skin hot, dry and harsh, and all this without a previous history of yellow fever; then we may unhesitatingly pronounce the disease yellow fever in its incipiency.

[illegible]

Appearance of the Face and Eyes.—Besides the hyperæmia of the face and conjunctiva, and the anxious expression of the countenance, there is always a mahogany coloration of the skin on the forehead, temples, *alæ nasi*, cheeks, and sometimes also at the sides of the neck and front part of the chest—this is called by some authors "the mask" of yellow fever. In an elaborate monograph of Dr. Juan Santos Fernandez, of Havana, Cuba, on the loss of sight in yellow fever, translated by me from the Spanish original,[1] this distinguished oculist calls attention to the hyperæmia of the eyes and the dilatation of the pupil, which in some cases is so marked that it gives to the face a vague and indefinite expression, very similar to that assumed by a drunken man. In the second stage the redness and brilliancy of the eyes diminish, and the rosy color of their tegumentary covering gives place to an icteric tint several hours before the discoloration of the skin is noticeable. Some practitioners pretend to find a direct relation between the intensity of the coloration of the conjunctiva and the severity of the attack, and others, more correctly in my opinion, base the differential diagnosis between yellow fever and malarial fevers on the absence of hyperæmia of this mucous membrane in the latter.

[1] Knapp's Archives of Ophthalmology, vol. x. No. 4, Dec. 1881.

Pulse and Temperature.—The action of the heart and the state of the blood and arteries, as revealed by the pulse in the first stage of yellow fever, are symptomatic of pulmonary engorgement, and this sudden afflux of blood is due, in my opinion, to the damping out of the portal circulation by the deranged liver. During the first two days the pulse is accelerated, with 90 to 110 pulsations to the minute, full and resisting, but at the commencement of the fourth day it changes completely—if the patient really enters in convalescence, the pulse is soft, rhythmical, and natural; but if this deceptive remission of the febrile symptoms is only the transition of the first to the second stage, the pulse shows a marked tendency to disappear, beating threadlike, so slowly as forty-five times, or even less, a minute in unfavorable cases.

Respecting the temperature in yellow fever, we possess the valuable observations of Dr. Joseph Jones, of New Orleans,[1] stating as the result of many investigations, that the maximum elevation of temperature is attained upon the first, second, and third days of the disease, ranging from 102° to 110°; from the third to the fifth it steadily falls, and sinks to the normal standard or below it, to rise again in some fatal cases in the stage of collapse, though it never attains the high temperature characteristic of the first stage.

Headache.—The cephalalgia of yellow fever is aggravating and astrictive, but, as a general rule, never pulsatile. Its prime characteristic is its seat, which is over the eyes, and seems to affect all the muscles of the ocular apparatus supplied by the third pair of nerves, principally the internal rectus muscle. Any movement of the eyeball, or a little pressure on the closed eyelids causes great discomfort.

Pain in the Back and Legs.—The seat of the pain in the back is the lumbar region, and it seems as though it irradiates from the renal plexus. The pain in the legs is located in the upper part of the calf near the popliteal space, and in severe cases it follows the course of the great sciatic nerve, the patient feeling the pain in the pubes twenty four hours before death takes place.

The Black Vomit.—The hemorrhages of yellow fever appear in the second stage, except in the *coup de barre* cases of the ataxic form, in which the two stages are almost blended into one. The blood is viscous, more fluid than natural, and little or not coagulable at all, owing to the loss of fibrin; it exudes from the mucous membrane of the mouth, the nose, the anus, the vagina, and sometimes it comes out also through the ears and eyes.

There are some cases in epidemics of the ephemeral and adynamic forms in which the black vomit is absent, and this so-called "unmistakable pathognomonic symptom" is therefore misleading. Vomiting certainly occurs either spontaneously or provoked by anything taken into the stomach, but the matter ejected has a bitter taste to the patient and all the aspect of bilious and mucous matter

[1] American Practitioner, Sept. 1875, and cited in Nouveau Dictionnaire de Médecine et de Chirurgie

combined, but by no means the characteristic coffee-ground appearance of true black vomit.

In the ataxic form the black vomit is always present, not very frequent or very abundant either, generally one or two a day only. It sometimes happens that just at the moment of dying the patient has one paroxysmal vomit of altered black blood and then dies.

The Urine.—The great peculiarity of this secretion is its constantly acid reaction. Another diagnostic characteristic, as we all know, is the presence of albumen, which, according to Dr. Vidaillet,[1] can be detected twenty-four hours after the onset of the attack by holding a few grammes of the urine in a test-tube, and letting five or six drops of nitric acid run along the interior of the tube, when almost immediately appears a whitish zone dividing the column of urine in two parts, the upper one retaining the same appearance it had before, while the lower assumes a reddish tint. This opaline zone is called by Dr. Vidaillet "the premonitory ring," which he claims is infallibly present in all cases of yellow fever during the second and third days, disappearing entirely during the second stage, when the column of urine divides into two distinct portions on the addition of nitric acid, no matter how carefully poured in. The premonitory ring is soluble in an excess of acid.

In severe cases, when the quantity of albumen has been constantly increasing, epithelial cells and bile are found in the urine, but during the first and second days of the disease, neither tube-casts nor pavimentary epithelium can be detected.

CASE OF PISTOLSHOT WOUND OF THE ABDOMEN, IN WHICH LAPAROTOMY WAS RESORTED TO.[2]

By JOHN H. PACKARD, M.D.,

SURGEON TO THE PENNSYLVANIA HOSPITAL AND HOUSE SURGEON AT ST. LUKE'S HOSPITAL, PHILADELPHIA.

H. W. L., aged about thirty-three, was admitted into the Pennsylvania Hospital, at about 1 A. M., February 10, 1887. He had shortly before been shot in the abdomen, with a ball from a pistol of the calibre known as 38, in the hands of a man much taller than himself, who was standing directly in front of him.

At the time of his admission he presented symptoms of marked, although not profound, collapse. His temperature was 97 5°; his pulse 120; his breathing apparently normal (not counted). When I saw him, at about 1.45, he had reacted in some degree; there had been some vomiting of food with a slight admixture of blood.

The bullet had entered the abdomen about two inches to the left of the umbilicus, and about half an inch below. Laparotomy was at once decided upon, and in its performance I had the advantage of the counsel and assistance of my colleagues, Dr. Hunt and Dr. Morton. Antiseptic precautions were, of course, strictly adhered to throughout.

The wound was first enlarged sufficiently to ascertain the fact that the cavity of the peritoneum had been penetrated, and that hemorrhage had taken place within it. A careful division of the abdominal wall was now made, from the umbilicus to just above the pubes. A catheter was introduced into the bladder, and a small quantity of clear urine was drawn off. The peritoneal cavity was irrigated with a solution of mercuric bichloride (1: 15,000), and the intestines systematically drawn out and examined. Eleven wounds were found, at various portions of the small intestine, one just at the ileo-colic junction. These wounds were all more or less ragged, and varied considerably in size. Lembert's suture, with fine chromicized catgut, was employed; the needle used was straight, and three-sided.

At one point the bullet had torn its way through the bowel, making two large ragged holes directly opposite one another. Here about one inch of the gut was cut away, with a V-shaped portion of mesentery. The edges of the gap thus left in the mesentery were sewed up separately, and then carefully apposed by single sutures. The cut edges of the bowel were brought together, and the Lembert suture used as in the other rents. I did not cut away any of the ragged edges of the wounds, but was careful to apply the sutures so that sound tissues only were placed in contact. No escape of fecal matter seemed to have taken place into the cavity of the peritoneum. At one point the omentum was torn and bleeding; it was caught up and included in a ligature. During the operation, which was necessarily very prolonged, the patient's general condition was for the most part fairly good. At one time the pulse fell alarmingly, but came up very promptly upon the irrigation of the peritoneal cavity with hot water. Very little bleeding was at first perceived, although some large clots were scooped out of the pelvic cavity; but we hoped these had accumulated by the oozing from the wounds above. When, however, the last part of the bowel was reached, fresh clots were found, and it was evident that free hemorrhage was going on at some point. This point became suddenly apparent on the right side of the pelvis at its upper part, where from an oval aperture there was a rapid gush of dark fluid blood, with some pulsatile movement. The tissues bordering this aperture were immediately transfixed with two tenacula at right angles to one another, and a ligature firmly applied. No more bleeding occurred.

The peritoneum was carefully cleansed, the intestines and omentum replaced, and the wound closed with silkworm gut sutures, the edges of the peritoneum being adjusted with special care. A rubber drainage-tube was placed in the wound, which was dressed very much as in a case of ovariotomy. The patient was then, at 4.30 A. M., very gently and cautiously transferred to his bed, with hot-water bags placed around him. His condition was, considering everything, good.

During the latter part of the operation several hypodermatic injections of whiskey were given, and

[1] Archives générales de Médecine, extracted from the Archives de Médecine navale.

[2] Read before the Academy of Surgery of Philadelphia, March 7, 1887.

seemed to have an excellent effect. Only very slight after-effects ensued from the prolonged anæsthesia. Brandy and morphia were given rather freely, until 9 A. M., when champagne was substituted, and gr. x of quinine sulphate were given by suppository. As his pulse flagged, he had a hypodermatic injection of ♏x of tr. of digitalis every hour. He, however, steadily sank, although his mind was clear, and he was able to make an intelligent statement as to the manner in which he received his wound. At about noon his temperature began to rise, and at 3 P. M., it was 103.6°. At 5 P. M., the abdominal cavity was washed out by a stream of distilled water, at 110°, passed through the drainage tube. The effect was good, but only for a short time. His pulse increased in force, his respirations became less shallow, and the tone of his skin improved. Soon, however, he again sank, and died at 6.45 P. M., about eighteen hours after the shooting, and about fourteen hours from the conclusion of the operation.

At the autopsy, eighteen hours after death, the abdomen only was examined. There were some evidences of peritonitis in slight coating of lymph on the serous surfaces, and some adhesion of the intestinal coils to one another. No wounds were found except those that had been sutured, although most diligent and systematic search was made. The intestinal tube was carefully removed, and a current of water made to distend it. Everything held until an extreme degree of pressure was reached, the whole tube being dilated excessively, when one of the sutures close to the border of the mesentery gave way. For practical purposes, the closure had been efficient. There had been no more bleeding. The wounded vessel was found to be the external iliac vein, just beneath Poupart's ligament. Beyond this, along the thigh, there was a track full of blood, along which the bullet had passed to its final resting-place close to the femur. It was very slightly furrowed by contact with the bone.

REMARKS.—Notwithstanding the fatal issue of this case, it seems to me by no means unsatisfactory in the retrospect; and it certainly presents some interesting and instructive points, to which I desire very briefly to call attention.

Although the operation failed to save the man's life, it did in the opinion of all who saw the case prolong it. The man was able to make a clear statement as to the way in which his injury was received, and could have attended to affairs of importance if it had been needful for him to do so.

Laparotomy for penetrating wounds of the belly belongs, of course, to the antiseptic or most recent period of surgery. It was dimly foreshadowed, however, as long ago as 1855, by Guthrie,[1] who says:

"When it is obvious, from internal hemorrhage, or from the discharge of fecal matter, or from the introduction of the finger, by which it can be felt, that a large hole or rent has been made in an intestine, the wound should then be enlarged so as to allow its being brought into sight, when the edges should be secured, be smoothed, and the continuous suture applied in the manner directed, Aph. 391."

Dr. Hunter McGuire, in an address on "Operative Interference in Gunshot Wounds of the Peritoneum," read before the American Medical Association, in 1881, urged that "the wound in the abdominal wall should be enlarged, or the linea alba opened, freely enough to allow a thorough inspection of the injured parts." In a foot-note he refers to the fact that he had advocated the same idea in 1873, before the Virginia Medical Society.

Otis, in the surgical volume of Part II. of the *Medical and Surgical History of the War of the Rebellion*,[2] published in 1876, expresses the opinion that "it appears probable that laparotomy . . . will henceforward be employed with increasing frequency, not only in the treatment of morbid growths, but in obstructions and wounds of the abdominal organs."

Dugas, in the same year, very distinctly and clearly laid down before the Surgical Section of the International Medical Congress the exact course pursued in the case I have reported,—a course which by antiseptic precautions is now rendered far safer than it was when he had the courage to recommend it.

McGuire, in the paper above quoted, refers to Otis and Dugas as having advocated "the suggestion of Legouest for operative interference in intestinal wounds." Legouest, however, can scarcely be considered as the pioneer in this bold advance, unless the following expression is very liberally construed:

"It is always to be feared, in gunshot wounds of the intestine, that one of the perforations may escape the search of the surgeon; hence it is proper to enlarge the wound in the abdominal wall, to draw out the portions of intestine in which the finger perceives evidence of damage, and to stop only when the investigation has reached its utmost limit."[3]

This is going very little farther than the position reached by Guthrie, eight years previously; and to neither of these eminent surgeons did the brilliant idea of abdominal section, properly so-called, suggest itself.

Legouest, in the passage just quoted, touches a question which has always been in my mind in reference to the closure of gunshot wounds of the intestines, and especially since the practice of laparotomy in these cases has assumed its present aspect; and that is as to the possibility of being sure that all the damaged points have been found and secured. The case now reported seems to me to go far to show the certainty with which this essential object can be attained. It is, within my knowledge of the cases on record, second to only one (the successful one of Dr. J. B. Hamilton), in the number of lesions of the bowel. Dr. Randolph Winslow has published[4] an instance in which there were twenty-eight wounds of the intestines and bladder; but these were only discovered at the autopsy, no operation having been performed during life. As to the far

[1] [illegible]

[3] [illegible] the Med. and Surg. Faculty of Maryland, 1885.

greater advantage in this respect of the modern practice over that recommended by Legouest and Guthrie, there can be no question.

Another and most important point gained by the later plan is in the cleansing of the peritoneum. When the surgeon, following the advice of Legouest, felt with his finger for a wounded bowel, drew it out, and sought for other wounds even "to the utmost possible limit," what security had he that there had not been, from some of the openings, an escape of fecal matters into the peritoneal cavity? How could he be sure that when he returned the carefully sutured bowel to its place, and closed the enlarged wound, he was not shutting up within the abdomen substances, which would inevitably provoke fatal peritonitis? It is surely in this respect, as well as in dealing with the mere injury to the bowel, that the extreme boldness of the modern practice is in the highest degree conservative.

I cannot but note with dissent one idea advanced, with some reserve indeed, by Dr. McGuire. He suggests that if his experience is confirmed by that of other observers, "the presence or absence of prolonged shock will help us to determine the presence or absence of visceral lesion." Several cases which have come under my own observation incline me to doubt the reliability of this test. Thus in one instance reported by me last year,[1] a wound of the stomach, liver, and internal mammary artery gave rise to so little shock that the patient, a woman, was able after her admission to the hospital to sit up in bed and undergo a careful physical examination. In another, the previous year, a man who had four wounds of the intestine, scarcely presented any symptoms of collapse until the approach of death from peritonitis several days later.

In the case now reported, the degree of shock manifested was certainly not such as to lead us to suspect not only such extensive damage to the bowel, but copious internal hemorrhage as well.

An important factor in producing death in my case seems to me to have been the great loss of blood from the wound of the iliac vein. And the question may perhaps be raised whether, in any case where upon opening the abdominal cavity a considerable quantity of blood is found to have been effused, it would not be better first to make search for the source of hemorrhage, to secure the vessel or vessels, and then to attend to the lesions of the bowel. There was here, however, a sufficient amount of oozing from different points to account apparently for the formation of the clots first noticed, in the time that had elapsed since the shooting. It would, of course, be the plainest dictate of common sense, if blood were seen pouring out, to stop it. But at the present stage of experience with these procedures, it may not be amiss to suggest that outside sources of hemorrhage,—outside, I mean, of the bowel itself,—should be first of all sought for, as a regular practice; and thus one cause of possible embarrassment, and even of grave risk, be set aside.

As to the actual process of suturing the wounds of the bowel, a few words may be said. None of the wounds were pared of their ragged edges, as generally advised. I omitted doing so on account of the delay that would have been occasioned; on account of the possible loss of substance in some places; and because it seemed to me that whatever was useless would, had the patient recovered, have been simply cast off into the lumen of the bowel, and carried away along with the fecal mass.

The Lembert suture was, as stated, used throughout both in closing the wounds and in uniting the cut ends of the gut where the resection had been done. I employed it because my colleagues favored it, and there was no time for discussion on minor matters. Yet the Gély suture seems to me to be, in some respects, preferable. Let me say, however, that I should not use it as generally described, and as I presume its inventor intended (for I have never seen his original account) that it should be executed. I should merely bring the ends together and tie them, instead of crossing them and reinserting them; thus making, not a continuous suture, but a succession of double interrupted sutures.

Less tissue need be taken up by Gély's suture, so that in a successful case the bowel would be left afterward with its calibre less encroached upon than by Lembert's. The sutures extend along the side of the edge of the wound instead of directly across it; thus there is a sort of splinting of the tissues which would seem likely to give greater firmness to the closure. Moreover, as the thread is carried along the edge of the wound, some time must be saved, since two points of the suture are made with each insertion of the needle.

As to the relative efficiency of the two methods in preserving the apposition of the tissues, I am not aware of any observations warranting a statement; but hope to be able at an early day to make some experiments with a view to testing the question.

The needles used had three-sided spear points; and several times the punctures made by them bled so freely as to demand attention. In any future case I should employ round needles much like those in common use, but shorter.

It will perhaps be noted that in the foregoing account nothing has been said of any search for the bullet. But, in fact, the survey of the abdominal cavity was quite complete, and it seemed certain that the wound of the iliac vein indicated the point at which the missile had passed out of the pelvis into a region where it would be comparatively harmless. It would have been worse than absurd to dissect down along the thigh for an article of so little value or importance, and I do not think the idea crossed the mind of any person in the room.

I offer this clinical record, with the brief comments which the pressure of my other work has allowed me the leisure to make, as a contribution to the accumulating experience of the profession in a most important, but as yet little explored field of surgery.

INTUBATION OF THE LARYNX.

By George W. Mason, M.D.,

Surgeon to St. Joseph's Hospital, Bloomington, Illinois

In the early history of any new and important operation, it is desirable that there be recorded as many cases as possible, from which to make a just

estimate of the value of the operation. For this reason, and because of some personal observations and experiences not noted by other writers, I desire to report the following cases:

Case I.—Dr. M. D. Hull, of Arrowsmith, Ill., attending physician. Eva C., æt. eight and a half years, well nourished and healthy appearing, had been attending school in a neighboring town, where diphtheria had been prevalent. She had been suffering from a "cold" for several days prior to December 10, 1886, when she was removed to her home. Dr. Hull was summoned December 12, and diagnosticated membranous croup, and gave an unfavorable prognosis. His treatment was energetic with chlorate of potash and tincture of iron, together with quinine and calomel, and steam inhalations.

13th. There was much dyspnœa.

14th. I first saw the patient with Dr. Hull at 10 P.M. She had a very labored respiration from laryngeal stenosis, and a "croupy" cough. She was endeavoring to obtain relief by inhaling steam. Her pulse was 144, and temperature elevated. Inspection showed some pharyngitis, but for the most part the fauces were pale and anæmic. On the anterior upper portion of the left anterior pillar of the pharynx there was a spot, the size of a pea, that appeared like the beginning of a diphtheritic patch. From her respiration it was supposed that the membrane had not yet extended below the glottis. A laryngoscopic examination was easily made, and revealed an acute general laryngitis, with no membrane above the vocal cords. A membrane was seen extending from the vocal cords downward, with a tongue-like projection upon the epiglottis.

Intubation was recommended, and promptly consented to by the friends. Assisted by Dr. Hull and the nurse, on the second attempt, I inserted the largest O'Dwyer tube. But, before the thread was removed, the nurse relaxed her hold on the child's arms, when she instantly snatched the thread, and so extracted the tube. After a few minutes rest, on a third attempt, I successfully introduced the tube, giving prompt and great relief to respiration.

Shortly afterward, with a severe cough, she ejected the tube, and immediately afterward, a perfect membranous cast of the trachea three and one half inches long, including the tongue of membrane on the epiglottis before described. The upper portion was thick, the lower thin. Respiration was so much relieved that it was not necessary to reintroduce the tube. The previous treatment was continued with calomel gr. ss every hour.

15th. Patient doing well. Respiration good. A spray of solution of pepsin was recommended.

16th. 9 P.M. I was summoned to introduce the tube again, but found no laryngeal dyspnœa to require interference. Pulse 130. Temperature 102.2°. Respiration fairly good. Tongue furred. Pillars of the fauces red. A diphtheritic membrane three-fourths by one and one half inches was seen on the posterior wall of the pharynx, where I had caused a slight abrasion of the mucous membrane with my finger-nail as I made my first attempt to raise the epiglottis when inserting the tube. The capacious pharynx gave another good opportunity to use the laryngoscope. There was general laryngitis, the membrane being intensely red. New membrane could be seen forming below the vocal cords, but not upon them. Whistling, sibilant, and subcrepitant râles were heard over the upper lobe of the left lung, and sibilant râles over the lower lobe of the right lung posteriorly. She complained of pain in her head and abdomen. The latter was ascribed to the calomel. Intubation was not indicated. Treatment was continued as before with local applications of a strong carbolic acid solution to the throat. Dr. Hull informs me that the patient died the next morning from congestion of the lungs.

Case II.—Dr. H. C. Littlejohn, of Farmer City, Illinois, attending physician. Milton S., æt. eight years, living in the same town where the first patient contracted her disease, was a slender boy, healthy, but not robust. Two weeks previous to this sickness he had had a mild "diphtheritic sore throat," from which he apparently recovered. He was taken ill on December 20, 1886, from exposure near an open window while at school, and was treated with domestic remedies. The next day difficult respiration developed, and Dr. Littlejohn was called. He gave a diagnosis of membranous croup, and an unfavorable prognosis. This opinion was subsequently concurred in by Drs. Gardner and Norris.

23d. By noon the symptoms became so urgent that the only relief to be offered was by a surgical operation. I was summoned by telephone to perform either intubation or tracheotomy. About 4 P.M., when I reached the patient, respiration was so difficult that the child could not have lived till midnight unless relieved. Pulse 150; temperature not high. Membrane thought not to be below the glottis. Laryngoscopic examination was readily made, and revealed general congestion and inflammation of the pharynx and larynx. There was no membrane above the glottis, but one extended from that point downward. The chink of the glottis was very much narrowed.

The operation was explained and readily consented to by the patient and his parents. With the assistance of Dr. Littlejohn and a friend, I at once operated, and in a few seconds had the largest O'Dwyer tube successfully in the larynx. The results were immediate. After a very few minutes of coughing, the respiration became as quiet as in health; the countenance became bright, and general relief was experienced. In ten minutes he had fallen into a quiet sleep. Half an hour later he had taken some water and a little nourishment. The irritation from the presence of the tube had entirely subsided within an hour. At 5 P.M. pulse 144; temperature 101.5°; respiration 21. At 9 30 P.M., pulse 136; temperature 100.8°. Has been sleeping most of the time. Wants to know "if he can go down town to-morrow." He has taken a small cup of coffee, and a tumbler and a half of milk and cream, besides hourly doses of $\frac{1}{64}$ grain of bichloride of mercury. Has difficulty in swallowing, which is to some extent overcome by sipping from a saucer. The air in the room is kept charged with steam.

24th. Temperature at one time, 104°.

25th. Pulse 118; temperature 102°; respiration 26. Swallows fairly well; complains of the tube hurting him in swallowing; takes nourishment well; stomach was slightly irritable, but is better; no signs of lung trouble. Has been taking digitalis and quinine, and using a steam spray with carbolic acid, and also pepsin, with relief. The membrane or mucus seems loose in the throat.

26th. Pulse 104; temperature 100°; respiration 24. Appears bright; has vomited a little to-day; the right lung is slightly affected.

28th. At 3.45 P.M., just five days after its insertion, assisted by Dr. Littlejohn, I removed the tube. There was very little coughing. Some rusty mucopurulent matter, as of broken-down membrane, was expectorated. The patient took nourishment better, having refused it for the last day or two. Laryngoscopic examination showed inflammation, but no membrane. There was some evidence of systemic infection, and a feeble respiratory murmur over the base of the right lung behind. The treatment, according to indications, had been digitalis, quinine, carbonate of ammonia, and whiskey. The bichloride of mercury, which had been increased to $\frac{1}{20}$ grain, was now discontinued. At 9.30 P.M. Pulse 114: temperature 101.3°; respiration 30.

30th. Dr. Littlejohn reports the patient doing very well. Pulse 104; temperature 99°. Lung clearing nicely; tongue has begun to clean; expression good; takes more food; breathing very natural. His convalescence was uneventful and his recovery complete.

CASE III.—Dr. J. L. White, of Bloomington, Illinois, attending physician. Ida L., æt. about four years, was an inmate of the Illinois Soldiers' Orphans' Home, at Normal, Illinois, having been recently admitted. She had been suffering from whooping-cough, and recently developed symptoms of croupous pneumonia, or, considering the subsequent history, membranous bronchitis. Still later, membranous croup supervened, about five days from the beginning of the lung trouble.

By the use of calomel and jaborandi, combined with steam inhalations from lime water, and supporting treatment, there appeared to be a beginning of resolution in the lungs. Laryngeal dyspnœa had existed about three days before the operation. A portion of membrane about as long as one's little finger had been expectorated with some relief.

January 15, 1887. 10 A.M. I first saw the patient. She was apparently moribund; face pallid; aëration of blood bad; respiration feeble and croupy; pulse rapid and feeble. Without delay I performed intubation with the assistance of Dr. White and the nurse. The patient rallied very soon. The eyes, which had been dull, half closed, and dry with inspissated secretions, became bright and clear at once; respiration and aëration improved immediately. There was but little cough from the presence of the tube. In ten minutes the patient was in a quiet, natural sleep, with good respiration and an improved pulse. It looked as though she might recover. At 8.45 P.M., Dr. White reported the patient as doing very well, having strength, and retaining rectal alimentation, and thought she would recover. She died about 10 P.M., with no sign of dyspnœa, but quietly—probably from asthenia. When the tube was removed next day it was found clear.

REMARKS.—Out of these three cases, one, the second, was saved—not an unfavorable showing when the character of the cases is considered. The first died probably from extension of the membrane to the lungs. The third case was as unfavorable as it is possible to imagine, and the final result was to be anticipated. Yet even in this case intubation did all that was possible, in that it prevented death from laryngeal stenosis.

It is interesting to note that satisfactory laryngoscopic examination was had in two of the cases:

CASE I., by the subsequent appearance of diphtheritic membrane in the fauces, has a bearing upon the identity of membranous croup and diphtheria. In each case the nature of the operation was carefully explained to the patient, and thus his willing coöperation was secured.

CASE III., from a retrospective view, appears to have been one in which the membrane first formed in the bronchial tubes, and afterward extended upward to the larynx—just the reverse of what usually takes place.

A little point, but none the less valuable, is that the nail on the index finger of the left hand should be trimmed as short as possible, that no injury may be possible from its introduction into the throat.

From my previous unfavorable results with tracheotomy, and from my experience so far with intubation of the larynx, I can mention the following points in favor of the latter operation:

1. It involves no cutting and is bloodless, hence,
2. Parents and friends readily consent to it when they would not to tracheotomy.
3. It gives a larger percentage of recoveries.
4. There is no perceptible shock after the operation.
5. There is no risk of systemic infection because of an open wound.
6. It does not expose the lungs to inflammation by the air not being prepared for inhalation by passing through the upper air passages.
7. It does not preclude a subsequent tracheotomy.

TOXIC EFFECTS OF SMALL DOSES OF DUBOISINE.

BY CHARLES W. KOLLOCK, M.D.,
OF CHARLESTON, SOUTH CAROLINA.

Two instances of poisoning by small doses of duboisine have lately come to my notice; one reported by Dr. Chadwick at a meeting of the Leeds and West Riding Medico-Chirurgical Society, recorded in the *Lancet* of January 8, 1887, and the second occurring in my own practice.

In the former, $\frac{1}{100}$ gr. of the drug "instilled for examination of a senile cataract, produced a state of delirium lasting many hours, leaving the patient totally unconscious of what had occurred. There was great muscular weakness, and strange actions were performed."

In the latter case a solution of duboisia sulph. (gr. j to aq. dest. f3 ij) was prescribed for the purpose of examining the refraction of the eyes. One drop was instilled in each eye at 2 P.M., after which the patient took a nap. He awoke feeling somewhat dizzy, but had another drop put in each eye at 4 P.M. Upon going to dinner soon after he became so dizzy and blind (as he expressed it) that he was obliged to leave the table and lie down. I saw him about an hour later—three hours after first instillation. He was in bed, face flushed, pupils widely dilated, and body moving uneasily from side to side. Although apparently rational, his speech was thick, and remarks frequently without meaning or irrelevant. There was no headache, but mouth and throat were very dry, and he drank copiously of water. I directed that he be kept quiet, and that no more of the drug be used.

The next morning he came with his sister for examination, having fully recovered from the toxic effects of the drug. His sister, a bright and intelligent young lady, told me that although he seemed at times sensible, still he did not get quietly to sleep until 5 A.M., and that he continually talked to her as if she was some one else, but when asked who she was, invariably said "sister." The patient had no recollection whatever after leaving the dinner-table about 4 P.M., until late in the night, and did not remember my call, though he answered questions rationally. He said that he frequently wished to address some particular remark, but almost invariably said something else, and, though aware of his mistake, could not correct it.

The druggist, a very reliable man, was sure the prescription was properly compounded, and the prescription was correctly written, as examination afterward proved. The patient is strong and healthy, twenty years of age, but his sister says he becomes very delirious with the slightest attack of fever.

Dr. Chadwick "suggested that the susceptibility to this drug reached its maximum in *old age* [italics mine], and that similarity between the symptoms and those of senile atrophy, popularly known as 'softening of the brain,' might suggest that its action was by causing spasm of the arterioles, and might indicate a possible liability to that form of pathological change." The similarity between the toxic effects of the drug upon the two cases is marked; but while one was old and probably not strong, the other was a young man, stout and strong, of twenty years of age. Whether the symptoms were due to spasm of the arterioles, or not, I do not pretend to say, but we can scarcely draw conclusions from the age, as the effects were the same and ages widely different. $\frac{1}{100}$ gr. was used in Dr. Chadwick's case, and in mine $\frac{1}{150}$ gr. was instilled in each eye, which equals $\frac{1}{75}$ gr. in all, and this amount was twice instilled, with an interval of two hours. An accurate test of the pipette used for dropping the solution into the conjunctival cul-de-sac showed two drops to the minim. The medicine was administered by the sister, with most careful instructions to instil one drop in each eye at a time.

I may add that the errors of refraction were as follows: R., +1.25 D.; L., +1.75 D.

THE FIRST FIFTY CÆSAREAN OPERATIONS UNDER THE SANGER METHOD.

By ROBERT P. HARRIS, M.D.,
OF PHILADELPHIA.

In this journal on July 17, 1886, I presented a full tabular record of 28 Sänger operations, and propose at a future day, when all the particulars can be obtained, to extend the same to fifty. Since this method has been so much modified and simplified, as compared with the original device of Sänger; leaving out both his muscular resection, and separation of the peritoneal coat, it has been contended by some writers that there is no propriety in any longer coupling his name with it. This I for one cannot advocate, for there are other important features still left, in the seroso-serous multiple suturing of the uterine wound, as originally advocated by Dr. Sänger, which constitute the chief value in the method, over the old Cæsarean section. It is true that the seroso-serous welting of the peritoneum originated with Jobert (de Lamballe), who applied it to intestinal wounds. It is also true that the interrupted superficial suture of the peritoneum, by which its serous surfaces are kept in apposition, was devised by Lembert, for intestinal closing. It is also to be admitted that Dr. Sänger did not test his method for four and a half years after its first trial by Leopold, of Dresden, and stands eleventh in chronological order in my table, and twelfth in fact, as shown by a recently communicated record; and that he was the tenth man to operate. But who was it who advocated first, in writing, the application of the Jobert-Lembert system of suturing to the uterine wound in the Cæsarean section: and who also advocated the importance of employing many deep and superficial stitches in this wound? The uterine wound was sutured in the United States more than twenty times before Dr. Sänger wrote his paper, but no one ever turned in the peritoneum, and few used more than six deep sutures, the maximum being ten, and that number in only two instances; in 1870, and in 1874. The case of 1874 recovered, but was not reported until 1885, after the operator had done a second operation. In his report, Dr. Ingram, of Montezuma, Georgia, says that he sutured the uterus with carbolized silk, inserting 3 deep stitches, 3 more superficial, and 4 into the peritoneum only. In the records of 151 American Cæsarean cases, this is the only mention made of using peritoneal sutures prior to 1882. The value of the multiple system of suturing lies in the fact that the gaping *force* is so divided, as to reduce very materially the individual tension upon each stitch, and thus is prevented what had been so often found on autopsy, a gaping wound, with escaped uterine discharge in the peritoneal cavity. To Dr. Sänger's writing is certainly due the improved results in the Cæsarean operation in Germany. He was the means of starting a series of improvements which have culminated in the present system of operation, to which, by an almost universal assent, the name of "Sänger" has been given.

At the time of Leopold's first trial of the Sänger method, on May 25, 1880, there had been seven trials of the Porro operation in Germany, all fatal

to the women, but saving four children. A subsequent experience diminished the percentage of mortality, but still 16 women were lost out of 27, and 8 of their children.

Out of the discouragement produced by the Porro mortality in Germany grew several modifications of the Cæsarean operation, only one of which has stood the test of experience and become popular by success. The Sänger method has certainly worked a Cæsarean revolution in Germany, and to-day the Porro operation, even when as successful as in Milan, has an unapproachable competitor; for the success in her Maternity is far exceeded by that of Dresden.

The early record of the Porro operation shows that 20 women and 41 children were saved under the first 50, and 20 women and 36 children under the second 50.

Under the first 50 Sänger operations 35 women have been saved, or 70 per cent. against 40 by the Porro; 43 children have been saved, and probably 46—3 are yet to hear from. These cases are distributed as follows:

Countries	Cases.	Women saved.	Women lost.	Children saved.	Children lost.	Number of operations.	Per cent. of women saved.
Germany,	33	29	4	36[1]	1	16	87 $\frac{8}{9}$
Austria,	5	2	3	5	0	3	40
United States	5	0	5	2	3	5	0
Italy,	3	2	1	3	0	2	66 $\frac{2}{3}$
Russia,	2	0	2	2	0	2	0
France,	1	1	0	1	0	1	
Switzerland,	1	1	0	?2	...	1	
Total	50	35	15	43[1,2]	4	30	

Leipzig Maternity,	operations	7,	women saved	7,	children saved	7		
Dresden	"	"	"	15,	"	"	14,	"	"	15
Innspruck	"	"	"	2,	"	"	2,	"	"	2
				24			23			24

Mr. Lawson Tait will be obliged to modify somewhat his opinion as to the mortality of the Cæsarean operation, which, when properly performed and promptly resorted to, is capable of securing such marvellous results to mothers and children. He will also have to reduce his comparative estimate of the Porro operation, which has taken a second place in its results. He, however, is inclined to favor the latter, because after the former the woman may again become pregnant, and require a repetition of the operation, which has eight times happened in the United States, and once again for a third time.

I return thanks to Dr. Sänger for repeated acts of kindness in furnishing me with the records of Cæsarean operations, some of which were communicated by their operators to him, and have not yet been published.

[1] Two to hear from; children probably living.

[2] One to hear from; child probably saved.

HOSPITAL NOTES.

GERMAN HOSPITAL.

Service of JOHN B. DEAVER, M.D.

TREPHINING FOR HEMORRHAGE FROM MIDDLE MENINGEAL ARTERY.

Reported by DR. GEORGE A. BODAMER, Resident Physician in Chief.

A. R., aged eighteen, was admitted to the German Hospital, December 17, 1886, with pistolshot wound over the left temporal region; the history of the case is as follows: While A. R. was playing with several companions, one of them, with a single-barreled 22 calibre pistol, attempted to shoot over his head, when the hand in which the pistol was held, being but about twelve inches away from the side of the head, was drawn down by another companion, and the pistol accidentally discharged.

Upon probing for the bullet the external table of the skull at the point corresponding to the wound in the scalp was found denuded of its periosteal covering and slightly roughened. The patient at the time of admission presented no head symptoms, was perfectly conscious, and suffered no more pain than usually accompanies such wounds. The wound was dressed antiseptically, and the patient was placed in bed. Upon making his visit through the wards the next morning Dr. Bodamer noticed that symptoms of aphasia had developed, and he notified Dr. Deaver, the attending surgeon on duty, of the nature of the case.

Upon the arrival of Dr. Deaver, the patient was taken into the clinic, and in the presence of the class was etherized and trephined. The outer wall of the cranium, at a point measuring two inches posterior to the external angular process of the frontal bone and two inches above the zygomatic arch, was exposed by dissecting up a horseshoe-shaped flap from the scalp. This was the point of the skull with which the ball came in contact, and being immediately over the base of the second and third frontal convolutions and the commencement of the ascending frontal convolution, the portion of the hemisphere in relation to the ascending limb of the fissure of Sylvius and the lower extremity of the fissure of Rolando, which region is known as Broca's convolution, or the region of speech.

The roughening which was detected at this point was caused by a small portion of the bullet imbedded in the outer table of the skull. The remaining part of the bullet was found one inch behind and below this point. It lay beneath the temporal muscle, and had assumed a rounded and flattened form. The trephine included the roughened portion of the skull. Upon removal of the section of bone, the internal table was found to be fractured with no depression of the fragments.

Upon the dura mater at this point was seen a clot of blood caused by hemorrhage from the middle meningeal artery. This was removed, catgut drainage was placed under the flap, the flap adjusted but not stitched, and the part dressed antiseptically.

As soon as the patient recovered from the effects of ether, no symptoms of asphasia remained, and he was again able to converse.

On the morning of the day of operation the tempera-

ture was 100° F., the following morning was 98.3° F., and remained from this time normal. He was discharged cured, January 22, 1887.

Treatment.—Ordinary treatment was pursued, viz., absolute rest; cold to the head; calomel, bromides, and a restricted diet. Patient was not permitted to get out of bed for four weeks.

Dr. Bodamer saw the patient on March 3d, when he stated that he was feeling as well as ever.

MEDICAL PROGRESS.

NEW TREATMENT OF PHTHISIS.—A new method of treating phthisis has been proposed, but apparently as yet but slightly tried, by PROFESSOR KREMIANSKI, who read a paper on that subject at the recent Moscow Medical Congress, which provoked a good deal of discussion. The idea is based, first, on the fatal effect of the most dilute solution of aniline on Koch's bacillus; and, secondly, on the fact that aniline seems to be but slightly, if at all, poisonous to the human body. Professor Kremianski proposes to introduce aniline into the lungs, and, indeed, the circulation generally, by inhalation, so that the phthisis bacilli should be bathed in a very weak solution of aniline, wherever they may be. This, he thinks, would kill them, and render even pulmonary cavities free from bacilli, so bringing them into the condition of healthy granulating ulcers, which may be expected to cicatrize. A committee has been appointed, including Professors Subbotin and Ostroumoff, who expressed themselves at the meeting as strongly opposed to the plan, for the purpose of observing Professor Kremianski's proposed experiments in one of the Moscow hospitals. Two cases in which the aniline treatment had been successfully tried were detailed. A lad of eighteen, who had undoubted phthisis, was ordered a four drop dose of aniline (but took by mistake three times the proper quantity) combined with nux vomica, mint water, and antifebrin, his diet being 'good, including dried meat, kvas and oranges. He was also given inhalations of atomized aniline. A remarkable change took place almost immediately, all the râles disappearing; his temperature, respiration, and pulse becoming normal. His skin, however, assumed a slightly blue tinge, but whether this was as permanent as the cure is represented to have been is not stated. The second case was a complicated one, there being tubercular peritonitis and meningitis, together with typhoid fever, present at the same time as pulmonary phthisis. Aniline inhalations, washing out the pulmonary cavities with corrosive sublimate and antifebrin, were employed, together with a special acid diet, as in the other case. Here, too, the results are said to have been remarkably good, the bacilli disappearing from the sputum, and the patient regaining his health entirely. No mention is made in the abstract published by the *Vrach* of any change of color in this patient's skin. Amongst the various replies that were made to Professor Kremianski, DR. ZAKRZHEVSKI, of Helsingfors, remarked that, admitting the facts as stated, still there was nothing to show that the aniline had been the cause of the cures. He himself had had surprisingly good results in phthisical cases, the disease becoming completely arrested by simply giving increased nourishment and prescribing antipyrin.—*Lancet*, March 5, 1887.

TREATMENT OF DIPHTHERIA.—The following is the treatment recommended by Dr. John Irving as quoted in the *Journal of Laryngology* for March, 1887. In cases uncomplicated by laryngeal symptoms the writer regards this as specific:

℞.—Liq. ferri dialysati . . . . ℥ss.
Glycerini acid. carbol. pur. (B.P.). ℥ss.
Glycerini pur. . . . . ℥iss.
Syrupi simplicis . . . . ℥iss.
Misce bene, et adde aquam ad ℥ij.

One teaspoonful every two hours, and continue for eight days.

In a case of laryngeal diphtheria, the author uses

℞.—Pot. iod. . . . . gr. v.
Sol. nitro-glycer. (1 per cent.) . ♏iv.
Vin. antimonialis . . . . ♏xlvis.
Glycerini pur. . . . . ℥ij.
Aq. ad . . . . . ℥ij.
Misce. One teaspoonful every two hours.

INTRAOCULAR CYSTICERCUS.—DR. VAN DER LAAN, writing in a Lisbon journal, gives an account of an ophthalmic case which puzzled him for some time. A man had been suffering from inflammation in the left eye for about a year. On examination there were found serious irido-choroiditis, almost entire loss of vision, opacity of cornea, and increased intraocular tension. Several times paracentesis was performed with some benefit. Iridectomy being refused, mercurials and purgatives were given for twelve months, during which time considerable improvement had taken place, ultimately permitting an ophthalmoscopical examination to be made. The retina was seen to bulge forward in one spot, where it was of a yellowish-white, the prominence increasing as time went on. It was observed that its form varied, being oblong and round by turns; the patient also said that he sometimes felt something moving in his eye. He then remembered that, when two years previously he had consulted a country practitioner, he had stated that he could "detect an organism, possibly the ovum of a tænia," a diagnosis which now proved to be correct. Dr. Van der Lann has published descriptions of the only two other cases of intraocular cysticerci he has seen in Portugal, which in many points differed from this case. He does not propose to operate until the cysticercus has succeeded in perforating the retina and thrusting its head and neck into the vitreous, when he hopes by means of a sclero-choroidal incision to free the patient from his parasite and to preserve the sight of the eye.—*Lancet*, March 5, 1887.

DIPHTHERITIC PARALYSIS OF THE OCULAR MUSCLES.—REMAK found this phenomenon present in 100 cases of diphtheria; it manifested itself from two to six weeks after the first symptoms of the malady and most often was accompanied by paralysis of accommodation.

Only one of those afflicted presented the association of mydriasis with paralysis of the ciliary muscles; twenty-eight were simultaneously attacked by paralysis of the soft palate with the ocular symptoms;

one patient had paralysis of the third and sixth nerves. The last mentioned patient presented in addition tabetic symptoms; at the autopsy hyperæmia and minute hemorrhages were found in the nervous centres.

Diplopia was present in most of the cases. The knee reflexes were lacking in four cases, and visual acuteness was diminished in the greater number. Remak does not share the opinion of Nagel, who attributes visual troubles after diphtheria to a neuritis caused by the diphtheritic virus.—*L' Union Médicale*, February 17, 1887.

Von Frisch's Conclusions upon Pasteur's Method.—At a recent meeting of the Vienna Academy of Sciences von Frisch reported his conclusions, after reviewing the work of Pasteur.

1. Hydrophobic poison exists in its most concentrated form in the central nervous system of the infected animal.

2. Small amounts of the cerebro-spinal substance of an animal which died from rabies, when injected subdurally into another animal, produce, after incubation periods of varying length, the same disease without fail; and this process may be repeated.

3. After subdural injection with portions of the spinal cord of men who have perished from hydrophobia, animals become ill with a disease which manifests identical symptoms, and has the same period of incubation; the identity of the process in men and animals seems established.

4. Hypodermatic injection of cerebro-spinal substance results in a less reliable infection and a longer incubation period than when the injection is subdural.

5. The quantity of the virus injected hypodermatically seems to be in inverse ratio to the length of the period of incubation; the less the quantity the longer the time.

6. By the progressive transmission by subdural injection of cerebro-spinal virus, there results, after a series of cultures, a shortening of the time of incubation, which is at first irregular, then regular, and finally cumulative.

7. The virus obtained from Pasteur, obtained by forty or fifty generations in rabbits, whose period of incubation is fixed for seven days, exceeds in strength the virus of "street rabies," not only in that its resulting disease appears earlier, but also in that animals inoculated with it by both subdural and hypodermatic injection invariably acquire the disease.

8. Pasteur's "seven days' incubation virus" varies in its period from six to twelve days; a virus of equal intensity results from the second and third generation of "street rabies."

9. The obtaining of a virus of seven days' incubation period can be accomplished by other methods than those followed by Pasteur, and a result obtained more quickly.

10. Drying the cerebro-spinal virus over potassium hydrate, at a temperature of 20° C., continuously diminished its power until, in from fourteen to sixteen days, it became inert.

11. Animals, the subjects of experiments, which had been inoculated with virus weakened by successive dryings, were protected by this weaker virus against the action of the stronger, provided inoculations with the stronger did not follow each other in too rapid succession.

12. Animals which had been inoculated by hypodermatic injection with virus increasing in intensity during ten days, were found not to be protected against infection with "street rabies," as Pasteur states, and must be treated by subdural injection to be positively safe.

13. Rabbits and dogs which had been inoculated by trephining in the subdural space with the virus of "street rabies," and then received preventive inoculation with a virus of sixteen days' time of incubation—Pasteur's method—became ill with rabies; a dog which escaped the disease from the first inoculation was reinoculated fourteen weeks later by trephining, and developed rabies eight days after infection.

14. In criticism of the above results Pasteur claims that the preventive inoculations were made too tardily. He recommends inoculation within twenty-four hours after the infection, inoculations every two hours, and repetition of the whole series of inoculations; experiments made by the writer gave not a single good result from this method; animals so treated acquired rabies.

15. These experiments, however, showed the following important results: That by the rapid repetition of inoculations with virus of increasing virulence, protection on the part of animals inoculated with weaker virus against subsequent inoculations with stronger virus is not to be expected. A number of rabbits and dogs which served in control experiments, and on which was performed intensive inoculation without previous infection, were, in the greater number of cases, attacked by rabies.

16. Animals which received the preventive inoculation after subcutaneous infection with "street rabies," were less liable to death from rabies, especially when the time extended to thirty-four days.

Von Frisch concludes that much more work must be done before it is demonstrated that animals can be protected from rabies by inoculation; that no real ground exists for the belief in the efficacy of preventive inoculation in the human subject, while there is a strong probability that through inoculation of virus disease itself may be transmitted.—*Berliner klinische Wochenschrift*, February 7, 1887.

Antipyrine as a Styptic.—Henocque and Huchard have used antipyrine for bleeding from the nose and on wounds on the hand and fingers. They applied eight grains by dusting on the wounds.—*American Journal of Pharmacy*, March, 1887.

Pregnancy in an Imperfectly Canalized Uterine Cornu.—Dr. Netzel mentions, in a Scandinavian journal, a rare case of pregnancy occurring in the imperfectly canalized half of a bicornate uterus. The movements of the child had ceased in the thirty-third week of conception, and from that time the woman became thin and felt ill. Five months later Dr. Netzel was called in; the diagnosis was uncertain. He could not find anything corresponding to an extrauterine pregancy, and it was clearly not a normal intrauterine one. He performed laparotomy, and thus discovered that conception had taken place in the right half of a bicornate uterus. An elastic ligature was applied round the base of the tumor. The uterus was opened and a macerated fœtus extracted. The half of the uterus was amputated with the tube and the ovary. All went well until a month after the operation, when an abscess

formed in the cicatrix of the abdominal wound, which was followed by a fistula. A quantity of silk and elastic ligatures came away a month later, and the woman ultimately recovered completely. Dr. Netzel thinks the rarity of such cases causes them to be confounded with extrauterine pregnancies, and with the "missed labors" of English obstetricians. He is of opinion that a more frequent resort to laparotomy would be of much service in throwing light on the subject. He mentions eight more or less doubtful cases as occurring in literature, including one reported by Dr. Keith, of Edinburgh. —*Lancet*, March 5, 1887.

IODOFORM AND SILVER.—A curious effect of iodoform upon silver is reported by Dr. Poncet, who had his attention directed to it by a patient, to whom he had been applying iodoform dressings, telling him that all soups and other diet for which she used a silver spoon had a very disagreeable taste, and the spoon itself had a garlicky odor. Upon investigating the subject Dr. Poncet found that silver that has been in contact with iodoform, or which is even touched by the fingers after they have been in contact with iodoform, acquires a nauseous odor, resembling that of garlic, which becomes more perceptible upon rubbing the silver. A drop of saliva from a patient fully under the influence of iodoform is said to be sufficient to impart this odor to silver, or the mere exposure of iodoform and silver in the neighborhood of one another. The odor is not that of iodoform, but is thought to be due to a decomposition product.—*Medical Press and Circular*, January 12, 1887.

CATALEPSY IN A MOTHER AND CHILD.—DR. VAN SCHOOT discusses in a Dutch medical journal a case of convulsive seizures of a peculiar kind in a woman in the seventh month of pregnancy. When he first saw her she was motionless, her face being cyanotic, but her temperature, respiration, and pulse normal. She was quite unconscious, and the slightly dilated pupils did not react to light. The arms were flexed at right angles, requiring some force to move the forearms. By means of chloroform all the contracted muscles relaxed, and some hours' sleep was obtained. Afterward she remembered nothing of the fit, but she stated that all movements of the fœtus seemed to have ceased, and no heart sounds could be detected. These attacks were repeated frequently for a fortnight, the urine being quite normal all the time. Large doses of bromide were given without effect, but some amelioration was produced by sulphate of atropine. Latterly the attacks were associated with considerable movements of the abdominal muscles. Some temporary benefit was obtained by subcutaneous injections of pilocarpine. At the conclusion of a fortnight from the first attack labor came on, a female child being born alive, which, however, died in a week's time, after repeated convulsions similar to those affecting the mother. The mother had no attack till the fifth day (the same day that the child's first attack occurred). After this there was only one more attack two days later, complete recovery ultimately taking place. The author, referring to the diagnosis, is disposed to exclude eclampsia, because, although there were clonic contractions of the abdominal muscles, the main spasm—indeed, at first the only kind of spasm—was tonic. The entire absence of albuminuria, too, tends to exclude eclampsia. Again, epilepsy may be excluded, as after the tonic no clonic spasms occurred, and as the limbs remained fixed in a certain position for one or two hours. He therefore considers that the attacks were of a cataleptic nature, both in the mother and child.—*Lancet*, March 5, 1887.

EXPERIMENTS UPON THE EFFECTS PRODUCED BY STEEL-COATED PROJECTILES OF SMALL CALIBRE.—At a recent meeting of the Surgical Society of Paris, M. CHAUVEL reported the following experiments with projectiles from ½ of an inch to 1¼ inches long and weighing from ½ to 1 ounce whose core was lead, but whose envelope was steel.

Ten experiments were made by firing with full charges at distances varying from 30 to 50 feet. The results were the same as those with other projectiles: the bones were split; the visceral wounds were considerable, and more cadavera, placed in succession, were perforated than with other missiles; the balls were not deformed.

In a second series of experiments but half a charge of explosive was used, and the velocity was lessened one-third. The wounds of the soft parts produced were not extensive, the apertures were not ragged, small, and the tracks of the wounds straight.

In bony tissues the cancellous extremities were pierced as by a trocar; the periosteal wound was small, but frequently of considerable length.

In the compact tissues the lesions were comminuted; there were numerous fragments and long fissures.

The conclusion was reached that these bullets were no more humane for use in warfare than those usually employed.—*Journal de Médecine*, February 20, 1887.

A NEW METHOD OF CULTIVATING TUBERCLE BACILLI. —In the *Annales de l'Institut Pasteur*, MM. NOCARD and ROUX describe some valuable experiments which they have been making on the tubercle bacillus. As is well known, Koch only succeeded in obtaining satisfactory cultivations in solidified blood-serum; and all who have attempted to cultivate these organisms have found it a matter of considerable difficulty. M. Nocard, in a previous paper, stated that he had obtained better cultivations when he added to the serum, before its solidification, 1 per cent. of peptone, 0.25 per cent. of chloride of sodium, 0.25 per cent. of cane-sugar. He noticed, however, that the surface of this material after a time became covered with a thin, dry, iridescent pellicle, due probably to desiccation and oxidation of the superficial layer; and that in this material the bacilli did not grow well. To obviate this, the authors added a small quantity of glycerine to the material, and found that they obtained better growth than previously. They then tried the effect of adding glycerine to nutritive material solidified by adding agar-agar, and found that, when 6 to 8 per cent. of glycerine was added, copious growth of the tubercle bacillus was obtained. This is a very important result, as the material is easily prepared, and as by its aid plate cultivations can be made. The authors have also found that, by the addition of 5 per cent. of glycerine to various cultivating fluids, excellent growth is obtained in the form of flocculi at the bottom of the flask, somewhat resembling cultivations of anthrax bacilli.—*British Medical Journal*, March 5, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

Address, LEA BROTHERS & CO.,

PHILADELPHIA.

SATURDAY, MARCH 26, 1887.

EXCISION OF INTERNAL PILES.

THREE hundred consecutive cases of internal hemorrhoids cured by excision, without a death, a single instance of secondary bleeding and not followed by such complications as ulceration, abscess, stricture, or fecal incontinence, is the record of WALTER WHITEHEAD, of Manchester, which may be found in *The Brit. Med. Journ.* for Feb. 26, 1887.

The modified operation of excision, as performed by Whitehead, is based upon the frequency of relapse after the ordinary procedures resorted to on account of the dread of hemorrhage, the cause of which recurrence is that the vessels not only constitute individual tumors, but that the entire plexus of veins surrounding the gut is involved. The removal of the main protuberances has, therefore, no effect upon the minute venous radicles which exist between and behind them, since they soon enlarge, and, in their turn, give rise to new tumors. This disposition of the vessels has been revealed by the numerous operations practised by Whitehead, so that the truth of his assertions cannot be denied.

The operation is performed as follows: The anæsthetized patient having been placed in the lithotomy position, and the sphincters paralyzed by stretching with the fingers, the mucous membrane is divided, with scissors and forceps, at its junction with the skin around the entire circumference of the bowel, every irregularity of the skin being carefully followed. In this stage of the operation the incisions through the mucous membrane should commence posteriorly, and then be carried along the sides in succession, before completing the circle above, so that any oozing of blood may be below the work as it proceeds. The attachments of the mucous membrane and piles to the sphincters is then rapidly severed with the closed scissors or fingers, when the former, thus separated from the submucous bed on which they rested, are pulled down, and the hemorrhoids brought below the margin of the skin. Up to this point there is practically no bleeding; but in the next stage of the procedure, which consists in transverse division of the mucous membrane above the piles, the vessels are necessarily cut. To guard against hemorrhage, the mucous membrane should be divided by degrees, and each vessel twisted as it is cut. Before making any further incision in the bowel, the free edge of the piece of mucous membrane first divided is sutured with carbolized silk to the corresponding portion of the skin at the verge of the anus. This procedure is repeated until the entire circumference of the bowel is secured to the skin, the result being that a complete ring of pile-bearing mucous membrane is removed. Before closing the wound iodoform is insufflated between the raw surfaces.

While the patient is still on the table, a suppository of two grains of extract of belladonna is inserted into the rectum, the external parts are dusted with iodoform, and a strip of oiled lint is retained as an outer dressing with a bandage. The patient sits up on the fourth day, and is able to resume work in a fortnight. Pain after the operation is rarely complained of, but retention of urine occasionally follows.

The loss of blood at the time of the operation is so small as scarcely to merit notice, if care be taken to seize each vessel as it is cut with forci-pressure forceps and twist it. Indeed, Whitehead states that he has frequently operated on severe cases, and not found it necessary to twist a single vessel, and very often only one or two. In addition to the freedom from primary bleeding, there was not a single instance of secondary hemorrhage, so that the dread of hemorrhage is a delusion in the improved method of operating.

From the foregoing account it appears that Whitehead's procedure is as safe as it is radical, and that the pain is less severe than after the other methods commonly practised. So large and successful an experience certainly entitles it to a full and fair trial, although we may expect some records of free bleeding when the operation is performed by inexpert surgeons. That the operation is an excellent one is evident from the praise given it, by Lange, in THE MEDICAL NEWS for February 12, 1887, who, however, erroneously claims it to be his own procedure.

MEDICAL INSTRUCTION IN ITALY.

PROFESSIONALLY considered, Italy is almost an unknown field to American physicians, who rarely visit the peninsula, except in search of health, or to ex-

amine its grand collections of paintings, antique works of art, and historic ruins. Few think it worth while to pay any attention to her hospitals, maternities, and surgical, obstetrical, or gynecological clinics, knowing little of the work done therein, and still less of the men engaged in it. Occasionally a surgeon will be heard to speak in complimentary terms of the progress made in his branch in Italy; but his language has only a general application. The late Prof. Francesco Rizzoli, of Bologna, who left a fortune of nearly $400,000, the bulk of which goes to found an orthopædic hospital, had a world-wide reputation. Prof. Edoardo Porro, of Milan, has achieved eminence by the introduction of a well-known operation that bears his name. Prof. Domenico Chiara is distinguished for his marvellous successes in obstetric surgery, first in Milan, and more recently in Florence. Prof. Pietro Loreta, of Bologna, earned reputation by his new operation, the digital divulsion of the pylorus, and the success which has attended it, in curing pyloric stenosis resulting from non-malignant ulcerative pyloritis. Prof. Ottavio Morisani has acquired distinction by reviving in Naples the much-condemned operation of symphysiotomy, and by the marked success attending its performance in saving mothers and children. Beyond these names, few are known on this side of the Atlantic, except to the small number who read Italian medical periodicals. The Italian professors feel that there has been a great revival in medicine in their country, and that they have been neglected too much by medical tourists in Europe, who have confined their visits to Great Britain, France, Germany, and Austria; going to Italy, if at all, simply as sight-seers.

There are more than twenty Royal Universities in Italy; the chief, in the order named, measured by their classes, are those of Naples, Turin, Rome, Bologna, Padua, Pavia, Palermo, and Genoa. There were in all the universities of the kingdom in 1885–1886, 14,633 students, of whom 5195 were engaged in medical studies. The professors who are best known for their obstetrical and gynecological work are: Prof. Domenico Tibone, of Turin; Prof. Domenico Chiara, of Florence; Prof. Ottavio Morisani, of Naples; Prof. Ercole Pasquali, of Rome; Prof. Fabbri, of Modena; Prof. Cuzzi, of Pavia; Prof. Calderini, of Parma; and Prof. Luigi Mangiagalli, of Catania. To whom may be added Prof. Edoardo Porro, Director of the Obstetrical School of Milan, and Prof. Paolo Negri, Director of the Obstetrical School of Venice. Of gynecologists not obstetricians, we specially mention Drs. Prelli and Berruti, of Turin; Dr. De Cristoforis, of Milan; Prof. Caselli, of Genoa; Dr. Ruggi, of Bologna; Prof. Bassini, of Padua; and Prof. D'Antona, of Naples. The most noted men of Italy engaged in general surgical work are Prof. Bottini, of Pavia; Prof. Bassini, of Padua; Prof. Corradi, of Florence; Prof. Durante, of Rome; Prof. Loreta, of Bologna; Prof. Novaro, of Siena; Prof. Caselli, of Genoa; Prof. D'Antona, of Naples; and Dr. Gerolamo Mo, of Turin. The chief ovariotomists of Italy, measured by the number of their cases and percentage of success, are Prof. Chiara, of Florence; Prof. D'Antona, of Naples; Prof. Negri, of Venice; Prof. Novaro, of Siena; and Prof. Porro, of Milan.

Obstetrical clinics are found in Palermo, Prof. Pantales; at Pisa, Prof. Minati; at Pavia, Prof. Cuzzi; at Padua, Prof. Frari; at Turin, Obstetrico-Gynecological Clinic, Prof. Tibone, and Chief Maternity, under direction of Dr. Michele Peyretti. Florence, Obstetrico-Gynecological Institute, Prof. Chiara; at Naples, Obstetrico-Gynecological Clinic, Prof. Morisani. The old Neapolitan Hospital for Incurables has an obstetrical department; Genoa, obstetrical clinic, Prof. Macari; School of Obstetrics in Milan, under Prof. Porro; Venice, "Maternity of the Civil Hospital and School of Obstetrics," Prof. Negri; Bologna, obstetric clinic, Prof Carlo Massarenti: Maternity, Dr. Cesare Belluzzi.

The larger cities of Italy are well supplied with hospitals. Bologna has: 1. The Clinical Hospital, about 250 beds; which has sections for medicine, surgery, obstetrics, diseases of the eye, of the skin, and for syphilis. 2. The Grand Hospital, with about 300 beds; two sections of medicine and two of surgery. 3. The Insane Hospital, with 700 beds. 4. The Maternity, 24 beds; attached to which is a Foundling Hospital, with 46 beds and 100 cradles. 5. The Military Hospital, 500 beds. In the Maternity, under Dr. Belluzzi, from 120 to 130 labors are conducted annually; and in the obstetric clinic, about 150 women are delivered; Prof. Carlo Massarenti is director, and attached to the service are Prof. Ercole Fabbri, Dr. Emanuele Bruer, Dr. Leopoldo Golineli, Dr. Ermanno Pinzarri, and Dr. Cesare Belluzzi. The University of Bologna celebrates next year her eight hundredth anniversary; her famous library occupies a hall 600 feet in length. The course of medical study in the Universities of Italy lasts six years. The lectures of each year are held from early in November to the middle or end of June, varying from seven and a half to eight months in the different schools.

In certain sections of Italy, rachitic deformity of the pelvis is frequently met with in obstetrical practice, and in other sections malacosteon is not rare. The treatment of such deformities has made her obstetricians skilful in pelvimetry; in the induction of premature labour with safety to mother and fœtus; and in the Porro-Cæsarean section. Prof. Chiara, of Florence, has had unparalleled success in this operation, and, more recently, saved two women with

their children, by the improved Cæsarean section, of Leipzig and Dresden, the last having been performed on February 9th. In Naples, rachitic deformity often presents itself, and delivery by the old Cæsarean method having been almost universally fatal, the operation of Sigault has been revived with a remarkable degree of success. But as this method cannot take the place of gastro-hysterotomy in extreme pelvic deformity, the improved Cæsarean section of Germany will be employed where symphysiotomy is inapplicable, as the mortality by it has been much below that of the Porro operation.

TUBAL DISEASES.

There is no subject in gynecology that has attracted so much attention of late years as the diseases of the Fallopian tubes and their operative treatment. The discussions on these topics have been voluminous, almost always partisan in character, and rather acrimonious, so that Martin's contribution to the *Zeitschr. f. Geburtsh. u. Gyn.*, B. xiii. H. 2, aside from the value attaching to a careful investigation of a larger number of cases, is the more acceptable from its judicial tone, from the absence of prejudice, on the one hand, in favor of indiscriminate operative interference; on the other, in favor of an exaggerated expectant treatment.

The views expressed by Martin are based upon the observation of 287 cases of tubal diseases and upon a microscopic study of the specimens of diseased tubes removed from 61 women, from the latter of which it appears that there are a catarrhal or endosalpingitis, an interstitial salpingitis, and a follicular salpingitis in which the mucous membrane dips down into the follicles of the walls of the tubes.

Regarding salpingitis from another point of view, one must take into account the changes in the walls of the tubes, their thickening from inflammatory products, alterations in their peritoneal covering, the sinuosities or the complete obstruction of the tubal canal, giving rise to isolated collections of fluid, and the entrance into the tubes of microorganisms, those so far observed being the microbes of puerperal septicæmia, gonococci, tubercle bacilli, and, in one instance, the microbe of actinomycosis. In these latter, the infectious diseases of the tubes, the puerperal form was, in the 287 cases observed, the most frequent, the gonorrhœal ranking next, while the tubercular form was the most disastrous in its results.

The course of tubal diseases ends, in the majority of cases, in recovery. In not one-fourth of all the cases observed was the operation for the removal of the uterine appendages considered justifiable. These statements are made by a man known everywhere as an unusually bold operator, and, coming from such a source, are of the greatest value, for the undoubted tendency of the discussions that have lately occupied medical societies and the medical press, has been to impress upon the minds, especially of younger men, the necessity for operative interference in tubal diseases, when, in point of fact, such operations, unless milder therapeutic measures have been first thoroughly employed, are often absolutely unjustifiable.

FIXATION OF A DISPLACED SEMILUNAR CARTILAGE.

In displacement or luxation of one of the semilunar cartilages, an accident that occurs during a twist or wrench of the knee-joint when the leg is rotated outward or inward, the anterior attachments of the cartilage, and most frequently of the internal one, are separated. Patients who have once suffered from such a displacement are particularly prone to a recurrence of the trouble, and in many cases the ordinary plan of treatment by reduction and retention by an apparatus is a complete failure.

Under these circumstances, the comfort and usefulness of the subject being seriously interfered with, the method of fixing the cartilage, first practised, in 1883, by Professor Annandale, and successfully resorted to by him in four cases, is worthy of adoption. The operation, described in the *British Medical Journal* for February 12, 1887, is performed in the following manner:

An incision is carried on the side corresponding to the detached cartilage, along the upper edge of the tibia from the ligament of the patella for a distance of three inches. Before opening the synovial membrane, bleeding points are secured, when the membrane is incised to the same extent as the superficial wound. The anterior margin of the cartilage having been brought into its proper position by a blunt hook, it is secured to the periosteum and fascia over the head of the tibia by several catgut sutures, when the external wound is closed by stitches, and the usual antiseptic dressings and a splint are applied. In the four cases recorded, the recovery was rapid, and good use of the joint was restored.

INTRAUTERINE INJECTIONS IN SEPTICÆMIA.

The value of antiseptic intrauterine injections in the treatment of puerperal septicæmia has been so often proved that few physicians would dare to treat a case of the disease without resorting to them. Such injections constitute the causal treatment of the disease. Their employment, too, is indicated not only when the lochia become offensive, but also, independently of this, in cases of unequivocal septic infection; for such infection while usually associated with that condition, may occur without it, just as in rare instances a badly smelling discharge may be present and the infection absent.

The excellent paper, by Dr. Davis, in the last

number of THE MEDICAL NEWS, shows some of the dangers which may result from the use of corrosive sublimate injections, and suggests means by which these may be prevented. It is probable, as Fritsch has pointed out, that the evil done by corrosive sublimate injections is caused, not by the portion of the solution brought in contact, temporarily, with the uterine mucous membrane, whether that membrane be wounded or entire, but by that which remains in the uterus or vagina, and from which the absorption is gradual and not immediate. To obviate this evil, after an injection is used, the operator ought to compress the uterus, so as to empty it completely, the free escape of the fluid through a patent cervical canal being secured. Further, he might wash out the vagina subsequently with water that has been well boiled, and thus prevent the retention of the corrosive solution. Were these precautions employed, we would more rarely hear of serious symptoms following such injections. The strength of the solution in most cases need not be greater than 1 to 2000.

It is only exceptionally that more than two injections in the twenty-four hours are required. Continuous irrigation has been tried in these cases, but, like drainage, has nothing to commend it, and therefore should not be employed.

UPON examining the list of officers of Sections of the American Medical Association for the next annual meeting, as published in the *Association Journal*, it will be observed that of sixteen positions Illinois has four, Missouri three, Maryland two, and New York, Pennsylvania, New Jersey, Ohio, Kentucky, Arkansas, and Minnesota, each one. As is seen, two States—Illinois and Missouri—furnish nearly one-half of the appointees, the former having one more than the latter; but as Missouri has the presidency of the Association, she will probably not complain of unjust treatment.

The American System of Gynecology, which is being edited by Dr. M. D. Mann, of Buffalo, we are informed, will be published shortly by Messrs. Lea Brothers & Co., of Philadelphia. Among its contributors are found such prominent authorities as Professors Barker, Battey, Engelmann, Garrigues, Goodell, S. W. Gross, Reeves Jackson, Lusk, Mundé, Reamy, Thomas, and Van de Warker. The work will doubtless present a complete and authoritative statement of the science in its most recent aspects, and will receive a deservedly warm welcome.

ACCORDING to a recent cablegram, a large canvas by Brouillet is expected to be the sensation at this year's Paris Salon. It represents Dr. Charcot giving a lesson at the "Salpêtrière" to his pupils and some invited guests. He stands at a table, one arm half extended toward the audience. His assistant, M. Babinski, stands near, holding a woman stricken with hysteria. The hospital nurse stands watching, ready to give any possible aid. Another realistic painting is by Gervex, representing Dr. Péan, in the hospital amphitheatre, giving a daily lesson in surgery. A female patient, under chloroform, lies on the table before him, an assistant surgeon kneeling beside her counting her pulse, while a Sister of Charity waits for the operation to begin.

REVIEWS.

PRINCIPLES OF HYGIENE FOR THE SCHOOL AND THE HOME, TOGETHER WITH SO MUCH OF ANATOMY AND PHYSIOLOGY AS IS NECESSARY TO THE CORRECT TEACHING OF THE SUBJECT. By EZRA M. HUNT, A.M., M.D., Sc.D. New York and Chicago: Ivison, Blakeman, Taylor & Co., 1886.

WHEN the new Drury Lane Theatre was erected upon the ashes of the old, an "Address without a Phœnix" was sufficiently rare,—as those of us who still read the writings of the brothers Smith can well testify. Nowadays, a school "Hygiene" without an intemperate discussion of the temperance problem is similarly rare. It is not impossible that the intemperate reformers do good. Fire must sometimes be fought with fire. But, as scientific men, we cannot give to their statements the welcome and endorsement which we gladly accord to a judicial exposition of the dangers attendant upon the use and abuse of stimulants and narcotics.

Dr. Hunt's book is of the latter class. The alcohol question receives the vigorous handling that it deserves, but the book is not subordinated to this theme.

The work throughout is abreast of the times; its statements are clear and terse. The discussion of the digestive process is, perhaps, rather too much condensed, but the chapters on Water in its relation to health, and on Heating and Ventilation are masterly.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, March 9, 1887.

THE PRESIDENT, J. SOLIS-COHEN, M.D. IN THE CHAIR.

DR. J. SOLIS-COHEN read a paper on the

ADMINISTRATION OF GASEOUS ENEMATA IN PHTHISIS.

The object in view, he said, is to supply to the venous circulation an antiseptic, such as sulphuretted hydrogen, in sufficient doses to be effective; a result impossible when supplied directly to the arterial current, a plan which would poison the patient. Sulphuretted hydrogen inhaled in far less than sufficient doses would suffocate the patient; taken by the stomach, it would produce other serious results. Administered by the bowels, however, and entering the venous current already deteriorated by organic refuse, it is quickly eliminated by the respiratory tract, which thus becomes subjected to

its beneficial local antiseptic effects without subjecting the system at large to injury, as when thrown into the arterial current. In other words, the parasite is killed, without killing the individual.

Its beneficial effects in phthisis are explained by the action of the gas on the suppurative and septic surfaces, and not by any influence on the bacillus tuberculosis; the consumption proper, the exhaustion, being due to the suppuration and to the consequent septicæmia, and not immediately to the bacillus, which, while it produces the destruction of tissue, does not produce the morbid phenomena. The method of administration utilizes the discovery announced by Bernard in 1857, that toxic material introduced into the economy through an organ at a distance from the arterial system could not penetrate into the arterial system because it is eliminated before that system can be reached. Volatile substances are eliminated by the pulmonary alveoli.

The antiseptic substance employed is preferably sulphuretted hydrogen. This is propelled by means of a current of carbonic acid. It is important that the carbonic acid be freshly made, and that the injection be made without any admixture of atmospheric air, the presence of which will cause griping.

The carbonic acid gas as evolved from the action of the dilute sulphuric acid upon sodium carbonate is collected in a rubber bag previously emptied of air by rolling it. This bag is then connected with a hand-ball compressor, by means of which the gas is propelled through natural sulphurous water in a sort of Wolfe bottle, driving off the sulphurous gas with it through a tube, the terminal extremity of which has been passed into the rectum. Within less than a minute the escape of the gas by the lungs can be detected in the breath.

The beneficial results obtained in pulmonary phthisis by Dr. Bergeon, and reported last July to the Académie des Sciences, have been confirmed by Prof. Cornil, in a communication last October, to the Académie de Médecine, by numbers of French physicians, and by Dr. Hughes Bennett, of Mentone. Bergeon stated that the patients he considered practically cured, had no more expectoration and only dry auscultatory signs of cicatrizing cavities, or other cicatricial results of old lesions. Some of them had become able to resume tolerably laborious employment, with full maintenance of the amelioration they had acquired.

In most patients, it is said, there is marked diminution of cough, expectoration, and night sweats within two or three days. Nevertheless, the trifling expectorations of those apparently practically cured, continued to contain bacilli. This fact may be taken both for an indication that the immediate danger in phthisis is less from the bacilli than from the septicæmia which they set up, and as an indication that this protective treatment, when successful, should not be discontinued until the general healthiness of the tissues is sufficiently restored to resist the further development and sustenance of the bacillus tuberculosis.

Dr. William Osler said that recently, at the University Hospital, a patient very nearly expired after an injection of a mixture of carbon dioxide and sulphuretted hydrogen. He was not aware at the time that sulphuretted hydrogen, if given in sufficient quantities, is capable of producing poisonous effects even when taken by the rectum. He mentioned this accident, lest similar mistakes may arise. Evidently the amount of sulphuretted hydrogen which is given must be small. At the Biological Society, at Paris, some experiments were related, which showed that even a few cubic centimetres are sufficient to poison a good-sized dog. In the experiences which are related in French journals, the odor of sulphuretted hydrogen is readily observed in the breath, but he had not noticed this in any of the Blockley patients. This is an exceedingly interesting, not to say comical, method of treating phthisis, but it is too early to say what the results are likely to be. Certainly, however, in Dr. Bruen's hands, at the Philadelphia Hospital, they have been extremely good.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting March 17, 1887.

The President, A. Jacobi, M.D., in the Chair.

Dr. T. Mitchell Prudden read a paper on

BACTERIA IN ICE AND THEIR RELATIONS TO DISEASE, WITH SPECIAL REFERENCE TO THE ICE SUPPLY OF NEW YORK—AN EXPERIMENTAL STUDY.

Our knowledge of the dangers of impure water, he said, had become much more precise since we had learned that many common and fatal diseases are caused by minute plants, called bacteria, which such water might contain, and as the questions relating to a pure ice and water supply are for the most part identical, he thought it well to call attention in the first place to the new methods of water analysis and the new facts which their use has elicited. Until recently, a considerable amount of organic matter, as determined by chemical examination, and particularly if this could be shown to be of animal origin, had usually been regarded as a sufficient evidence of its unfitness for drinking purposes, because it usually signified decay, putrefaction, or the presence of animal excretion. Organic water had been of late looked upon as indicative of the presence or action of bacteria; but chemical examination could determine only inferentially the presence of these organisms. In the new methods of research, however, it is no longer necessary to *infer* the presence of bacteria, but they can be actually seen, counted, and their species and action on the animal body definitely determined. The new method of water analysis, which has to do with its living contaminations, is called the biological analysis. This, and the older chemical method are in most cases supplementary; but, so far as a certain class of diseases, which may be transmitted by water, are concerned, such as typhoid fever and cholera, it is safe to say that the biological is by far the more important.

Having explained the technique of the biological analysis, he said that in the course of from two to four days the colonies of bacteria, each now containing thousands of the organisms, had become large enough to be readily visible to the naked eye or with the aid of a low magnifying power. It was only necessary now to count these colonies in order to know exactly how many living bacteria were present in the cubic centimetre of water used for analysis, because each visible colony was the result of the growth on the spot from a single in-

visible bacterium, which was caught here when the gelatine of the culture medium solidified. In order to identify the species of the bacteria and test their effects upon animals, a little bit was taken from one of the colonies with a sterilized wire, and put into a fresh tube of nutrient gelatine, where it would grow until enough could be obtained for further experiments. In this manner we could get, growing in separate tubes, pure cultures of all the different species which had been growing side by side on the gelatine plate on which the water was, so to speak, planted.

It was always a matter of surprise to one unaccustomed to such a delicate mode of water testing to find what large and varying numbers of these living organisms ordinary water may contain. We usually congratulate ourselves that in New York, said Dr. Prudden, we have an especially good water supply, and this is in a certain sense true. But a series of 32 analyses of the Croton water, as it was delivered through one of the faucets at the College of Physicians and Surgeons on different days during the past five months, shows the lowest number of living bacteria to one cubic centimetre to be 57, and the highest 1950, while the average of the 32 analyses is 243. When the first accurate biological analysis was made it was supposed that any water which contained a large number of bacteria was unfit for drinking purposes, but as our knowledge had increased it became necessary that this view should be very materially modified; since, so far as is yet known, a large proportion of the bacteria which are everywhere so common and abundant are perfectly harmless. Their *rôle* is to tear down organized bodies into their simpler constituents, a small part of them being used for their own nutrition and growth, while the larger part is given up to other organisms for their life purposes. The bacteria are thus indispensable and omnipresent factors in the working out of the organic processes of nature. It still remains true, however, that a certain number of species, which can live in water, as well as elsewhere, can and do produce deadly diseases and are responsible for some of the most frightful epidemics.

When, then, we know the bacterial contents of a given specimen of water, we have still other things to learn before we can pronounce upon its salubrity. It is necessary to ascertain whether it has been stagnant; whether part of the bacteria are those at least relatively harmless bacteria (which live and proliferate to an enormous degree in pure water); and, above all, whether there has been any chance of sewage contamination. A great variety in the species of bacteria present in a water is rather indicative of sewage contamination, and our lack of knowledge concerning the larger proportion of all bacteria compels us to be most cautious regarding them; erring, if we must, on the side of safety. In a general way, it may be stated that water containing more than from 50 to 100 living bacteria to the cubic centimetre should not be used for drinking purposes without filtration or other mode of purification; and it should always be remembered that absolutely pure water contains no bacteria at all. In any case in which sewage contamination can be positively excluded, judging from the source and surroundings of the water supply, the limit of safety mentioned might, perhaps, be placed considerably higher.

Having remarked that all of these data concerning bacterial water contaminations and water analyzed applied equally to the problems which ice impurities present, Dr. Prudden went on to say that the biological analysis of ice is conducted in precisely the same way as that of water, except that the ice must be thoroughly cleansed and then melted. While the popular belief, that water in freezing purifies itself, has some foundation in fact, it is to be remembered that the bacteria are so minute that they may exist in water in enormous numbers without in the slightest degree impairing its clearness and transparency. The consideration of bacteria in ice is, in the light of modern methods of research, an almost untrodden field, and he had thought it well, therefore, to get some positive data about the action of low temperatures under conditions which we could control in the laboratory, to guide us in our interpretation of nature's processes carried on in a large scale and under varied conditions. With this purpose in view he had conducted a series of experiments on the effects of cold on pure cultures of six different species of bacteria when these were suspended in water. These experiments he described and then summarized their results in six tables. One of the species experimented upon was the bacillus of typhoid fever, and the result showed that while many of the individuals were destroyed, many still remained alive, even after prolonged freezing.

ALTERNATE FREEZING AND THAWING OF BACTERIA SUSPENDED IN WATER.

The experiments in general showed that a large reduction in the number of viable individuals occurred at the first freezing, while more gradual destruction went on as the low temperature was maintained. Subsequent experiments were made with results which are embodied in three additional tables, and from these it was seen that the typhoid bacilli, as well as other microbes experimented on, were soon exterminated after alternate freezings and thawings.

FREEZING OF NATURAL WATERS.

The examination of the water from a given pond or river, and the ice formed from it in the natural way, did not, even if the water was taken in winter, when the ice was forming, give a very accurate distinctive percentage, because the water beneath was always more or less in motion, and in both water and ice there was a very unequal distribution of the bacteria. Approximate accuracy might, however, be obtained by collecting water from various sources in winter, and, after determining from each sample the average number of bacteria in one cubic centimetre, comparing the results. This was done with water taken from Van Cortland Pond and from the Hudson and Croton Rivers, and Dr. Prudden summarized the results in a general way by saying that natural waters containing bacteria on being frozen and remaining so for a few days, may purify themselves by the destruction of as much as ninety per cent. of the bacteria. Furthermore, the number of bacteria is gradually reduced in the ice as time passes; but this reduction does not go on to the complete extinction of all species. He then proceeded to a consideration of the problems which our ice supply presents.

SOURCES OF NEW YORK ICE.

The ice used in New York City, as well as to a certain extent in Brooklyn and Jersey City, is supplied almost entirely from these sources, viz.: the Hudson River, a few lakes and ponds adjacent to the Hudson or near the line of some of the suburban railways, and Maine. The Hudson constituted the principal source of supply, and the Maine supply was, as a rule, drawn upon only when the ice season in this region had been a poor one and the domestic stock ran low. The total storage capacity of the ice-houses along the banks of the Hudson reached the enormous amount of more than three million tons. Dr. Prudden then went on to speak in more or less detail of the various bodies of water from which the ice for New York is taken. In describing Rockland Lake, the ice-houses of which have a storage capacity of about 150,000 tons, he stated that the possibility that the drainage of a number of small dwellings near it might reach the lake without that thoroughness of soil filtration which a strict attention to hygiene demands, seemed worthy of consideration.

In regard to the Hudson River, he said that it must be borne in mind that this stream is in fact a great estuary of the sea, and that the water is at times brackish as far up as Poughkeepsie; while the influence of the tides is felt by the rise of more than a foot at Albany. The fall of the river from Albany to New York is so slight that at times the current at Albany is reversed, and runs northward for some hours. The river for a few miles below Albany is really a long narrow archipelago, so besprinkled is it with low islands of sedimentary origin. The main ice harvesting fields lie between Poughkeepsie and Troy, and at the upper part of this section is the city of Troy, emptying its eight million gallons of sewerage daily into the river, already charged with contributions from Cohoes and Lansingburgh, to say nothing of the impurities brought by the Mohawk from the west. A few miles below Troy lies Albany, with over 90,000 inhabitants and an efficient sewage system pouring directly into the river. Having spoken of other sources of pollution, he stated that the Hudson just below Albany had been shown to consist of about 1100 parts of dirty river water from Troy and 1 part of Albany sewage. "But," he went on to say, "if one should require more proof of the filthy condition of the Hudson just below Albany, he has only to stand on some summer or autumn day, when the tide is at the ebb, on the shores of the so-called Albany basin, a walled inclosure of some thirty acres made for the purpose of increasing the city dockage, and into which fifteen sewers empty, carrying the waste of over thirty thousand people. Under these circumstances the observer will certainly be rewarded with both ocular and olfactory evidence of a most convincing nature. Yet within sight of the walls of the Albany basin, down the stream, stands one of the houses, with its sewage-laden ice-fields, in which this delectable harvest is stored for the comfort of a considerable number of New Yorkers. It was from this region that the ice actually being distributed in an outlying district of this city, was found to contain from 20,000 to 50,000 living bacteria to the cubic centimetre—that is to about one-third of a teaspoonful." Taking the Hudson River ice altogether, it was found that about two-thirds were cut within thirty miles of Albany, and nearly one-fourth within twelve miles.

Having referred to certain other unfavorable conditions of the upper Hudson, he said that, on the other hand, it should not be forgotten that in the comparatively still water behind the islands and dykes there was given tolerable facility for sedimentation of the bacteria, by which means, as experiments showed, a considerable proportion of them might settle down from the upper strata of the water. It was this latter consideration which warned us against an unqualified condemnation of the Hudson River water for ice purposes, since only careful series of experiments could show at what distance below a source of pollution the water might have so far deposited its bacteria (if it did so to any considerable degree) as to render it fit for ice harvesting purposes. In the meantime we must look at the ice itself, and see to what extent bacterial contaminations actually exist in the product from various parts of the river.

Dr. Prudden has made nearly three hundred complete analyses of ice taken at different times from the Hudson, and from the ponds and lakes, and taking the results of all these analyses, he finds that the average number of living bacteria for one cubic centimetre is 2033. He also found that different parts of the same block of ice may contain vastly different quantities of bacteria. In his series of ice analyses the ice was carefully grouped into two classes: first, clear ice, or that which contained but few scattered bubbles, and, second, snow ice and that with very bubbly streaks. Having exhibited charts of his analyses of the Hudson river ice, he said that it was evident from these that by natural agencies the water of the river is freed to a certain degree from bacteria after running for some distance. But the ice did not, as one might expect, get freer and freer from bacteria as the distance from Albany increased, but from six to fifty miles below Albany, with unimportant local fluctuations, remained very nearly the same. A very much more extended series of experiments, he thought, would be necessary before he could determine with any very great degree of accuracy how far the river has to run below a source of sewage pollution in order that the water may by freezing and other natural agencies free itself to a proper degree from its bacterial contaminations, or if it does so at all.

In a series of analyses of the two forms of ice in the same cake, tabulated for this purpose, he found that on the average the snow ice contained about seventeen times as many bacteria as the clear ice. The very bubbly streaks contained, as a rule, many more bacteria than the adjacent clear ice, but still not as many as the snow ice. It is extremely probable that the excess of bacteria in the ordinary snow ice is due to the washing down of material from the shores during rains, or the settling of organisms from the air. The bacterial excess in the very bubbly streaks might perhaps be explained by the fact that certain species of bacteria are capable of making rapid movements in water, and are also great lovers of air. It was possible, therefore, that when the air bubbles collected underneath the ice, these made their way through the water toward them, and got caught there when the water froze. The average number of bacteria in ice from all sources taken together, he went on to show, was far beyond the general

standard which even a moderate degree of purity would allow.

There now remained to consider the most difficult, and at the same time the most important part of the subject, viz., the interpretation of the results obtained, and the suggestion of its practical lessons. The natural situation of the ponds and lakes was good, and evident sources of contamination with sewage and excrementitious material could be largely excluded. As regards the lake and pond ice, then, it could be concluded that, although the product from some of them contained a larger number of living bacteria than was consistent with the highest hygienic standard, the conditions could be readily changed, so as to render them quite unimpeachable; while in some instances the ice, so far as Dr. Prudden's analyses showed, was well within the ordinary standards of excellence.

The Hudson River, on the other hand, stands on an entirely different basis. Now, given the Hudson River ice as we find it, and knowing what we do of the character of the stream, what actual danger have we to fear, he asked, from the use of the ice for drinking purposes? A considerable number of the bacteria which it contains are undoubtedly the relatively or absolutely harmless species which may exist in any natural river or spring water; but a large number might with equal certainty be assumed to originate from animal excreta. Here again it was scarcely to be doubted, although not yet demonstrated, that a considerable proportion of the bacteria existing in sewage, and coming from human and other animal excreta, and the varied putrefying fluids which form a prominent ingredient in the waste of populous towns, might not be positively dangerous if taken into the body in moderate quantities in drinking water. On the other hand, in every large town, like Albany, and in smaller towns in lesser degree, there is a considerable number of bacteria which are the cause of serious disease, more or less constantly passing into the sewers, and here the use to which this diluted sewage should be put, involved the interests of the public health.

There are some varieties of diarrhœal disturbance, sometimes severe and sometimes mild, which often seemed to depend upon impure water or ice; but whether they are occasioned by sewage or other bacteria, or by organic matter, or by both, is not yet certain, so that this class of cases can be left out of view. Fortunately, cholera and anthrax, both bacterial diseases transmittable by drinking water, are not ordinarily present in the sewage of the region under consideration; so that these diseases, although they should not be ignored by those having the public health in charge, did not fall within the scope of the present study. But there are two very common and very important bacterial diseases which are almost constantly present in large towns like Albany and Troy, and frequent enough in villages like those which lie along the upper Hudson. These are typhoid fever and the affections associated with acute suppuration, and the so-called blood-poisoning from wounds, or pyæmia. Now it is unfortunately true, as Dr. Prudden's studies had shown, that the bacteria causing these two forms of disease are markedly resistant to the temperature at which ice forms. The most important of these is the typhoid bacillus. For the past three years the number of deaths from typhoid fever in Albany (the health records did not show the number of cases), during the ice-forming and harvesting months—that is, from December to March—had averaged about sixteen for each year. Reckoning the death-rate at thirty per cent. (which was unusually high), there would be each year about fifty cases of typhoid fever from whom excreta would pass directly into the Hudson River from Albany alone during the ice-forming season. He had been informed that in Albany, as in most American towns, both in hospital and private practice, there was no systematic disinfection of the typhoid discharges. The bacteria of typhoid fever had been repeatedly shown to be capable of living for a considerable time in water, and according to Frankland, and other authorities, they might even proliferate in water. Dr. Prudden had also found, as had been stated, that when frozen up in ice, a certain proportion of these bacilli may live on for long periods, ready, when thawed out and placed under favorable conditions, to go on growing or proliferating just as before their hibernation.

Here, then, as it seemed to him, was the positive source of danger in the use of the Hudson River ice directly for drinking purposes, without some form of filtration, at least until it could be ascertained at what distance, if at all, below Albany and other towns whose sewage drains into the river near the ice fields, a safe degree of bacterial purification of the water by natural means might have occurred. The typhoid bacillus had not been detected in the Hudson River ice, and to find it, even though present in considerable numbers, in its mixture with other species and in the large dilution which exists, presented very great practical difficulties. It had been detected in several instances in water suspected to be the cause of outbreaks of typhoid fever, but the conditions for its discovery were much more favorable than in the present case.

If, on the other hand, we looked at the cases of typhoid fever as they are constantly occurring in New York and the adjacent towns in which the Hudson River ice is used, he did not find, and we should not expect to find, any marked excess of typhoid fever among those who habitually use ice for drinking purposes, over those who do not. This was because the sanitary surroundings of the classes which use little ice are so much less favorable, as a rule, than those of the habitual ice consumers that other sources of infection, equally or even more efficient, would abundantly cover any difference in the number of cases in the two classes that might otherwise be noticeable. Whether infection through impure ice is of frequent or infrequent occurrence is not now known. That it is not, however, so important a factor in the transmission of the disease as to render the typhoid fever statistics of New York worse than those of other towns whose residents use clearer ice, is certain. But there was a considerable number of cases of typhoid fever in which the most painstaking examination of the sanitary surroundings of the victims, and their personal contacts, failed entirely to account for the origin of the disease; and some of these might well be cases of ice poisoning from the typhoid bacillus.

It is to be remembered in considering this, as all other bacterial diseases, that the bacteria themselves are only one factor in determining the disease. There is to be taken into this account also the number of

the bacteria—that is, the size of the dose—and the conditions of predisposition or susceptibility of the individual. Unfortunately, however, we know nothing about the number of typhoid bacilli necessary to induce the disease in man, and we are nearly equally ignorant concerning the nature of the predisposing conditions. So, then, if we summed up what we really knew about the relation of Hudson River ice to typhoid fever, we could only say that it is certain that the ice from some parts of the river must contain the bacteria of typhoid fever, and that these may be taken into the system in a living condition with ice water. Whether the necessary relationship between the number of bacteria thus taken and the condition of predisposition of the individual occurred frequently or infrequently, or even occurred at all, we could not positively say; but the grave character of the disease should warn us against indifference and impress upon us the urgent necessity of the adoption of such measures as will secure the consumer against even the possibility of such infection.

With the bacteria of suppuration and pyæmia the case seemed much less serious, because of the very general antiseptic treatment of wounds now in vogue; but the fact that the staphylococcus pyogenes might be in the Hudson River ice in a living condition should not be lost sight of.

Finally, Dr. Prudden considered that practical measures, as these theories seemed to show, should be adopted in order to guard against a not only possible, but very probable, source of danger in the Hudson River ice. He would not leave out of sight the great and important private and corporate interests which are involved in the supply and consumption of ice; nor would he wish in any measure to suggest by these studies a curtailment in the consumption of ice, even for drinking purposes. The measures which might be adopted in view of the present condition of affairs were of two kinds; *first*, such as would come under the supervision of health officers, and, *second*, those which belonged in the province of the individual consumers.

In the first place, then, it would seem necessary that the State Board of Health, or some other authorized body, should be placed in charge of the ice harvesting fields, and, by a system of inspection not less strict than that which should exist in the case of the ordinary water supply, determine which, if any, of the sources of ice supply are so situated as to imperil the health of consumers of ice. In view of Dr. Prudden's investigations, this would appear to be comparatively simple in all cases except that of the Hudson River. Here it would be necessary to establish by a most thorough scientific examination the distances from all sources of sewage pollution at which it might be safely assumed that the water freed itself from bacterial and other impurities sufficiently to form safe ice.

It might in this way be possible to remove any chance of danger by permitting the questionable or bad ice to be sold only for cooling purposes, if such a classification were practicable, and thus not materially interfere with the interests of the ice companies. A compulsory system of disinfection of excreta in infectious diseases might be instituted, as it has been in other countries in which the purity of the water supply is under constant supervision.

As regards the precautions which the individual consumer might adopt, it was evident, from the facts that had been brought forward, that if he could be certain that his supply came only from the lakes or ponds, he would secure for himself a fair degree of immunity from danger. Remembering that the larger and more responsible ice companies did not, so far as he was aware, cut ice in the immediate vicinity of Albany, but at a considerable, and in most cases at a great distance below, the householder might eliminate to a large extent his hazard by finding out as accurately as possible just what part of the river his ice came from. Whatever the source of supply, however, the large excess of bacteria which in almost all cases the snow layer harbored, over transparent or sparsely bubbly ice, would render imperative the avoidance of snow ice for any but cooling purposes. Still, it is not to be forgotten that perfectly clear ice may contain very large numbers of living bacteria.

A variety of devices could be adopted in the use of ice for cooling drinking water, so as to avoid placing it in the water itself; or, recourse might be had to artificial ice, made from pure water, which, as abundant experience had shown, could be furnished at a cost not greatly exceeding that at which the natural ice was furnished. This artificial freezing of pure water is already done in some of the continental cities in which the natural ice contains large bacterial impurities.

From these studies Dr. Prudden said it would appear that we now know with tolerable certainty just what series of questions are to be answered, and what investigations made, in order to decide upon the safety of any given source of ice supply; but these detailed investigations could only be made under the sanction and direction of the public authorities.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, March 3, 1887.

The President, Thomas M. Drysdale, M.D., in the Chair.

Dr. D. Longaker read a paper on the

TREATMENT OF LABOR IN CONTRACTED PELVES.

The most frequent forms of contracted pelves are the flattened and the generally contracted; in the former the conjugate diameters alone are shortened, and in the latter all are less than normal. The paper was limited to the consideration of those cases where the narrowing is moderate and not sufficient to render the birth of a living child impossible; this embraces flat pelves having a conjugate of three inches or a little less, and generally contracted pelves having a conjugate of at least three and one-third inches. He gave a description of the peculiarities of the flat non-rachitic pelvis, and the flat rachitic pelvis, and reported six cases.

He urged that it will be best to restrict version to cases in which there are other reasons for it than the mere existence of flattening; some of these being the presence of the occiput on the smaller side of an unequally contracted pelvis, the sagittal suture over the symphysis pubis, presentation of an ear, and prolapse of the cord. He extolled the axis-traction forceps in these cases and exhibited an instrument of his own devising, which he had used in two cases. He had no

hesitation in applying the forceps high up in the uterus when the head is arrested at the brim of the pelvis, and cited fifteen cases of such application in proof of his opinion. After some remarks on estimation of the conjugate diameter, he concluded with the following propositions:

In the flat pelvis and in the flat rachitic pelvis decided degrees of disproportion at the brim may be overcome by the natural efforts when the head presents.

In the forceps, and especially in the axis-traction forceps, we have the means of extending still further the possibilities of successful delivery when the head is arrested at the brim.

The forceps, judiciously used, is a safe instrument for mother and child.

The existence of contraction of the pelvis in itself is no reason for preferring version.

In flat pelves with a conjugate diameter of not more than three and a fourth inches and not less than two and three-fourths inches, premature labor should be induced.

DR. HIRST differed from Dr. Longaker on two points: The propriety of always applying the forceps in flat pelves before the head has become engaged instead of turning and delivering the breech; and, on the propriety of applying the forceps over face and occiput in transverse positions of vertex presentations, as in this latter operation the biparietal diameter must be increased.

DR. H. A. KELLY agreed with Dr. Hirst. He considered the paper of Dr. Longaker's a very timely one, which in all its leading features he most heartily commended. It is certain that an intelligent use of the axis-traction principle is destined to revolutionize the treatment of labor in contracted pelves. In cases in which craniotomy has been the custom, axis-traction will save many lives. A few important rules should be borne in mind. First of all, Dr. Kelly would differ from the speaker most decidedly in one practice and lay down the rule that "axis-traction" cannot be applied to the head above the brim. There is no axis above the brim and any traction on the rod merely caused the head to rotate around its own axis, but can under no circumstances be efficient in inducing it to engage. Axis-traction applies to heads engaged in the pelvis. Again, the ordinary use of this principle should be to *assist the pains*. Further, it is important in using Tarnier's forceps of this model to attend constantly to keeping parallel the shanks of the prehensile blades and the proximal end of the traction rod.

If the handles of the forceps rise during a traction, and it is felt by the examining finger that the head has not really advanced, then either the head has rotated in consequence of an excentric grip or the forceps has slipped, and here lies the great difficulty of the Tarnier instrument. The frequency of this accident, together with some other considerations regarding the mechanical construction of the instrument have demonstrated, to my mind, the fact that it is only approximately axis-traction. He exhibited a pair of forceps with which he delivered a dwarfed woman two weeks ago of a full-sized living female child through a three inch conjugate. This pair of forceps was shown him first by Dr. Porak, of Hospital St. Louis, Paris; and he believed that by them he attained the most perfect axis-traction which has yet been devised. The principle is applied in a very simple manner to any long forceps. Each of the four blades of the spoon is perforated with a small oval hole as near the centre of the oval of the spoon as possible. Two long tapes are passed through the hole of one side, the four free ends are brought down under the forceps, and after their application, hang out at the vulva. These ends are brought through a hole at the extremity of a traction rod curved as ordinary traction rods, with the usual transverse handle at the outer extremity; this is then drawn up to the head and the ends of the tapes fastened on the rod at the apex of the angle where the vagina turns down into the perineal curve. The advantages of this forceps are many. 1st. The application is extremely simple. 2d. It can be applied to any forceps. The Tarnier can not be, as it is only suitable to narrow tubed instruments. 3d. The child's head is grasped by the centre of its figure owing to the position of the attachment of the tapes. 4th. This same factor renders unnecessary the screws which are so dangerous in Tarnier's forceps, as the traction does not tend to force the blades apart but approximates them. 5th. The perfectly movable connection between forceps and rod—*i. e.*, the tapes—allows the head to flex and follow the curve of the pelvic canal.

He had used Tarnier rods and the Pollet forceps on the same patient several times and his experience accords with that of Dr. Porak, where the Tarnier rods fail and the forceps slip, the Pollet forceps holds and works easily.

An interesting incident of a short time since shows well the comparative value of axis-traction. He described his Pollet forceps to a friend who has a large obstetric practice. He soon called him out with a note, "bring your French forceps." He found the head well engaged but wedged tight. He had made many well-directed vigorous efforts with his own forceps and finally gave up in despair, producing no effect. He applied the Pollet forceps and with a moderate traction on the rod the head moved gently and steadily until it came directly to the outlet without apparent effort.

DR. LONGAKER had not had time to read Dr. Winter's article in the original, *Zeitschrift für Geb.*, but gained his information from an editorial in THE MEDICAL NEWS, which stated that an expectant plan of treatment and forceps are advised for primiparæ and early version for multiparæ.

He still thinks the occipito-frontal application of the blades does not appreciably increase the biparietal and bitemporal diameters of the fœtal head. It may increase the vertical diameters as the cervico-bregmatic and sub-occipito-bregmatic. A simple experiment on the manikin of Budin demonstrates the truth of this proposition. A full term fœtus, stillborn, was placed in position at the brim, the sacrum being thrown forward so as to make the conjugate measure three inches. With the axis-traction forceps the relative disproportion between the head and the pelvis, which was considerable, was easily overcome. With blades having a sufficiently marked cephalic curve the compression need be but slight.

There seems to be some misconception as to what is meant by the head being at the brim of the pelvis. The head is at the brim until the greatest transverse

diameter, the biparietal, has passed the plane of the superior strait. With a head entirely above the superior strait the use of any forceps would hardly be appropriate. If fixation of the head could not be secured, version would be the best measure.

He did not see how traction exerted by means of tapes could be more efficient than with stiff rods.

The fixation screw is a necessity, there being no free hand to make the necessary compression by the handles. Moreover, it is not objectionable. Continuous pressure is avoided by relaxing the pressure in the intervals. This was one of the chief objections urged by the late Albert H. Smith.

A little reflection and application of well-recognized principles would dictate the proper method of applying traction. Simpler axis-traction forceps have been devised by Bruns and by Braun.

As version is in almost universal favor in Germany and Vienna these instruments have little chance; they are scarcely used there.

Dr. W. H. Parish reported a

PORRO-MÜLLER OPERATION,

performed by Drs. O. H. Allis and W. H. Parish because of an impacted shoulder presentation. Mary L., æt. twenty-six years, of small stature, but good general health. When about six months pregnant she had been hooked by a cow and narrowly escaped a miscarriage. She reached full term and had been in labor seven days when Dr. Allis was telegraphed for. The membranes ruptured four hours after the pains began, on the sixth day the pains became more severe and the cord prolapsed; about the same time a hand protruded from the vagina. The child died about this time. Version was tried without and with anæsthesia but could not be effected. The child was evidently of large size, the patient was restless, exhausted, and with a pulse of 120 per minute. The pains were constant and the uterus was firmly contracted about the child. The patient's surroundings were unfavorable, the ignorance and poverty of the family rendered proper nursing impracticable. An offensive, sanious fluid was escaping from the uterus; the cervix was rigid and but slightly dilated. It seemed impossible to deliver the patient by either cephalic or podalic version, and the conclusion was made that evisceration was not advisable because there was every reason to believe that the uterus had done itself irreparable harm by reason of its prolonged retraction against the eminences of the child. The contusion incident to the retraction and the admission of atmospheric air over a period of seven days, with the character of the discharge, rendered it certain that gangrenous changes had been going on in the endometrium and placenta, and that septic inflammatory action of the uterine lymphatics had already begun. The patient was in a condition of exhaustion. Evisceration alone would not have sufficed to secure delivery, it would have been necessary to have bisected the child in the lumbar region and to have removed separately the lower and upper sections. The condition of the uterus and the small size of the pelvis would have rendered this procedure a lengthy and an exceedingly difficult one, and would have added additional serious injury to the uterine tissues. The removal of the child would have left a putrefying endometrium and septic lymphatics.

Dr. Parish felt certain the patient would die if thus delivered. All present thought Cæsarean section indicated. The operation was performed by Dr. Allis. The uterus was elevated from the abdomen and a rubber tubing was placed about the cervix securely controlling the hemorrhage. Escape of fluids from the uterus was guarded against by means of warm antiseptic pads adjusted about and over the abdominal incision. A vertical incision was then made and the child extracted without difficulty, the placenta was not in the line of incision and there was no hemorrhage. Two transverse pins were carried through the cervix and a constricting wire was substituted for the rubber tubing about the junction of the cervix with the body of the uterus. With the uterine body were removed also both broad ligaments and their contents. The uterine stump was secured externally by means of the transfixion pins, and wounds closed by carbolized silk sutures. Antiseptic measures were taken throughout the operation, but the spray was not used. Immediately after the operation the pulse was 130 per minute.

The patient died in forty-eight hours, apparently from heart failure.

Dr. R. P. Harris remarked that the Cæsarean operation has been performed in the United States in cases of impaction of the fœtus in a transverse position, twelve times. In eleven cases the fœtus was dead. In the twelfth it was saved, but the operation was believed to have been uncalled for by a physician who performed laparotomy with success after the woman had ruptured her uterus, in her next labor. The pelvis had been computed to have a conjugate and a transverse diameter of three inches. In one other of the twelve cases the pelvis was deformed, and the woman saved. The arm was protruding in seven cases, five of which recovered. In two the shoulder presented, one saved; and in three the presenting part is not named. Of the twelve cases, nine, or seventy-five per cent., recovered. Of the three cases lost one was ninety-six hours in labor, three days in charge of a midwife; another was twenty-six hours under a midwife who had given ergot and ruptured the membranes; and the third had been long in labor, but time not stated. Her death was caused by fright and exhaustion; she rose from her bed to defend her mother against her husband who had come home drunk on the third day.

He knew of but one case of impaction in Europe, in which the Porro operation was performed, but in this the pelvis was deformed. The operation was by Fehling, of Stuttgart, and the woman was saved. Putridity of the fœtus may require the removal of the uterus in a case of impaction. One woman was saved without its removal in the United States after seven, and another after ten days of labor, by uterine suturing to prevent escape of fluid; but it is safer to remove the organ where there is danger of poisoning, and particularly where the patient appears to be already threatened with it. In the Porro case of Candido Ramello, of Turin, the woman had been six days in labor, the fœtus was putrid, and the mother in great danger of septicæmia. The removal of her uterus with its contents was followed by an improvement of her symptoms and she recovered.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PRACTICE OF MEDICINE.

Stated Meeting, March 13, 1883.

THE CHAIRMAN, E. DARWIN HUDSON, JR., M.D., IN THE CHAIR.

DR. C. E. BILLINGTON read a paper on

LOCAL TREATMENT IN DIPHTHERIA.

Local and constitutional treatment in diphtheria, he said, are each of vital importance as the essential complement of the other. Having mentioned that on account of the magnitude of the subject he did not feel that he could do justice to both in the limits prescribed to him, he stated that he had selected the local treatment as being that in regard to which there is the greatest diversity of opinion in the profession, and then proceeded to inquire what are the objects rationally aimed at in the local treatment of diphtheria.

He, accordingly, spoke of the factors to be dealt with in this disease; referring first, to the entrance into the system of a specific poison or contagion, which in many cases seems to act by direct local implantation upon some portion of the air-passages. This naturally suggests the local use of antiseptics.

The second factor, he said, is inflammation. This, if preëxisting from other causes, is very apt to invite the disease. Inflammation is an essential constituent of diphtheria, and ceases only with the cessation of the disease itself. The therapeutical indications furnished by the inflammation are, *first*, the treatment of catarrhal trouble, and, *second*, the employment of the most active antiphlogistic remedies, local and general, in the hope of cutting short or modifying the course of the disease. There is also an important contraindication, viz., the avoidance of all local applications which have the effect of causing irritation of the parts.

The third factor is a membranous exudation. This, he thought, is probably an invariable element, though it varies very greatly in extent and in its characteristics in different cases. Besides acting as a local obstruction, the membranes have the effect of covering up the diphtheritic poison, thus preventing whatever antiseptic measures which might be resorted to from accomplishing their purpose properly, and permitting septic absorption to go on. The presence of diphtheritic membranes, however, is sometimes the lesser of two evils; the greater being the premature removal of the membrane, whether intentional or accidental. When this occurs, the general inflammatory action and the membranous exudation are both apt to become more marked than before. Indeed, the forcible separation of the membrane may be attended with very considerable danger. The destruction of the membrane by prompt caustics or the actual cautery has been repeatedly resorted to, in the hope of substituting a simple ulcer for the diphtheritic deposit; and undoubtedly this is the true indication present in cutaneous diphtheria. But this plan is difficult or impracticable as regards the mucous membrane of the air-passages; and the use of such agents has now been discarded by the great majority of the profession. Even if the rapid destruction of the membranes could be accomplished without setting up more active inflammation, Dr. Billington believed such a measure would be detrimental, since the membranes undoubtedly serve to protect the tissues beneath from external irritation. When the membrane is very superficial, it can be removed with but little danger; but when this is the case recovery is generally sure to take place anyway. In the severe cases, however, the sudden removal of the membrane would expose a raw and irritated surface, and the sequel would almost surely be an increased absorption of the diphtheritic poison.

The rational indications in regard to the membrane, are, first, to effect its gradual softening and thinning by the local use of non-irritating solvents; and, second, in exceptional cases, in which its prompt removal is necessary, to accomplish this by such means as will cause the least irritation. The true object, in treating diphtheria, Dr. Billington went on to say, is not so much to cure the disease as to bring the patient through it alive.

The fourth factor in the disease is the absorption of the poison, with its attendant evils. In the earlier stages of diphtheria the condition of the throat is not distinguishable from that existing in ordinary angina. The absorption of the poison begins with the exudation, and it seemed to him that the disease is at first probably a local one. Dr. Billington here referred to the series of cases reported by him in the papers read by him before the Academy in 1876 and 1880, in which the plan of local antiseptic treatment was carefully carried out. The result was that in a large number there was little or no evidence of constitutional disturbance; while the number of deaths from toxæmia was extremely small. As shown by his experience, nature is capable of tolerating and successfully eliminating a certain amount of the poison absorbed.

The fifth factor is the emanation of poison from those affected with the disease.

The indications of local treatment are:

(1) To subdue inflammation.

(2) To effect a gradual and superficial thinning and softening of the membranes.

(3) By antiseptic measures to minimize septic absorption.

Passing on to speak of the means by which these ends are to be accomplished, he said that, in the first place, the frequent swallowing of water, milk, or other bland fluid, has a good effect in washing the parts clean. Ice and iced beverages also have a beneficial effect upon the inflammation present. Of medicinal agents, tincture of the chloride of iron and chlorate of potassium have long been regarded by many as holding the first place. When employed with glycerine, in the proportion of one to eight, the tincture of iron is very grateful to the taste, and can be given every hour, with a little water. The chlorate of potassium may be employed in the following formula:

R.—Potass. chlorat. . . . . gr. xl.
Glycerinæ . . . . . ℥ss.
Liquor. calcis . . . . . ℥iiss.
Dose, a teaspoonful.

In certain cases the tincture of iron is found too irritating to the throat. While Dr. Billington regards this agent as of positive value, he does not think it essential to the successful treatment of diphtheria. There are other agents which may be employed in its

place, and, among those to which he referred, benzoate of sodium and bromine. As to gargles, which are frequently recommended by writers, many patients are too young to use them at all, and even in the older ones they are wearisome and inefficient.

The use of the syringe is more generally applicable. Any ordinary syringe holding half an ounce or an ounce will answer, and warm water with common salt in solution is, perhaps, as good as anything else to employ with it. Still, the use of the syringe has its limitations and dangers. The pharynx, with its delicate mucous membrane, was never intended for rough treatment, and hence it is necessary to proceed with great gentleness. This method should never be practised when any of the membranes is partially detached. In nasal diphtheria the syringe has been so long in use that it is unnecessary to speak of its advantages; but here, also, it is necessary to use the greatest caution. The principal difficulty with it arises from the resistance of young children; but this will be found to vanish if proper care is taken. Dr. Billington here quoted from one of his papers a description of the method which he had found most serviceable for holding the child while the injections were being made. The fluid should be thrown in with sufficient force, and the injection kept up long enough, to cleanse thoroughly the passages. He thought that the physician should always use the syringe himself, to be sure that the procedure is properly performed, and he thought two or three times a day often enough to repeat it. More frequent resort to it only tends to exhaust the patient, and results in increased irritation of the parts. Some physicians are in the habit of repeating the injections as often as every hour; but, as a rule, he thought this was a grave mistake. The frequency should never exceed the tolerance of the patient.

Spraying, he went on to say possesses certain advantages in the fact that the method is gentle and unirritating. In nasal diphtheria, however, it is not of as much service as syringing. For this form of the disease Delano's or some other similar atomizer, is the most convenient, and care should be taken not to insert the nozzle too far into the nostril. As regards solvents for this membrane, lime water is of no service if it is necessary to secure a very rapid effect; but in general it is of positive therapeutical value by its gradual action. A simple formula is ten minims of carbolic acid to four ounces of lime water; which may be employed every half hour.

Lactic acid, pepsin, and other similar agents have often been recommended, but their practical value as solvents has not as yet been satisfactorily demonstrated. Trypsin and papayotin, however, have been used with good results, and the following formula for trypsin has been found useful:

R.—Trypsin	gr. xv
Soda bicarb.	gr. v
Aquæ	f℥j-ss

Papayotin is used in a five per cent. solution. Inhalations of vapors are often resorted to as adjuncts. It is to be remembered, however, that the vapor of lime water when heated is simply water, and that to get a vapor really charged with lime it is necessary to have slaking lime. Turpentine, eucalyptus, and other substances have also been employed in this way. As an escharotic, nitrate of silver is to be recommended on account of its superficial action. Tincture of the chloride of iron in the proportion of two to one and Monsell's solution are also of service in certain cases.

Dr. A. Jacobi remarked that it had been proposed to treat diphtheria with the galvano-cautery, but this presupposed that the membranes are always within reach of this agent. Caustics are objectionable except when their action can be limited strictly to the affected tissues. Nasal diphtheria is very apt to prove fatal unless local treatment is resorted to at an early period. The treatment which he practises consists of repeated injections, kept up at short intervals both day and night, whether the glandular swelling is great or not. The whole procedure, including the syringing of both nostrils, can be accomplished in half a minute, but great care should be taken to do it properly. Lime water, boracic acid, carbolic acid, and bichloride of mercury, the latter in the proportion of one to ten thousand, are useful for this purpose. Spraying can often be alternated with the injections with advantage.

Dr. Jacobi said that he had formerly supposed that in order to have any effect upon bacteria it was necessary to use very powerful agents; but later investigations have shown that this is really not the case. While permanent irrigation of a three per cent. solution of carbolic acid is dangerous, Koch has shown that while they are not destroyed, the activity of bacteria is checked by a carbolic solution of a strength of only one to twelve hundred. It is his invariable practice to have the room constantly filled with the vapor of either turpentine or carbolic acid, or both; a tablespoonful of crude turpentine or a teaspoonful of carbolic acid being added from time to time to a pot of water heated at the fire-place, and care being taken that the vapor should not be allowed to escape up the chimney. It is better not to heat the water over gas, on account of the oxygen that is thus withdrawn from the atmosphere of the sick chamber.

(To be concluded.)

CORRESPONDENCE.

DEATH RATE IN AMERICAN AND EUROPEAN LYING-IN HOSPITALS.

To the Editor of The Medical News,

Sir: In the issue of March 5th of The News is found an article by Dr. Barton Cooke Hirst, on "The Death-rate of Lying-in Hospitals in the United States," in which he has taken the trouble to collect the statistics of thirty-four lying-in institutions in the United States for the six years 1880–85, and finds an average mortality of 2.59, and one of more than twice that in some of them. Then he compares this result with those obtained in institutions abroad, and finds great reason for dissatisfaction with what we have done in this direction, in this country.

If the publication of these tabulated statistics should have the effect of stirring up some institution that is thus exposed with a particularly bad record, and bring it to amend its ways, I can only hail Dr. Hirst as a welcome collaborator in a field in which I have been working for years. But in my opinion the plan of the paper

is wrong, and some of its details give an entirely erroneous idea of what has been done in the way of improvement of lying-in hospitals in this country. I will only take the records attributed to the two largest institutions of the kind in the United States, namely the New York Maternity Hospital on Blackwell's Island, because I am Visiting Obstetric Surgeon to that hospital, and have initiated the new era there, and the Boston Lying-in Hospital, because Dr. William L. Richardson has publicly stated[1] that the marked improvement in the results obtained in that institution, was brought about by adopting many of the suggestions contained in my first paper on "Prevention of Puerperal Infection," published in the *Medical Record* of Dec. 29, 1883.

Dr. Hirst, in his table, quotes the New York Maternity with 2842 confinements, 2.92 per cent. deaths, and 1.82 per cent. deaths from sepsis, and the Boston Lying-in Hospital with 1599 confinements, 3.81 per cent. deaths, and 3.10 per cent. deaths from sepsis. Now it happens that the author for his statistics has just chosen six years, the first four of which were particularly bad and pressingly called for reform, and the last two of which represent the new treatment begun at the New York Maternity on the 1st of October, 1883, and adopted, immediately after it had been made known, in the Boston Lying-in Hospital. This gives as clear an idea of the real condition of these institutions as if a naturalist, instead of describing a rattlesnake and a blindworm, should strike a balance, and content himself with the description of an adder. Dr. Hirst seems to have had some misgiving in this respect, and in order to show that "an earnest effort toward improvement will accomplish much," he gives the death-rate by years "in two large hospitals." These two large hospitals are the Boston Lying-in Hospital, and the Philadelphia Almshouse. Of the New York Maternity, the largest lying-in institution in the country, which has more confinements than the two others together, he says nothing—and still it was this latter hospital which took the lead in the United States in showing that even in comparatively large institutions, drawing their patients from the very lowest layers of female society, delivery can be made as safe as in the palatial residence of rich and healthy virtue.

Dr. Richardson, in a paper on the "Use of Antiseptics in Obstetric Practice," published January, 1887, in the *Boston Medical and Surgical Journal*, has shown how the results obtained during the last three years, 1884–1886, in the Boston Lying-in Hospital and the New York Maternity Hospital are almost identical. The strange omission, in Dr. Hirst's paper, of the New York Maternity, in regard to improvements is so much more surprising, as I, at least three times, have called public attention to the fact. Beside the article in the *Record* more than three years ago, we have my paper on "Puerperal Diphtheria," read in 1885 before the American Gynecological Society, and finally, my *Guide in Antiseptic Midwifery*, published in 1886. By taking cognizance of these publications, either directly or by one of the numerous abstracts that have been made of them in the medical press of all parts of the country, Dr. Hirst would not only have seen that the improvement in obstetrical practice he calls for has begun and advanced considerably, but likewise how the change was brought about, a circumstance to which there is not found the slightest allusion in his paper.

Beginning at the first date as Dr. Hirst's table, and going on till the end of last year, I find in the Maternity Hospital a record that, when properly divided in its two natural groups, contains a lesson that cannot fail to make an impression on any fair-minded man who is unfortunate enough to have a high rate of mortality in a lying-in institution entrusted to his care.

FIRST GROUP.

Year.	Confinements.	Deaths.	Deaths from sepsis.
[illegible]	1[illegible]7	8[illegible]	[illegible]
1881	382	10	8
[illegible]	[illegible]91	14	[illegible]
[illegible]	44[illegible]	[illegible]	[illegible]
Total,	1409	62 (4.40 per cent.)	42 (2.98 per cent.)

SECOND GROUP.

Year.	Confinements.	Deaths.	Deaths from sepsis.
[illegible]	[illegible]2[illegible]	[illegible]	[illegible]
[illegible]	537	[illegible]	[illegible]
[illegible]	44[illegible]	[illegible]	1
Total,	[illegible]	[illegible] per cent.)	[illegible] per cent.)

The great change in the management of the service was begun on October 1, 1883, and during the last three months of the year 102 women were confined without a single death, whereas during the preceding three months 133 women were confined, 15 of whom, or 11.20 per cent., died, and during the last month before the change was made 51 women were delivered, 10 of whom, or 19.6 per cent., died. The difference between the two groups would, therefore, be still greater if we draw the line between them at October 1, 1883, instead of January 1, 1884. Still, even as the groups are limited in order to conform with Dr. Hirst's table, we see that [illegible] *less than one-fourth of what it used to be, and the deaths from sepsis even to one-ninth of what it had been during* [illegible].

How the change was brought about, it is not here the place to consider; those interested in it will find all the details in my above mentioned *Guide in Antiseptic Midwifery*.

How far this movement has spread I cannot tell; but I have reason to believe that the treatment has been adopted with immaterial modifications in very many places, Dr. Richardson, of Boston, Dr. Lusk, Dr. Clark Thomas, and Dr. Emily Blackwell, of this city, adopted it immediately in the institutions under their care, and by request from prominent obstetricians all over the States I have sent them specimens of my perineal pads. I should, therefore, not wonder if in many other of the institutions found in Dr. Hirst's list, a new era of safe delivery had begun. These statistics are unjust to our country, and give the reader the erroneous idea that they represent the present status of our lying-in institutions. Whoever will use the statistical method now in dealing with the question of lying-in hospitals, must first of all examine if and when true antiseptic treatment has been adopted in them, and compare the results obtained before and after that period.

Before concluding, I would like to say a word about the future. When Dr. Hirst says that "we should in every lying-in hospital strive, at least, to equal the results

[1] Trans. Amer. Gynecological Soc., vol. x. p. 114.

obtained by Tarnier in 1884, when in the Maternité he had 1000 successive accouchements with but a single death," I fully agree with him that we should strive, but as to the institution with which I am connected I am pretty sure we will never reach the goal. Maternity Hospital forming, as a matter of fact, only a department of Charity Hospital, in which all diseases and injuries are treated, and being under the special supervision of men largely engaged in general practice, there is always great danger of infection being brought to it by doctors, nurses, clergymen, helpers, and other officials. Then in the Maternity, of Paris, as in all European lying-in institutions, there are one man permanently at the head of the institution, and clinical assistants, who occupy their positions for years, and who often are themselves obstetricians. In the New York Maternity four men alternate as visiting obstetrical surgeons, and every six weeks we have a new house surgeon, whose whole experience consists in having been junior and senior assistant, six weeks in either capacity. Under such unfavorable circumstances, and with so divided a responsibility, it is very unlikely that Tarnier himself would obtain results similar to those he obtained in his securely secluded and scrupulously guarded Maternity of Paris.

I do not think that "our greater wealth, and the superior physical and mental condition of our populace, as compared with the peasantry of Europe," will help us any; nay, I incline to the opposite view. I do not admit that our women are physically stronger than a European peasant girl, quite the contrary; their greater wealth, and their higher mental development, make them much more delicate, and deprive them of that wonderful power of resistance which, in my opinion—of course, together with antiseptic precautions—renders possible the marvellous results obtained in several of the European lying-in hospitals.

Regulations of the Georgia Board of Health Regarding Cadavera for Dissection.—After the usual regulations giving such material to Medical Colleges the following is added:

No body of a stranger or traveller dying suddenly in the State shall be so delivered, but buried at public expense.

Bodies are to be divided in proportion to the number of *bona fide* students.

After a body has been received *it must be embalmed and kept untouched by the knife for a period of sixty days, during which time any relative or person otherwise interested may claim it and have it delivered to him properly prepared for burial.* After this length of time, sixty days, the body, if not before claimed, may be used for dissection, and after use must be properly interred.

For the faithful carrying out of these provisions a bond of $5000 is required from each college.

It is made a felony, punishable by imprisonment for from one to ten years in the penitentiary, for any one to sell or buy such bodies, or to convey them out of the State for the purpose of selling. Robbing a grave, or receiving a body known to have been so disinterred is made liable to the same penalty.—*New Orleans Medical and Surgical Journal*, March, 1887.

Pasteur's Inoculations in the Laboratory of Cantani at Naples.—In September, 1886, a regular service was established for the practice of Pasteur's treatment of hydrophobia. Up to January 17, 1887, 79 persons had been registered, of whom 7 had been bitten by non-rabid animals. 52 have been treated and discharged, 18 remain still under treatment. The rabidity of the animals which had bitten 18 of the patients treated and discharged, was proven by inoculation with preparations made from their tissues; in the cases of 34 of those discharged as cured the rabidity of the animal was attested by outside physicians.—*Deutsche medicinische Wochenschrift*, February 10, 1887.

Vent, not Ventilation.—In the course of an address on "The Laws of Nature in Relation to Health," given before the Hertfordshire Natural History Society, Professor Attfield, F.R.S., in speaking of the prevention of infectious disease, said a possibly serious source of contamination of the air of towns was to be found in the delivery of foul vapors from certain of the gratings at our feet as we walked along the streets and roads. There was, he observed, a general impression—probably a right one—that we had gone too far in the matter of sewer-ventilation—a little too far in a wrong direction. Fifty and a hundred years ago certain fevers which decimated the inhabitants of our towns were said to be, and probably were, largely due to the emanations from open urban ditches and other collections of impurities. We had now filled up the unsightly conduits, got rid of pestilential accumulations, and had substituted closed pipes and drains. But now, under some fancy that these tubular channels needed ventilating, we adopted mechanical contrivances which often brought the noisome vapors to the feet of adults or children as they played near or perhaps actually peered into the grid-guarded caverns. True, the contents of the passages were not allowed to stagnate as in old days, but so far as we ventilated them—that is, washed them out with air—and brought that possibly pestilential air to the lungs of human beings, to that extent, Professor Attfield contended, we were making a retrograde movement toward the fever-breeding conditions of pre-sanitary times. To prevent the vapor-laden air being driven by great pressure within the drains past the water-traps of our homes into the rooms in which we lived, he would suggest some judiciously disposed vent-pipes with no such current of air through them as constituted true ventilation, kept clear by an annual or semi-annual inspection. There was no danger to be apprehended from the generation of poisonous gas in these sullied-water passages. Such small quantity of gas as would be present even in stagnant stuff would be harmless. Ground level gratings should be done away with altogether; what is required is vent, not ventilation.

Castration of Criminals.—The following is the recommendation of an enthusiastic sociologist who proposes castration as a means of limiting crime. The

good effects of this kind of punishment upon the criminal class would be fourfold:

1. No offspring with an inherited tendency to commit crime.

2. An added terror to the punishment inflicted for breaking the laws.

3. A gradual improvement in time of the morals of the public at large, and

4. An improvement in the disposition of the person operated upon.

WOMEN DENTISTS IN ENGLAND.—The Committee of the National Dental Hospital have resolved to admit registered female medical students to the practice of the hospital; moreover, we find upon looking through the *Dental Register*, which is issued by the Medical Council, the names of twenty two women, sixteen of whom are practising in England, two in Scotland, and four in the colonies. All these are registered on the ground of being in practice before the passing of the Dentists' Act. The College of Surgeons of Edinburgh have also decided to admit women to the examination for the licence in dental surgery, but we believe, so far, none have applied. The question arises, Are women fit to be dentists? A great deal has been written and said recently about the ill effects of those occupations for women which necessitate long-continued standing, and how much worse it must be when to the standing is added the strained and cramped position necessitated in stopping, which takes up the greatest part of the time of the dentist of the present day. That the long-continued confined position is a severe strain is shown by the occasional occurrence of neuralgia of the anterior crural or external cutaneous nerves of the leg, which is known by the name of "the dentist's leg." We think that women must often fail in extracting teeth from sheer want of muscular power. Again, in mechanical ideas women are particularly wanting; a fact, perhaps, due to their training, but nevertheless a fact; and in what department of dentistry does not mechanics play a large part?—*Lancet*, February 26, 1887.

A HORN GROWING FROM THE HUMAN HEAD.—An interesting addition has just been made to the Museum of the Hôpital Saint Louis, in Paris, in the shape of a strong and solid horn, which has been surgically removed from the head of a woman residing at Hyères, in the Riviera. This appendage grew from the scalp, was twenty-one centimetres (eight inches) long, and in appearance and consistence resembles the horn of a goat. This deformity is rare, but not so much so as is generally imagined. Cloquet, the eminent anatomist, records a case; and Demarquay has collected fifty-nine cases. The late Sir Erasmus Wilson gives a very complete account of the deformity in the 27th volume of the *Transactions of the Royal Medical and Chirurgical Society*. Out of 90 cases mentioned therein 44 were in females, 39 in males, and the sex of 7 is unrecorded. In the *New York Medical Repository* of 1820 is described the case of a man from whose forehead grew a horn which had three branches and was fourteen inches in circumference. These growths have their origin in a diseased sebaceous gland: and their treatment is removal. It is necessary to destroy all remains of the offending sebaceous gland, or recurrence may happen. —*Dublin Medical Journal*, March, 1887.

THE ETIOLOGY OF FOGS.—MR. JOHN AITKEN'S theory of fogs is gaining credence, and it is certainly one that has much to recommend it. There can be no question that it covers the ground better than any other. As our readers are aware, Mr. Aitken attributes the production of mists, fogs, and rain to the presence of particles of solid matter in the atmosphere. Professor Tyndall was the first to demonstrate how the atmosphere could be filtered, and to show it in a comparatively pure state. Mr. Aitken is of opinion that water vapor clings to and condenses on these particles, either bringing them down as rain, or remaining suspended with them as mist or fog. Chloride of sodium derived from the sea is the most extensive fog producer, but sulphur is the common base of town fogs; and he suggests that it is well that it should be so, because the sulphur has an antiseptic effect on the stagnant air, and saves us from worse evils than fog. This is good news to the sufferers from an annoyance which, if the theory broached be true, cannot possibly be got rid of. There is no special cause of uneasiness as to the sulphur fogs, and, on the whole, they are blessings in thick disguise. We may therefore go on throwing our three hundred and forty-seven tons of sulphur in the air every winter's day in London, not only with impunity, but with something of a sanitary pride in the achievement, because, if we did not thus disinfect the stagnant atmosphere, matters might be worse with us than they are at present. All the same, if we strained our smoke a little so as to get rid of the dirty carbon, it would be more cleanly, and altogether better for us.—*Lancet*, February 26, 1887.

NOTES AND QUERIES.

STEATITE.

In THE MEDICAL NEWS of March 12th, on page 308, a formula for "A New Dentrifice," calls for steatite. What is the ingredient "steatite?" INQUIRER.

By steatite is probably meant what is known in this country as [illegible]. ED.

THE TREATMENT OF AFFECTIONS OF THE RESPIRATORY PASSAGES AND OF BLOOD-POISONINGS BY GASEOUS ENEMATA.

A Clinical Demonstration before the members of the Philadelphia County Medical Society, at the German Hospital of Philadelphia, March 30, 1887.

BY J. SOLIS-COHEN, M.D.,
PRESIDENT OF THE SOCIETY.

IT is now some four years since Dr. L. Bergeon, lately Professor in the Medical School of Lyons, commenced a series of experiments in the treatment of pulmonary consumption, by injections of hydrogen sulphide in small quantities, propelled by currents of recently prepared carbon dioxide (carbonic acid gas of the old nomenclature). On the 12th of July of last year, he communicated his results to the Académie des Sciences,[1] and on the 20th of August to the Congress of the French Association for the Advancement of Sciences. On the 19th of October, Professor Cornil read a paper on the subject before the Parisian Academy of Medicine.[2] The beneficial results claimed therein have been confirmed by a number of French physicians, and have been favorably commented on by Dr. J. Henry Bennet, of Paris. A letter from Dr. Bennett in the *British Medical Journal* for December 18, 1886, so strongly impressed me that I wrote to Paris at once for an apparatus, having previously procured a pamphlet on the subject by his pupil Dr. V. Morel, of Lyons, who devised the apparatus which will be used before you; and from whose pamphlet[3] I have obtained most of the information that I propose to communicate—much of it in his own phraseology.

Mr. Kyner, of the Polyclinic, has made for me and for some of my friends, a number of apparatus imitated from this one of Morel, which answer just as well, and which can be procured for $10, less than one-half the cost of the imported one.

I have them in use in this hospital, in St. Joseph's Hospital, in the Home for Consumptives, in the Hospital of the Polyclinic, and in private practice. While unprepared, at this early date, to express a positive opinion as to the value of the method in curing consumption, I do not hesitate to state that sufficient evidence exists to demonstrate its value as a legitimate therapeutic measure; and I have invited you to a clinical demonstration because it is of importance that those of you who have not had access to the original sources of information should see how the administrations are made, in order that you should not submit yourselves to unnecessary disappointment should you feel disposed to give the method a trial, as I believe you should do. As you will see, the process is simple, but requires some precautions which necessitate the presence of the medical attendant at the first few administrations.

The principle upon which the treatment is based is that the disastrous results of pulmonary tuberculosis are due to septicæmia set up by absorption of the noxious products of suppuration in ulcerous lesions in contact with the atmospheric air; and that repeated prolonged bathings of the suppurating surfaces with a safe antiseptic agent, controls the suppuration and gives the lesions an opportunity to undergo cicatrization. When an attempt is made to administer such an agent by inhalation, the quantity required to produce the desired effect is so large that it is poisonous to the individual. The same may be said of administrations by the stomach, or by the subcutaneous connective tissue. Dr. Bergeon, reasoning on some experiments reported by Claude Bernard in 1857,[4] has found that certain antiseptic agents, of which he has found hydrogen sulphide the best, can be administered in sufficient quantities by the rectum with impunity, provided that care is taken not to introduce too much at a time. Claude Bernard demonstrated that when a toxic or medicinal agent is introduced into an organ at a distance from the arterial system—the digestive tube, for example—it could not penetrate into the arterial system because it becomes eliminated before it can reach that system. It has to traverse the portal system, the liver, the hepatic veins, and the pulmonary tissue; during which transit it may be eliminated in the liver by the bile, or, if volatile, in the lungs by exhalation. To demonstrate this point, Bernard rapidly poisoned a bird by enclosing it in a bell glass containing hydrogen sulphide; and then he injected a syringeful of the gas into the veins of a dog with impunity; and, with like impunity, a solution saturated with hydrogen sulphide into the rectum of a dog. In both these instances the gas was detected in elimination within a few seconds by blackening a paper saturated with plumbic acetate and held before the muzzle of the animal, and elimination had ceased at the end of five minutes. Hence he came to the conclusion that this substance could be safely introduced into the digestive tube or into the veins, provided care be taken not to introduce too great a quantity at a time.

The first experiments of Dr. Bergeon were made on animals with chlorine, turpentine, ether, ammonia, and bromine; but these agents had to be abandoned because they soon produced a violent inflammation of the rectum, and even points of sphacelus in the mucous membrane. On the other hand, a mixture of carbon dioxide and sulphuretted hydrogen was thoroughly tolerated when these two gases were pure and completely deprived of admixture with atmospheric air. In their

[4] Leçons sur les substances toxiques et médicamenteuses.

union, the carbon dioxide plays somewhat the part of an inert agent, and attenuates the irritant properties of the hydrogen sulphide. Sulphur is well known as a powerful microbicide long recommended in pulmonary disease. Carbonic acid gas is likewise rapidly absorbed by the venous system, and rapidly eliminated by the lungs, provided it is injected slowly and in small quantity. The good effects of carbonic acid gas in pulmonary phthisis, in asthma, and in other affections, have long been known to the profession, as I had occasion to refer to it some twenty years ago in the first edition of my little *Treatise on Inhalation*, and in which I referred, likewise, to some experiments made by Dr. James Collins and myself. In addition to this, the anæsthetic effect of carbonic acid gas may have some influence in preventing colic of the intestine in the introduction of the gas, and in subduing irritation in the pulmonary tract in its elimination. Those of you who, like myself, have been practising medicine in Philadelphia some twenty-five years or more, may remember the experiments as to the anæsthetic effects of carbonic acid gas made by the late Dr. Demmé, at that time Demonstrator of Anatomy in the Pennsylvania Medical College.

Dr. Morel's apparatus for administering gaseous enemata, is based on the principle that a current of carbon dioxide passing over certain gaseous or volatile substances produces a disassociation of the gaseous elements, and drives them forward with it. It is necessary to produce a pure carbon dioxide; and then to pass it through a medicated liquid or over a volatile substance, and to force this gaseous combination into the intestine without permitting any reflux into the reservoir of carbon dioxide.

The carbon dioxide is prepared by dropping a solution of dilute sulphuric acid (200 grammes of sulphuric acid to the litre of water) on sodium bicarbonate. Chlorohydric acid was used in the earlier experiments, but a portion always escaped with the carbon dioxide, and produced irritation of the rectum and kidneys.

Carbon dioxide generator and reservoir.

Glass tube, containing volatile medicament between two tampons of cotton.

T. Medicament.

V. D. Connections.

The apparatus for generating the carbon dioxide (Fig. 1) consists of a square bottle in which three tablespoonfuls of sodium bicarbonate are placed. The bottle is hermetically closed by a rubber cork with two apertures, through one of which a glass tube extends to the bottom of the bottle, the upper portion (C) being expanded into a funnel and reservoir for the dilute sulphuric acid, beneath which is a glass stopcock (B) to regulate the descent of the liquid. The second aperture in the cork is filled with a curved glass tube (E) for the escape of the gas, and this exit tube is prolonged by a section of rubber tubing (F) for attachment to a rubber bag (I) of six litres capacity, in which the carbonic acid gas is to be collected. The mouth of this bag is furnished with a stopcock (H). The sodium bicarbonate being placed in the bottle, the cork is inserted, and the stopcock of the sulphuric acid reservoir is closed. This reservoir is then filled with the dilute sulphuric acid, say four ounces, and the stopcock is turned so as to allow the acid to drip on the soda. The carbonic acid gas is evolved immediately, the activity of the disengagement being controlled by the stopcock. A little gas is allowed to escape into the atmosphere, so as to drive off the atmospheric air in the bottle. Meanwhile the reservoir is rolled tightly so as to drive out all the air it contains, as far as possible, and is then attached to the exit tube for the gas and allowed to become filled with the carbonic acid. It is then removed and its stopcock is closed. It must be removed before the stopcock is turned, in order that pent-up gas in the bottle shall not break the apparatus. This is one of the points to which the physician must direct the attention of his nurse, before entrusting the patient to the attendant. Another point upon which stress must be distinctly laid, is the rolling of the bag to prevent retention of atmospheric air.

The gas is now ready for use. The reservoir (I) is

attached to a handball aspirator (J) with check valves at each end (Fig. 2). This is attached to a metallic T tube (D) passing through a cork which is intended to be placed in the neck of a bottle containing the medicated solution, preferably a highly charged natural sulphur water. The vertical portion of the tube is furnished with a double valve (P) to prevent aspiration of the liquid through which the carbonic acid gas bubbles, and contains an orifice at top for the escape of the gas into the distal horizontal branch, to which is attached a tube (L) connected with a nozzle (N) for introduction into the rectum. As this tube could not be made here in time to supply me with the number of instruments I required, Mr. Kyner, Superintendent of the Polyclinic, has imitated the contrivance at my suggestion by two glass tubes placed in the cork just as in the cork of a modified Wolff bottle; the longer tube being supplied with a valve to prevent regurgitation. It answers equally well with the original. This T branch is placed in a bottle three-fourths filled with the sulphurous water—in this instance the Red Sulphur Spring water, of Virginia—and the aspirator is worked two or three times to drive out the atmospheric air in the bottle, another point to which the physician must emphatically direct

the attention of his nurse. The nozzle is then inserted into the rectum of the recumbent patient and the injection made slowly. All clothing must be loose. With the hand on the abdomen, the amount of distention of the colon is noted, and when this is marked, or when pain is complained of, the process is suspended until absorption takes place, as manifested by relaxation of the tension; and then the process is resumed. Fifteen to twenty minutes are consumed in the process of driving the six litres of carbon dioxide through the sulphur water. The sulphur salt—*e. g.*, sodium sulphide—is decomposed, hydrogen sulphide being formed, a portion of the carbon dioxide taken up to form sodium carbonates.

The only modification of the process I have permitted myself (for I deem it due in justice to Dr. Bergeon and Dr. Morel to test their method of administering the gas in their own way) is to place the mineral water bottle in a bath of warm water, which renders the injection more grateful. Within four minutes, sometimes within one, the sulphuretted hydrogen can be perceived in the breath, and be detected by paper saturated with plumbic acetate. It is prudent to have a bed-pan at hand in case there should be a call to stool. The injection should not be made upon the full stomach. This may produce emesis, it is said. You want all the room possible in the abdomen to prevent pressure upon a distended stomach and upon the diaphragm.

Three or four hours after a meal, or just before one, is the best time for injection. Two injections are given daily. I have found three hours after breakfast and three hours after supper the best periods. My patients have slept better after an injection just before bedtime, than after one, three or four hours after the midday meal.

At the first injections but half the contents of the reservoir of carbonic acid should be used, so that the parts and the system may be gradually accustomed to the process.

If the bottle of sulphurous water remain strongly impregnated after the injection, it may be tightly corked for use a second time. It is not necessary to have the bowels moved before an injection. Hæmoptysis and the presence of the menstrual period do not contraindicate the process. Indeed, Dr. Bergeon has seen amenorrhœa relieved during this treatment, even when that condition had failed to yield to the ordinary methods of treatment for that special condition.

When the pulmonary lesions are extensive, and, in consequence, elimination of the gas takes place slowly, the injections must be made very slowly, or they will produce sensations of fulness in the thorax and in the abdomen.

Now, as to therapeutic results. All published observations recount rapid amelioration of the suppurative phenomena; a marked diminution in cough, expectoration, dyspnœa, and night-sweats, being noted within two or three days. Similar prompt improvement, with reduction of temperature, has been noted in some of my own cases, not in all. Some of his more than 200 patients Dr. Bergeon considers cured. These, he states, no longer expectorate, and present no other stethoscopic evidences than the dry sounds due to cicatrized or cicatrizing cavities, or to cicatricial bands consecutive to old lesions. Some of them have been able to resume laborious occupations, and to ascend several flights of stairs many times a day without injury to their respiratory apparatus, or loss of the ameliorated condition which had been secured. Some who considered themselves cured at the end of a few weeks, abandoned treatment, despite the advice of Dr. Bergeon, and underwent recurrence. It is, therefore, important that the treatment should be continued for some months, until all the pulmonary lesions have been cured, lest incompletely cicatrized surfaces undergo suppuration afresh, and reproduce septicæmia. They should be renewed from time to time, even after apparent cure, and especially upon any reappearance of cough, expectoration, fever, or emaciation.

Not only are pulmonary lesions said to be cured by these enemata, but pharyngeal and laryngeal tuberculous ulcerations are said to undergo cure likewise, and that without any topical applications whatever, simply from the contact of the gas in its elimination from the lungs.

Of the cases treated under my own supervision I have as yet little positive to state. With a single exception, they have done quite well so far, and some of them are very pronounced cases—cases that I have had no hope of benefiting very greatly by any treatment with which I am more familiar. One of my patients insists that she is well, but she is not. Some of these cases are here for the purpose of receiving the treatment in your presence. They will answer for themselves that they are better in several ways. Hope of recovery has much to do with this, but not all. I went through a similar experience more than twenty years ago with inhalations of oxygen in phthisis. Hope buoyed the patients up until they found that oxygen had not the power of curing them, and then some of them, I fear, sank all the sooner for the disappointment. In the present instance the prospect is better, the treatment being more in accord with scientific principles, despite the awkwardness of the method. Try it, gentlemen, and within a few months Philadelphia will be able to prove whether this treatment is to be regarded as a novelty of the moment, or whether it has the therapeutic value that has been claimed for it. In the one instance, it is hardly to be supposed that your patients will have been injured; in the other, they will have had all the advantage of an early resort to a beneficial agent.

Should it be desired to administer some volatile medicament, as iodoform, carbon sulphide, eucalyptol, or the like, the bottle of mineral water is replaced by a bottle of common or distilled water, and between the T-tube and the injection-pipe a glass tube is inserted, in which the volatile substance has been introduced between two tampons of cotton. (Fig. 1, V, T, D.)

In addition to pulmonary phthisis, the following diseases are said to be usefully treated by this method, the therapeutic principle being the same in all of them: asthma, whooping-cough, bronchitis, pulmonary catarrh, typhoid fever, the eruptive fevers, puerperal fever, and general septicæmia. If this be true, the list can be extended, as stated by Dr. Morel. The gas acts on the mass of infected blood in the right cavities of the heart, and upon its entire transit through the ramifications of the pulmonary artery, so that the venous blood is disinfected in its course to the pulmonary alveoli and reënters the branches of the pulmonary veins in a purer condition.

THE TREATMENT OF PULMONARY DISEASES BY GASEOUS ENEMATA.

A PRELIMINARY REPORT.

BY EDWARD T. BRUEN, M.D.,

[illegible] PHYSICIAN TO THE PHILADELPHIA HOSPITAL.

In the Philadelphia Hospital for the past seven weeks, the treatment of various forms of pulmonary disorders by the use of carbonic acid gas impregnated with sulphuretted hydrogen has been practised, according to the plan inaugurated by Dr. Bergeon, of Lyons, and described by Bennett.[1] In carrying out the treatment upon a considerable number of cases, much care and attention to detail have been necessary. Dr. McLaughlin, Resident Physician-in-Chief of the hospital, and Dr. Taylor, the Resident Physician in charge of my wards, have devoted a large share of their time to secure the proper administration of the gas, and owing to their valuable assistance it has been possible to give the attention necessary to a careful trial of the treatment.

The twenty-five cases of phthisis chosen on which to make a trial of the gas, included mostly patients suffering from advanced lesions, nearly all associated with cavities, marked bronchial catarrh, and some laryngeal lesions. At this time we are engaged in making a series of critical observations in reference to many essential features bearing upon the permanent value of the treatment, such as the best mode and frequency of the administration of the gas, the quantity and quality to be employed, and the effect upon the sputa, including the bacillus of tuberculosis. Our investigations into these subjects are still in progress; moreover, time is necessary to secure a proper estimate of the permanent beneficial effects of the treatment upon the lesions in the lungs. This report is, therefore, preliminary in character, and designed simply to record the results thus far secured.

The histories of the cases under treatment have shown that the element of suppuration, as it occurs in the pulmonary cavities, and in the bronchial passages, has been positively and promptly antagonized. The temperature has been reduced in a few days, and within two weeks has frequently been brought to a normal point. In grave cases with advanced pulmonary lesions, the temperature has continued to rise a degree or so above the normal standard, but during the period of treatment in more than twenty cases, the temperature chart has always been positively modified.

Together with the reduction in temperature has followed the cessation of night-sweats in most instances, and in all, this symptom has been markedly lessened. In cases in which evidences of bronchial catarrh have been present, such as râles, and copious muco-purulent expectoration, the râles have disappeared, or have been decidedly decreased, and in nearly all instances the digestive system has been favorably affected, the tongue has become clean and natural, the appetite has increased, and also the ability to assimilate and appropriate food.

In most cases the gain in weight has been progressive and considerable, and the nervous symptoms incident to phthisis decidedly influenced for the better, and a more cheerful disposition secured. The immediate effect of the introduction of the gas upon the pulse, has been to lessen it by fifteen to twenty beats, and the respiration *temporarily* increased. The pulse-rate has subsequently been proportionate to the general condition of each individual case.

The effect of the treatment upon cases of bronchitis associated with emphysema has also been tried and the bronchitic element conspicuously modified.

A woman æt. forty, entered the Philadelphia Hospital February 5th, with entire consolidation of the left lung of the variety frequently described as catarrhal or broncho-pneumonia. She had taken cold in December, 1886; had previously been a healthy, rather stout woman. The following symptoms, as abstracted from the clinical history, were present: Abundant muco-purulent expectoration, more than a pint in twenty-four hours; profuse sweats; pulse 120, temperature ranging from 100° to 103°; anorexia, with coated tongue, and inability to receive and appropriate food. After treatment with the gas, administered twice daily since February 10th, she now seems to be convalescent. The temperature is normal, pulse 90, appetite excellent, and flesh increasing. The apparent beneficial effects were noticed within the first week, but it was four weeks before the patient was free from fever. The appetite improved within a few days from the first employment of the treatment, and simultaneously, the nervous symptoms, such as hysterical tendencies and excitement, disappeared. In this instance all treatment, except the gas, was suspended. At this date the physical signs of pulmonary lesions seem to be disappearing, and the lung seems to be approaching the normal condition once more.

Four other cases among the group seem deserving of special mention. One of these is a case of basic cavity, involving almost the entire left lower lobe. In this case the effects of the gas treatment upon temperature, sweating, appetite, etc., were conspicuous, and the gain in flesh the first four weeks was two pounds per week, but during the last two weeks there has been a loss of two pounds, although the other symptoms continue to improve.

Another case, also one of basic cavity, with marked pleural thickening, copious muco-purulent expectoration, but without other pulmonary lesions; in a word, a case suitable for treatment by the introduction of a drainage tube. The same good effects were noticed, yet although this case has been under treatment for several weeks, the temperature still remains somewhat above normal, and the secretion of pus in the cavity evidently continues, showing that some additional measures, such as those which may tend to secure perfect drainage, are still required.

Another instance is one of pneumo-thorax localized to the lower zone of the chest by adhesions of the

[1] [illegible] Journal, December 18, 1886.

lung. In this case constant cough, entirely preventing rest, night-sweats, elevated temperature, anorexia, and loss of flesh, were all marked. The gas treatment has been employed four weeks. The patient's condition has steadily improved, hectic and night-sweats and cough have ceased, and there has been a total gain of ten pounds. The patient takes daily exercise with freedom, and marked improvement in the pulmonary lesions can be recognized.

Finally, in the most sadly diseased case of the group, a man forty-five years of age, five feet ten inches in height, with cavities in both lungs, profuse bronchial catarrh, and weight reduced to 100 pounds, the progress of the disease has apparently been arrested, and although the lesions are too advanced to make it possible for him *ever* to leave his bed, yet the relief of the distressing symptoms of fever, hectic, cough, and expectoration, have certainly been manifest.

Summary.—1. In nearly all cases lasting effects have been secured in the reduction of temperature, suspension of night-sweats, lessened cough, and expectoration, and in some, all physical signs of bronchial catarrh abolished.

2. Temporarily reduction of pulse-rate fifteen to twenty beats, and temperature one-half a degree to one degree during the administration of the gas.

3. The amount of gas introduced into the bowel has varied from three quarts to a gallon at each injection. It has been introduced very slowly, from fifteen minutes to half an hour being demanded by the operation. The administration has been practised in most cases twice in the twenty-four hours. No injurious effects from the gas have as yet been observed.

4. Administration of the gas in different amounts and varying degrees of concentration is now being practised, and also investigations into the characteristics of the sputa.

5. In only one of the cases of phthisis the effects of the gas have been entirely negative.

6. In cases of phthisis complicated by intestinal lesions, experience is still insufficient to make it possible to state positive results.

7. The ultimate value of the treatment can certainly only be established by time. The probable mode of action would seem to be antiseptic, and by reducing suppuration the relief of the attending serious symptoms, the patient is permitted to gain by food, exercise, and general treatment. Thus far, the value of the gas seems to be that of a useful therapeutic measure, rather than a curative plan of treatment.

8. The method of preparing the gas for use in the hospital is as follows: The carbonic acid gas is passed through a solution of chloride of sodium and sulphide of sodium in twenty-two ounces of water. The proportion of the salts has been increased in some cases, and some trials of other combinations are being made.

PRELIMINARY NOTE ON THE CHEMISTRY OF TYROTOXICON.

By VICTOR C. VAUGHAN, M. D., PH. D.,
PROFESSOR OF CHEMISTRY AND TOXICOLOGY IN THE UNIVERSITY OF MICHIGAN.

Mr. F. G. Novie and I have been engaged in the study of the chemistry of tyrotoxicon, and while we have by no means completed our work, we have reached some results which may be of interest to students of putrefaction.

Having a concentrated alcoholic solution of the poison, which we had obtained from milk, we added to it platinum chloride and began to evaporate it on the water-bath, hoping that the platinum would hold the poison and prevent its evaporation at that temperature. Great was our surprise when, as soon as the alcohol was driven off, the contents of the dish exploded with considerable violence. The experiment was repeated several times with the same result. After removing the platinum with hydrogen sulphide gas, the substance was found to have lost its explosive property.

We remembered that the diazo-compounds form explosive preparations with platinum chloride and that they are decomposed by hydrogen sulphide; also that the same compounds give with sulphuric and carbolic acids together a deep coloration. So we tried this test with the tyrotoxicon and obtained a color which varied from a brownish-red to a cherry-red. We then made artificially some diazobenzol nitrate, and found that with the platinum salt it gave a highly explosive compound, that it was decomposed by hydrogen sulphide gas, and that with sulphuric and carbolic acids it produced a deep coloration. But there was this difference: the diazobenzol nitrate gave a green to black color, while, as stated above, the tyrotoxicon gave a red coloration.

Remembering that our tyrotoxicon was obtained by extracting an alkaline solution with ether, we dissolved some of the diazobenzol nitrate in water, added a drop of potassium hydrate solution, shook with ether, removed the ethereal layer, allowed the ether to evaporate spontaneously, and applied the color test to the residue, when we obtained the same shade of color as with the tyrotoxicon. We also found that the ether extract reduced ferric salts in the same manner that tyrotoxicon does.

The diazo-compounds decompose rapidly when exposed to the air. This I had found to be the case with tyrotoxicon. Thinking it not likely that the diazobenzol existed in the cheese and milk as a nitrate, we prepared some diazobenzol butyrate and found the crystals of this to agree exactly with those separated from the cheese, and that they decomposed with the same rapidity when exposed to the air.

So much for the chemical resemblances. From them we supposed it probable that the tyrotoxicon which we had obtained from the cheese, milk and ice cream, consisted of free diazobenzol, some salt of diazobenzol, forming the crystals, and probably some decomposition product.

Next, as to the physiological action of the diazo-

benzol salts. Here I may say that diazobenzol was first prepared by Griess, who made the nitrate and some other salts. We cannot find that the butyrate or lactate has ever been studied, nor can we find that there has ever been any study of the physiological action of any of the diazobenzols.

To a large cat we gave a small bit of diazobenzol nitrate dissolved in water. In a few minutes the animal began retching, and in three-quarters of an hour she vomited freely and later she was purged. The next day the cat was unable to take food. She was then etherized and the abdomen opened. The stomach contained a frothy fluid and its mucous membrane was blanched. Thus, not only were the symptoms identical with those of tyrotoxicon, but the post-mortem appearance was the same as that observed in cats poisoned with tyrotoxicon obtained from cheese, milk, and ice-cream.

From the above noticed facts, we think we are justified in suspecting that tyrotoxicon and diazobenzol are one and the same thing. I should have stated also that a second cat was poisoned with another extract of the diazobenzol butyrate, with the production of the same symptoms as were observed in the one poisoned with the nitrate.

Chemists will now appreciate the great difficulty that has been experienced in isolating the active agent of poisonous cheese. Again, it is altogether likely that the phenol which has been obtained by Brieger and other students of putrefaction results from the splitting up of diazobenzol during the process of distillation to which they have resorted. It has not, heretofore, been supposed that so complex a substance as diazobenzol is formed during putrefaction.

From some oysters which poisoned nearly seventy people in this State lately, we have also obtained the tests for diazobenzol. The symptoms produced by the oysters were identical with those observed after eating poisonous cheese, ice-cream, or milk. It is altogether likely that the active agent in all those foods, which when partly putrid produce the same group of symptoms, is diazobenzol, probably combined with different acids.

It should be stated that the diazobenzol is only a transition product of putrefaction, and soon decomposes itself. For instance, after the oysters had stood for a few days in a warm room, they were tested, and no diazobenzol could be found.

We are conducting some experiments with the hope of ascertaining the nature of the microörganism which produces this poison, but are not ready yet to make any definite report on this point. We will only say that it seems to be a germ which develops best in the absence of air or with only a limited supply of air. We have inoculated two samples of milk with the same material, leaving one sample open to the air and placing the other in a stoppered bottle, and after a few days have found the poison in the stoppered bottle, but not in the open beaker. though this may be explained by supposing that decomposition goes on more readily in the open jar and the poison does not accumulate. Fresh oysters, inoculated with poisonous material and left in an open beaker, became poisonous, and the same was true of some thick custard. Though here, again, the upper layers of the oysters or custard may have prevented free access of air to the underlying portions. This matter needs further investigation and nothing definite can be said on it at present.

Since writing the above we have obtained a precipitate of tyrotoxicon with gold chloride, which corresponds with the salt obtained by Griess from diazobenzol. It is insoluble in water, but soluble in hot alcohol, from which it is deposited on cooling. We hope soon to be able to obtain enough of this compound to make an ultimate analysis, by which we can determine the question of identity with absolute certainty.

THYMOL IN THE TREATMENT OF ATROPHIC NASAL CATARRH.

By RALPH W. SEISS, M.D.,

Adjunct Professor of Pathology and Instructor in Pathology and Microscopy in the Philadelphia Polyclinic.

The great difficulty in curing or even permanently improving atrophic nasal catarrh is but too well known to laryngologists, and any agent which promises somewhat better results than those ordinarily obtained deserves the closest study.

Some eighteen months ago I began a series of experiments with thymol, being led to think that it might be of value in nasal diseases from observing its effects when used as a dressing on some general surgical cases. After prolonged and careful trial, the following four standard solutions have been adopted: No. 1. Thymol gr. ss; Alcoholis ℥ss; Glycerine ℥ss; Aq. dest. q. s. ad. ℥j. M. No. 2. Thymol gr. jss; Alcoholis ℥jss; Glycerine ℥ss; Aq. dest. q. s. ad. ℥j. M. No. 3. Thymol gr. v; Alcoholis, Glycerine ää ℥ss; and No. 4. just twice the thymol strength of No. 3. Nos. 1 and 2 have been used in the atomizer, Nos. 3 and 4 are applied by means of a tuft of absorbent cotton on the cotton carrier.

In early cases of atrophic rhinitis where the epithelium is still intact, and the accumulation of discharge is not great—which are characterized by atrophy of the turbinated erectile bodies, with consequent enlargement of the nasal chambers, and by a peculiar shining red hue of the mucous membrane—the No. 1 solution has been used with the most satisfactory results. This form of atrophic catarrh is invariably preceded by the hypertrophic process, and its pathology is briefly described as being a degeneration from pressure and loss of blood supply; the new-formed fibrous tissue of the advanced hypertrophic rhinitis pressing upon the glands and nutrient bloodvessels, and so causing atrophy. This disease may exist side by side with the hypertrophic variety: I have never found either large abrasions (shedding of epithelium) or an offensive odor in these cases. Under the thymol treatment used two or three times per week, the nasal secretion becomes more liquid, the mucous membrane regains its normal pink color, and, from the peculiar stimulation of nutrition, the turbinated bodies increase in size, so narrowing the nasal cavities to nearly their normal lumen; and in connection with tonic treatment and

careful cleansing of the nasal chambers, the disease has been finally very greatly improved in from three to nine months, in these but slightly advanced cases.

In what I am accustomed to consider *typical* cases of atrophic rhinitis, the following conditions will be found: The patient complains of great, often almost choking dryness in the throat, and of accumulation of mucous crusts, particularly in the vault of the pharynx; loss of the sense of smell; and an intolerable sickening odor may or may not be present in greater or less degree. On inspection the mucous membrane is found to be dry and shining, the turbinated bodies nearly or entirely destroyed by atrophy, and erosions (stripping off of epithelium) may occupy nearly the entire mucous membrane. The nasal chambers are greatly enlarged, so that the pharyngeal wall can be plainly seen by anterior rhinoscopy. The surface of the turbinated bodies is rough and irregular from unequal degeneration, and intense congestion from crust irritation is generally present. By posterior rhinoscopy the pharyngeal glandular tissue is found to be almost totally destroyed, and the vault and nasal fossa are blocked by often intensely offensive dark crusts, which may be either dry, or soft and mucous in character, and often completely occlude the Eustachian tubes and posterior nares.

The lower pharynx presents a most peculiar and typical appearance; the posterior wall is dry, often puckered from lack of moisture, and intensely congested, the posterior half arches appear drawn much nearer together than in the normal condition, and on pressure with a probe the mucous membrane is found to be practically resting on the bodies of the vertebræ. Deeply congested and frequently abraded tissues are found on examination with the laryngoscope, and the trachea and bronchi are frequently also diseased.

This advanced stage of turbinated cirrhosis is almost invariably confined to individuals of a so-called "tubercular tendency," or at least to those whose physique is much below par and average resistance. The profound systemic disturbance resulting from typhoid fever, diphtheria, and the like, is frequently the commencement of this disease. But too often rapid intra-nasal atrophy of this variety is the forerunner of phthisis.

In this form of atrophic rhinitis the No. 2 thymol solution is used with the greatest care; the nares are repeatedly sprayed with it until *clean*, and the spray is then driven with a strong atomizer into the mouth and as high up in the pharynx as possible, the treatment being carried out not less than three times a week. After the thymol spray I occasionally touch the deeper abrasions with a solution of nitrate of silver, 100 grains to the ounce of distilled water, and more rarely make applications of properly diluted tincture of *galanga* to the mucous membrane, using a small tuft of cotton on a delicate applicator for the purpose. The pharynx is then painted with the No. 3 or 4 thymol solution, the applicator being gently carried up until the vault is reached. No. 3 is used until it ceases to give pain, when the stronger solution is applied—the applications being made at each sitting to the mucous membrane previously cleansed by the spray.

In all cases of atrophic rhinitis I invariably follow the thymol solution with fluid cosmoline used in an atomizer, and have found this preparation of great value in protecting the mucous membrane and preventing the formation of dried crusts. Patients frequently state that this application gives them greater apparent relief than any other used. The usual tonic and cleansing measures are used in addition, as without them but little permanent improvement will be gained; outdoor exercise and systematic "training" are insisted upon, and strychnia and chloride of ammonium are usually given internally, along with alcohol and careful dieting. Dobell's solution and dilutions of "Listerine" (Lambert) are most frequently ordered as cleansing agents for the patient to use at home, at least twice daily in an atomizer throwing a coarse, strong spray, or by simply snuffing the fluid through the nose; the nasal douche I have entirely abandoned as troublesome and dangerous.

Under the most careful treatment a cure cannot be hoped for, and marked permanent improvement can rarely be obtained in less than seven to nine months; and I have recently seen cases which although but little improved by six months treatment, were greatly benefited at the end of a year by the thymol treatment.

There is a third class of cases of so-called *rhinitis cirrhotica*, in which I have found the use of thymol particularly beneficial; this form occurs in neglected syphilitic or tubercular children, and occasionally in young adults of the same diathesis. The atrophic process is here very rapid and irregular, the turbinated bodies or their remnants having sometimes an almost honeycombed appearance, or may be entirely destroyed. The amount of secretion thrown off is enormous, the nasal cavities literally *leaking* into the pharynx and down the lips, giving a most disgusting appearance. On inspection the nares are found more or less completely occluded with fluid mucus, abrasions may be numerous and deep, and slight hemorrhages are common. The general appearance of atrophic rhinitis accompanied with congestion obtains: caries of bone and cartilage, and involvement of adjacent sinuses are common. According to Forchheimer, of Cincinnati, ozæna is invariably either syphilitic or tubercular in character, and he states that the bacillus tuberculosis is present in the nasal secretions in all tubercular cases.

This is perhaps the most difficult to cure of any of the forms of atrophic catarrh, but by the use of thymol we have achieved better results than by any other method. The treatment is carried out as for the second class of cases, with the addition of pencilling the turbinated bodies with a solution of tincture of *sanguinaria*, *myrrh*, or *galanga* properly diluted with glycerine; the solution selected being applied after careful cleansing with the thymol solutions. Applications of nitrate of silver in the solid form I think positively injurious from its well-known semi-cauterant and constringing effect; and the insufflation of powdered starch containing a percentage of silver nitrate is as unscientific from the standpoint

of the chemist, as useless to the rhinologist, the metallic salt being converted by the starch into an inactive oxide, and the starch only serving additionally to occlude the nasal chambers. And drugs applied in the form of powder, with the exceptions of iodoform and boric acid, are the reverse of beneficial in this as in all forms of atrophic rhinitis. Specific treatment, tonics, hygiene, and thorough antiseptic cleansing are, of course, insisted upon.

In cases of syphilitic origin I believe that a practical cure may be obtained by prolonged treatment, although atrophied nasal structures will never be replaced; the tubercular cases rarely improve greatly, and usually die of some intercurrent disease before reaching adult life.

The *causes* of rhinitis cirrhotica are as yet uncertain; why one case of advanced hypertrophic catarrh should remain *in statu quo* throughout the life of the individual, and another rapidly degenerate, has not been demonstrated. Ozæna in infants is probably preceded by an intrauterine catarrh of the hypertrophic variety, since turbinated cirrhosis *ab initio* is scarcely conceivable by the pathologist. A chronic rhinitis is frequently set up at birth in tubercular or syphilitic children, to degenerate speedily into a true ozæna at the end of a few months of life. I have yet to see a case of advanced turbinated atrophy in even a comparatively otherwise healthy individual, and believe that a "tubercular tendency" is the strongest predisposing factor in the disease, and a weak vitality a necessary soil. Why also we should find in one case the intolerable odor of ozæna, and in another apparently structurally identical no odor whatever, is as yet unproved. I cannot accept the statement of Lefferts that the odor is due solely to decomposition—from destruction of the serous glands, consequent sticky and tenacious character of the discharges, and damming up and putrefaction of the same within the nasal chambers,—having seen malodorous cases without any considerable amount of pent-up secretion, and observed no odor of consequence in other cases where the nares were completely blocked, the accessory sinuses not being diseased in either case. I think with Mackenzie, of Baltimore, that ozæna from "constitutional causes" is much more likely to give the characteristic stench than that originating from simple inflammatory conditions.

Advanced disease of the *middle ear* is almost invariably found in all cases of turbinated atrophy of long duration; retraction, thickening, and binding down by adhesions of the membrana tympani, with consequent deafness, tinnitus aurium, and aural pain, being the most frequent form of disease. Frequently the drum is deformed by cicatrices, and the history of recurrent, acute purulent otorrhœa may be obtained; a marked tendency to these subacute inflammatory attacks of the middle ear, and to the establishment of a chronic purulent otorrhœa, are characteristic of the ear lesions of advanced rhinitis cirrhotica. No improvement can be made in the aural conditions until the nasal disease has been so far as may be "cured," and I have found thymol of especial service in improving the condition of the aural lesions.

Turbinated cirrhosis cannot be considered a curable disease except in the very earliest stages; highly organized structures once destroyed cannot be replaced; and in consequence of the destruction of the serous glands and the great enlargement of the nasal chambers the patient cannot clear his nose by blowing, consequently even a "normal" amount of mucus speedily dries into scales if cleansing measures be discontinued, with the result of fresh crust-irritation and the rapid lighting up of the atrophic process. The best that can be done in advanced cases is to palliate or improve, and cleansing measures must be continued at intervals throughout the life of the individual to insure no active return of the disease.

After having tried almost every form of treatment, a description of which has been published, I now use thymol almost exclusively, and think that by it better results can be obtained in many cases of atrophic catarrh than by any other form of treatment known to me.

BACTERIOLOGICAL NOTES.

BY GEORGE M. STERNBERG, M.D.,

The Liquefaction of Gelatine by Bacteria.

ONE of the principal advantages to be derived from the use of solid media in the cultivation of microörganisms results from the fact that in such media many species exhibit special characters as to their mode of growth, which serve to distinguish them from other species with which they appear to be identical so far as morphology is concerned.

One character, which is common to quite a number of organisms of this class, and which Koch was quick to seize upon as of value in defining specific characters, relates to the power of liquefying gelatine. When one makes a "stick-culture" in gelatine, certain organisms grow along the line of puncture, or upon the surface of the gelatine, and the mode of growth is in some cases quite characteristic. Other organisms liquefy the gelatine. This liquefaction, commencing along the line of puncture, or upon the surface, extends more or less rapidly until all of the gelatine has become fluid and the organisms which have caused this change are found in a mass upon the bottom of the test-tube.

Eisenberg, in his *Bakterio-logische Diagnostik*, divides the non-pathogenic bacteria into two classes, viz.: Those which liquefy gelatine (including fourteen species), and those which do not liquefy gelatine—ten species. The following named pathogenic bacteria liquefy the gelatine: spirillum of Asiatic cholera, Finkler-Prior's spirillum, cheese spirillum (Deneke), bacillus of malignant œdema, B. anthracis, Staphylococcus pyogenes aureus, Staph. pyog. citreus, Staph. pyog. albus, Bacillus pyrocyanus, Bacillus alvei (foul blood).

So far as the writer is aware, no satisfactory explanation of the cause of this liquefaction of the gelatine has been given, although it is evidently connected in some way with the growth of the liquefying organisms.

In the course of my recent experiments upon the thermal death-point of pathogenic organisms I have ascertained that this liquefaction is due to a soluble chemical product which is formed during the active growth of the liquefying organisms; and that a comparatively small amount of this substance will liquefy gelatine quite independently of the living organism. This is shown by destroying the organisms in a liquefied gelatine culture by heat and then adding a small amount of the culture to flesh-peptone-gelatine which has been rendered fluid by gentle heat. Upon placing the gelatine aside in a cool place it will be found that it has lost its capacity for becoming solid.

This I have demonstrated incidentally, in numerous experiments made to determine the thermal death-point of liquefying organisms, and recently in the following experiment:

Into capillary tubes having an expanded end to serve as an air-chamber, I introduced about one-tenth cubic centimetre of an old culture of each of the following organisms:

Bacillus prodigiosus, B. indicus, B. pyocyanus (green pus), and Finkler-Prior's spirillum. The extremities of the glass-tubes were then sealed by heat, and they were placed in a water-bath maintained at 80°C. (=176°F.) for ten minutes. My previous experiments had shown that a temperature considerably lower than this insures the destruction of all of these organisms. The contents of each of these capillary tubes was then forced into a test-tube containing about 3 cubic centimetres of flesh-peptone-gelatine, liquefied by heat. This is accomplished by breaking off the extremity of the capillary tube and heating the expanded end containing air. A control-tube containing the same quantity of the same gelatine was placed with these tubes in a cool place. The following day the gelatine in the control-tube was found to be perfectly solid, while that in the other four tubes was entirely fluid.

Having thus shown that liquefaction of gelatine is due to a chemical product of some kind, produced during the active growth of certain organisms, and that a comparatively small amount of this substance causes liquefaction quite independently of the organism, I trust that some chemist will take up the question with a view to ascertaining the exact nature of this substance.

MEDICAL PROGRESS.

The Treatment of Granular Ophthalmia with Carbolic Acid.—Dr. Collins writes as follows in the *Reports of the Ophthalmic Hospital*, of London, for January, 1887, on this subject:

So intractable a disease as granular ophthalmia has necessarily from time to time had many and varied forms of treatment tried for its cure. Of the numerous caustic preparations that have been used, nitrate of silver and sulphate of copper continue most in favor. Of late I have in several cases applied pure carbolic acid just liquefied, and believe it to be quite as efficacious as these caustics; it has this advantage also, that its application is a much less painful procedure, on account of the local anæsthetic action possessed by carbolic acid. Further, it does not stain the conjunctiva when used for a prolonged period, as is the case with nitrate of silver. I paint it on the inner surface of the everted eyelids with a camel's hair brush, at intervals of one or two days, applying it more particularly at the seat of the granulations. I then syringe any excess off with a stream of water, being careful not to let the undiluted solution go either on the cornea or skin. The surface of the conjunctiva is turned white, and in a minute or two rendered anæsthetic; a slight amount of inflammation is set up, and destruction of the epithelium follows. Absorption of the granulations is stimulated, and the trachoma-coccus (supposing such to exist) is doubtless killed by the carbolic acid.

Hospital Dressing Material of the French Army.—The French military authorities are causing all the stores of materials for surgical dressings to be rendered antiseptic, as was done a short time ago with the field hospital bandaging materials in the German army. The necessary processes for the purpose are being carried out in accordance with a recent order from the French War Office, in which minute instructions have been issued regarding the steps to be taken in the proceeding. The principal dressing for wounds in the French army is still charpie, which in a great measure takes the place of the lint, cotton-wool, and tow, employed so largely in English hospitals. The order states that the whole of the charpie existing in the military hospital establishments, and in the stores and packages provided for active service in the field, is to be rendered antiseptic; a certain proportion being antisepticized by phenic (carbolic) acid, another by boric acid, and a third proportion by *bichlorure* (perchloride) of mercury. As soon as the charpie is rendered antiseptic, it is to be compressed and packed in parchment paper, which is tinged red for the "charpie *bichlorurée*," blue for the "charpie *boriquée*," and left plain for the "charpie *phéniquée*." Each packet is to be plainly labelled and hermetically sealed, and no packet is on any account to be opened until it is required for use.

The steps to be taken for purifying the charpie before rendering it antiseptic, and the mode of imbuing it with the several kinds of antiseptic preparations, are laid down with great precision. To purify the charpie, four litres of boiling water are to be poured on each kilogramme; this is to be allowed to cool, and the charpie is then to be removed and washed freely in fresh water until the water passes off perfectly clear. The charpie, after the water has been pressed out, is next to be soaked for three-quarters of an hour in six litres of a solution, 1 in 30, of chloride of lime, and again washed in water until all odor of the chloride has disappeared. The charpie is then put into six litres of dilute hydrochloric acid, 1 in 30, and half an hour afterward, is withdrawn and washed, until it does not redden litmus paper. It is now pressed, dried, and rubbed until it is sufficiently supple.

The following are the preparations employed for rendering the purified charpie antiseptic. For the charpie *bichlorurée*, 1 gramme of the bichloride of mercury is dissolved in 100 grammes of alcohol; and this solution, together with 10 grammes of glycerine and 10 grammes of Senegal gum, is added to 2½ kilogrammes of distilled water. Into this solution 1 gramme of the purified

charpie is plunged; and, in order to distribute the bichloride throughout its substance, the liquid is pressed out and reabsorbed several times. It is then withdrawn, dried, and packed as previously mentioned.

To prepare the boric charpie, 100 grammes of crystallized boric acid are dissolved in a sufficient quantity of water; 100 grammes of glycerine, and 20 grammes of Senegal gum previously dissolved, are added to the solution; and pure water is added to make up the amount to 2½ kilogrammes. One kilogramme of charpie is treated in this solution in the same manner as has been described with the mercurial charpie.

To prepare the carbolized charpie, two plans are given, but the following is the one recommended as the most simple and equally effective. A layer of the purified charpie is laid on a piece of oiled silk (*taffetas gommé*), and over this is placed a piece of filtering paper of sufficient size. The paper is sprinkled with carbolic acid dissolved in alcohol of 95° strength. The whole is then rolled up in the oiled silk, secured firmly by cord, and placed in a chamber at a temperature ranging from 68° to 77° F. If the charpie is required to be carbolized 10 per cent., the blotting-paper is sprinkled with 100 grammes of the carbolic acid dissolved in 50 grammes of alcohol at 95°; if 5 per cent., then with 50 grammes of the carbolic acid in 50 grammes of alcohol at 95°.

The cost of the several preparations is described as being very small, and the manipulations very simple.—*British Medical Journal*, March 12, 1887.

TREATMENT OF DYSENTERY IN CHILDREN.—Simon gives the following prescriptions for this affection:

℞.—Sod. bicarbon. . . . . gr. viij.

[illegible] . . . . .

[illegible] . . . . .

[illegible] . . . . .

M.—Div. in chart. xx. in num.

Sig.—One powder before the two principal meals, in water or mixed with non-leavened bread.

If this is badly taken, the following may be substituted:

℞ [illegible] . . . ℥ ..

Tinct. rhei. . . . . ♏ xxx.

Tinct. colombo . . . . ♏ xxx.

Tinct. nucis vomicæ . . . ♏ viij.

of which doses of five or ten drops should be given before each meal, either in cold water or water charged with wine of quiniæ.

The diet should be reduced to pulp; eggs, meat pulp, beans carefully boiled and thoroughly mashed; starches in the form of purée of potatoes.—*Les Nouveaux Remèdes*, March 8, 1887.

THE SIGNIFICANCE OF THE RETENTION OF THE MEMBRANES AFTER LABOR.—The importance to be attached to the retention in the uterus of portions of membrane after the completion of the third stage of labor has been variously estimated by different obstetricians: some—*e.g.*, Winkel, Dorn, Ahlfeld, and Graäfe—holding that grave dangers are to be apprehended when this occurs; while others—as Alshausen, Credé, Fischer, and Cohn (who has reported two cases in which nearly the whole membrane had been retained for five days without causing any pyrexia)—believe that little or no danger of hemorrhage, septicæmia, or other puerperal mischief is caused by the retention of even considerable portions of the membrane. An explanation of this divergence of view has recently been attempted by Professor Lazarevich in the opening article of the new Russian *Obstetrical and Gynecological Journal*. His explanation is founded on the fact, unrecognized by most obstetricians, that "the membranes," even at the full term, are composed of and more or less separable into three distinct layers representing the chorion, the decidua, and the amnion. The strength of these has been investigated by Poppel, Duncan, and Ribemont, and the amnion showed by them to be much tougher than the chorion in conjunction with the decidua. Professor Lazarevich has also made a number of researches on the subject by means of an apparatus consisting of two rings covered with India-rubber, between which the membrane to be examined was stretched, the resisting force being estimated by means of a wooden hemisphere on which weights were placed, which the membrane was made to support, more weights being added until it gave way. These observations showed that the integrity of the ovum depends almost entirely on the amnion. During labor some separation of the membranes from one another usually occurs, and this is especially the case when the chorion, split or torn below, maintains a close connection with the decidua, and the decidua with the uterine wall; the progress of the labor also separates the amnion from the chorion. Roemer explains the separation of the membranes from one another by their unequal elasticity, and Professor Lazarevich declares that the chorion, being less elastic as well as more easily torn than the amnion, is frequently ruptured in several different places, some portions coming away attached to the amnion, and some being left behind attached to the uterus. The causes of retention of the chorion with the decidua are (1) the presence of villi on the chorion; (2) extravasation of blood on the decidua, with consequent formation of fibrous adhesions; and (3) adhesions in consequence of endometritis and choritis. The amnion may be retained in consequence of—(1) occasionally occurring adhesions between it and the chorion and decidua; (2) early rupture and escape of all or part of the liquor amnii; (3) a low attachment of the placenta or placenta prævia; (4) intrauterine manipulation; (5) anteversion of the uterus after the birth of the child; (6) exceptional weakness or thinness of the amnion. Retention of the decidua (which is formed from the uterine mucous membrane, not from the ovum) is, as a rule, of little moment, though it is perfectly possible for endometritis decidualis to occur, and for the retained portions of the decidua to serve for the development of microörganisms introduced from without. Shreds of the chorion, if retained either by themselves or together with the decidua, do little harm, as they rapidly undergo chemical and mechanical destruction, and are carried away with the lochia. The amnion, when retained, is much more liable to become the developing ground for bacteria, and it is to the retention of this part of the membranes that alarming symptoms are usually due. Professor Lazarevich lays considerable stress on the importance of straightening or replacing the uterus in its proper

position after the birth of the child, before the afterbirth comes away.—*Lancet*, March 12, 1887.

The "Forced Heart" of Soldiers.—Duporchal, a Surgeon-major of the French Army, reports, in the *Archives de Médecine Militaires* for March, 1887, his studies upon this condition as follows:

In his observations the contour of the heart was carefully studied during repose and after severe exercise, as forced marches; marked dilatation was found to follow great exertion.

The conclusions reached are:

1. That the condition of "forced heart" is not a morbid entity, but a symptomatic phase common to many diseased conditions of the heart.

2. This phenomenon appears most frequently in diseases attended by modifications in the texture of the myocardium.

3. The symptoms of this condition are palpitation, breathlessness, oppression, precordial pain, "arythmie" (lack of rhythm), and dilatation of the heart. Murmurs may or may not be present; the most frequent are systolic tricuspid murmurs and extracardial systolic murmurs heard in the third intercostal space.

The occurrence of these cases among troops is explained by the constant admission into armies of men suffering from the incipient stages of heart disease, which develops to dilatation under the strains put upon them.

In campaigns these developments occur with especial readiness from the fatigues and bad hygienic conditions under which men are placed.

Incompatible Prescriptions. — The following familiar formulæ, whose combination results in an incompatibility of the ingredients, are taken from the *Therapeutic Gazette* of March 15, 1887:

A common and dangerous action is that resulting from the mixture of alkaloids with alkalies or alkaline salts, of which the following is an example:

℞.—Strychninæ sulphat. . . . gr. ss.
Elixir. brom. chloral. . . . ℥viij.—M.
Sig.—A teaspoonful morning and evening.

The result of this mixture is a colorless solution, from which is deposited in a few hours a crystalline precipitate, which is the greater portion of the strychnine ordered. Although the elixir is not officinal, it is frequently prescribed, and its potassium bromide will deposit the strychnine as an insoluble bromide. The last dose taken, unless great care to shake the mixture well was observed, would result disastrously.

The following prescription may also result badly:

℞.—Morphin. sulphat. . . . gr. ij.
Liq. ammon. acet. . . . f℥ss.
Aq. destillat.,
Syr. simpl. . . . . aa f℥ij.—M.
Sig.—Teaspoonful doses as ordered.

When the diluted acetic acid has been neutralized, and an excess, although not great, of ammonium carbonate is present, the precipitation of the alkaloid will result as in the first instance.

The following may also prove incompatible:

℞.—Potass. iodid. . . . . ℥j.
Spts. æther. nitros.,
Aquæ . . . . . aa ℥j.—M.

When the spiritus ætheris nitrosi is not free from nitric and acetic acids (a result which is produced by the action of the air) iodine will be set free, and a colored solution take the place of a colorless one. The chemistry of the decomposition of the spiritus ætheris nitrosi is as follows:

$$2\,C_2H_5NO_2 + 3O_2 = 2HC_2H_3O_2 + 2HNO_3.$$

A familiar example of decomposition occurring in the organism when chemical substances are given is found in the simultaneous use of calomel and potassium iodide, as follows:

℞.—Hydrarg. chlor. mit. . . . . gr. iv.
Sacchar. lactis . . . . gr. x.—M.
F. pulv. No. 10.
Sig.—A powder three times daily.

Also

℞.—Potass. iodid. . . . . ℥j.
Aq. destillat. . . . . ℥iv.—M.
Sig.—Teaspoonful every three hours.

A reaction between the calomel and potassium iodide occurs in the stomach, and bad results, through the irritating mercurial formed, may occur.

An explosion or unfortunate formation of gas may result from this prescription:

℞.—Ammon. carbonat. . . . ʒij.
Syrup. scillæ . . . . f℥j.
Syrup. senegæ . . . . ℥j.—M.

The acetic acid in the syrup of squill has been overlooked in this combination: its union with the ammonium salt would result unfortunately through the liberation of carbonic acid gas.

An Epidemic of Boils in the Lying-in Hospital at Nancy.—A woman was delivered in the hospital, where antiseptic precautions are rigorously enforced, on April 22. On the 24th the back and buttocks were found to be covered with a copious eruption of small boils, which disappeared under the usual treatment in the course of a day or two. On the 28th another woman was confined in the same ward, and on the following day a crop of boils showed themselves on the upper and inner aspects of the thighs and over the gluteal region. Washed with boracic-acid lotion, these subsided. On May 18 the same phenomenon was witnessed in the case of a young woman who was delivered on May 6, successfully treated in the same way, and two other cases occurred, the site of the eruption being the same in every case, on the 15th and 16th of the same month. Dr. Hergott, after investigating the circumstances, arrived at the conclusion that the boils in the cases after the first were attributable to infection conveyed by an imperfectly cleansed bed-pan. This utensil being carefully washed with a solution of corrosive sublimate, no further cases occurred. The possibility of conveyance of infection by such means is evident, and points clearly to the necessity for the greatest care and cleanliness.—*Archives of Gynecology*, February, 1887.

A New Adulterant for Cod-liver Oil.—Paraffin oil is said to be a new adulterant for cod-liver oil. It

can be recognized by saponification—paraffin does not saponify.—*American Journal of Pharmacy*, March, 1887.

RATIONAL THERAPEUTICS OF CHRONIC CONSTIPATION.—DR. SPENDER writes as follows in an article which we abstract from *The Practitioner* for March, 1887:

We assure ourselves of the absence of malign tumor, of stricture of the bowel as a relic of past peritonitis, and of any obstructive difficulty in the rectum and about the anus. These disturbing elements being excluded, constipation is almost certainly due to one or more of three causes: (*a*) imperfect glandular secretion; (*b*) slow peristaltic motion; (*c*) a sluggish habit of sympathetic nerves.

The discipline should be not of the whip or the spur, but a soothing appeal to the dormant resources of nature. Let a pill be prepared containing from a quarter to half a grain of the Socotrine extract of aloes, with a grain or a grain and a half of sulphate of iron. People sometimes (without meaning to do so) exaggerate their difficulties, but this must not tempt us to order more than a minimum dose; and the cases are not a few for which one-sixth or one-eighth of a grain of extract of aloes is quite sufficient. With these indispensable constituents, the aperient and the tonic, a little extract of belladonna (say one-eighth of a grain) may be blended: doubtless it is often helpful, but more often it disturbs vision and insalivation so uncomfortably that it has soon to be withdrawn. We begin, then, by desiring an adult patient to take a pill composed as above three times a day, immediately after the principal meals. He is cautioned that at first there will be probably no apparent effect, and that two or even three days may pass before any medicinal evacuation of the bowels takes place, difficult and perhaps painful. But within the next forty-eight hours there will be most likely an evacuation of the bowels once, or possibly twice in the day; but *nothing approaching to purgation ought ever to be permitted*, and, therefore, the patient must be instructed that when the first loose motion occurs a pill must be withheld, and that he should take only one in the morning and one in the evening. For a time he continues his morning and evening pill, and is pleased to discover that so slender a medicament has such a decided effect. At the end of another interval of two or three weeks (varying with the original difficulty of the case), the patient is compelled by the same reason as before to omit another pill, and he finds that the same result is brought about by one pill daily as was originally produced by three pills. Within another month the allowance of medicine may be reduced to a pill twice or three times in a week; and, finally, the whole scheme of medical treatment becomes merely preventive in its design and scope, and he takes a pill occasionally for the sake of maintaining health and keeping off old troubles.

THE DISINFECTION OF EUSTACHIAN CATHETERS.—Induced by the publication of Lancereaux on infection of syphilis by means of a catheter, in the *Gaz. des Hôpitaux*, of February 23d, MÉNIÈRE describes his method of disinfecting catheters. He uses silver catheters solely, which are kept in a vessel filled with alcohol. Before using a catheter he exposes it for some moments to the heat of an alcohol flame. The alcohol within the catheter is thus set on fire, and the instrument radically cleaned; it is then dipped in cold water. The catheter is then thoroughly cleaned with copper wire. Using this method, it is impossible (?) to produce any syphilitic infection, even using the catheters employed in the treatment of syphilitics. The author soaks the rubber bougies used in dilating the tube in alcohol, and keeps them in a bottle containing tincture of iodine. Every patient, suspected to be syphilitic, is treated with his own bougie.

In January of this year LANCEREAUX discovered in a patient unmistakable symptoms of secondary syphilis. In seeking for the source of infection, the only point elicited was that a profuse epistaxis followed the introduction of a Eustachian catheter. Upon this the author based his conclusion that the catheter was the medium of infection. According to data, the first catherization, the infectious one, took place in the middle of September. As the epistaxis followed a repetition thereof in November, indications would point to a preëxisting chancre in the interior of the nose. In December, three months after incubation, at the time of observation, the patient presented an exanthema. Although it is very doubtful whether the disease can be attributed to the source ascribed by the author, the importance of thoroughly disinfecting all catheters after use cannot be overestimated.—*Archives of Otology*, March, 1887.

UTERINE TENTS AND THEIR EFFECTUAL DISINFECTION.—DR. DIRNER, of Buda-Pesth, has recently written in the *Centralblatt für Gynäkologie* on the effectual disinfection of tents used for gynecological purposes. He observes how, after the greatest precautions, serious pelvic inflammation may follow the introduction of sponge or laminaria tents. This accident is clearly due, not to the mere ulceration of the dilated structures, but to the introduction of septic material through the wounded mucous surface. The preparation of tents by soaking or coating in antiseptic media is insufficient. Septic matter may be introduced with the aseptic tent; surgeons handle and throw about samples at the shops, nor is the process of manufacture always properly superintended. Fritsch's method of coating tents with wax requires warm water to be at hand when the wax has to be melted, and that water may be septic. Dr. Dirner has detected cracks in the wax, allowing the admission of dust. The most carefully prepared dry tents can convey septic germs on their surfaces. For a year Dr. Dirner has employed in Professor Tauffer's wards a special system of disinfecting laminaria tents. He immerses them in a 1 per cent. solution of corrosive sublimate in absolute alcohol contained in a wide-mouthed bottle. When required, a tent is taken straight out of the solution and passed into the canal of the cervix, the patient being previously placed in the semiprone position, and the vagina disinfected. He takes care to inspect hollow stems before introduction, and should any crystals of sublimate be detected in the channel of a stem, it is dissolved with pure water. The results of this practice have been admirable, and he has seen no bad effects follow the introduction of the disinfected tents; provided that absolute alcohol be employed, the expansive power of laminaria is in no way damaged.—*British Medical Journal*, March 5, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, APRIL 2, 1887.

RECTAL INJECTIONS OF GAS IN THE TREATMENT OF PHTHISIS.

THE general hopelessness of the treatment of phthisis is shown by the avidity with which new methods are sought after. Cod-liver oil, the hypophosphites, respirators, pneumatic differentiation, have in turn been extolled as curative agents, and then, after a variable period, have quietly found their place as useful remedial agents in certain cases and under certain conditions. In our issue of January 29th we referred to the treatment by rectal injections of gas, introduced by Bergeon, of Lyons, and we predicted that we might shortly expect to see a Wolff's bottle by the side of each phthisical patient. We had no idea that our prediction would so soon come true.

This is a progressive age, and knowledge acquired in the wards and in the laboratory no longer filters slowly through the professional press to reach the public in the stillness of the sick room. The ubiquitous reporter, undaunted in his ignorance, and anxious only for a sensational article, hears of the new plan of treatment under trial with some success, and announces it to the public in a widely read Sunday paper, with the startling headings, "A Doctor's Triumph," "Consumption Cured." Telegraphed everywhere, even cabled to Europe, there has been aroused an extraordinary excitement in phthisical circles, and the applications for information at the Philadelphia Hospital are numberless. The demand for rubber bags and Wolff's bottles has exceeded the supply. Other daily papers have taken up the question, and even our esteemed contemporary the *Ledger*, usually so conservative, has had an editorial on the subject, not remarkable for exactness in medical knowledge.

This premature publicity is greatly to be regretted, particularly as very many of the statements which have been spread broadcast over the country are absolutely false. So far as we know, there have been no *cases cured*, certainly not at the Philadelphia Hospital, and even those of Bergeon's patients who were most benefited continued to have slight expectoration containing bacilli. The results at the Philadelphia Hospital, in the limited series of cases which have been under treatment, and which are given in the preliminary report of Dr. Bruen elsewhere in this number, have been in the reduction of the fever and the sweats, the lessening of the expectoration, and in the increase of weight. These are gains to be thankful for, and encourage us to hope that we may have here a remedial measure of some value, but further than this nothing can be said. Phthisis, as we usually meet it, is not an acute disease, and an experience of seven weeks is far too short a time in which to form a judgment of the permanent beneficent effects of the treatment. The greatest care must be exercised in the analysis of the cases, and we must have specific details as to the pulmonary condition. We are glad to learn that it is proposed to follow up accurately the clinical history of the twenty-five cases already under treatment, as from their careful study we may hope, in a year, to receive more valuable and definite information than many scores of cases observed for but a limited period could afford.

The technical details of the method are fully described in Dr. Cohen's paper, which appears in another column. We would earnestly advise those practitioners who will employ this method to state frankly to their patients that it is not a well established plan of treatment, but only an experimental effort which may or may not succeed. It will take a year or two at least to test its value thoroughly; and meanwhile it is sad to think that so many poor victims of this direful disease will suffer also the delirium of false hope aroused by the premature and unreliable statements which, unfortunately, have been given wide currency by the daily press.

THE TREATMENT OF EXSTROPHY OF THE BLADDER.

IN THE MEDICAL NEWS for July 3, 1886, we called attention to the admirable method proposed in 1861 by TRENDELENBERG for the relief of exstrophy of the bladder. In a subsequent communication to the Fifteenth Congress of German Surgeons (*Archiv für klinische Chirurgie*, Bd. xxxiv. Heft 3), he points out the imperfections inseparable from any operation for exstrophy of the bladder, which aims only to unite the soft parts by means of flaps, and repeats his conviction that the best results can be obtained only when an attempt is made to approximate the separated pubic bones. After a number of fruitless

experiments, he announces that he has arrived at a method which comes very near to perfect success.

This method, as we have already stated, consists in dividing the sacro-iliac synchondroses, and bringing the pubic bones together by means of external compression. The first step of the operation is as follows: The patient is anæsthetized and laid on his belly; the operator's index finger is carried into the rectum and serves as a guide to the sacro sciatic notch. The skin and other tissues are then divided down the synchondrosis on each side, in the line of each synchondrosis, and this is incised sufficiently deep to permit each ilium to be sprung away from the sacrum. This makes it possible to bring the pubic bones together. The wounds are treated antiseptically with small drainage tubes, and the skin closed over them. The pelvis is now encased in a girdle, crossing in front and bearing a weight on each side, which presses each ilium toward its fellow. From four to six weeks afterward the bladder defect—which has meanwhile become narrower—is operated upon directly. The edges are fastened to a considerable width all the way down to the orifice of the urethra, and united with fine silver wire sutures. The sutures overlap, but do not include the mucous membrane, and the wires may be supplemented with superficial thread sutures. A small rubber tube or silver catheter is left in the newly formed urethra. The after-treatment of the patient requires great care to prevent bedsores, and dangerous movements. Trendelenburg has never yet attained a healing by first intention, and his two most successful cases required a second operation. In neither did he secure continence of urine.

In the same number of the *Archiv für klinische Chirurgie* there is an elaborate paper upon the treatment of exstrophy of the bladder by PASSAVANT, who recommends gradual approximation of the pubic bones by compression, as a preliminary step, before attempting to unite the edges of the defect in the soft parts. Passavant points out the analogy between harelip and exstrophy of the bladder, and calls attention to the fact that DEMME, before 1855, succeeded in two cases in approximating and securing firm union of the pubic bones, and in increasing the capacity of the bladder, when assisted by a retentive apparatus. Unfortunately, Demme does not appear to have attempted to complete the cure by closing the edges of the defect. Passavant, who appreciates the promise of Trendelenburg's method, prefers gradual approximation, without a cutting operation, as less dangerous, while he admits that, if Trendelenburg's operation can be shown to be safe, it will be preferable, because more rapid. Passavant has tried his own method in three cases, with satisfactory results as to approximation of the pubic bones; but he has not yet proceeded to the step of closing the defect in the soft parts.

The chief interest in Passavant's paper is in his thorough and scholarly consideration of the anatomico-pathological conditions of exstrophy of the bladder and epispadias. These may be briefly illustrated, as has been done by Thiersch, by the relative condition of a book when it is closed and when it is opened so that the covers come together at the back. The space between the back of the cover and the bound pages represents the urethra, which in the normal state occupies the lowest part of the penis; but in the state of epispadias occupies the uppermost part. In epispadias the lateral parts of the penis are separated widely above and draw the urethra up between them and even above them. The cure must consist in bringing the sides up to their normal position and keeping them there. This can be accomplished only by correcting the deformity in the pelvis, and to do this Trendelenburg, as we have seen, advises division of the sacro-iliac synchondroses and rapid approximation of the pubic bones, while Passavant advises gradual approximation by compression without cutting.

We entirely agree with Passavant that Trendelenburg's method would seem to be the preferable one, if devoid of danger. And the latter's experience appears to indicate that it is unattended with risk, if properly conducted.

Both methods give the greatest promise of success when undertaken very early, even in infancy, because of the yielding character of the pelvis at this age, and Passavant suggests a resection of the pelvis after the age of puberty. In doing this he fears that the separation of the parts might lead to dangerous inflammation. This possibility we do not think so serious as Passavant does, in view of the results of aseptic surgery in our day. And, so far as the danger depends upon the formation of gaps in the bony parts, we recall the experience of Schede, in securing healing by means of blood-clot, which we commented upon in THE MEDICAL NEWS of September 25, 1886. If the principles of Schede's method were applied to the operation of resection of the pelvis, we think it likely that it would not prove to be so formidable as Passavant thinks.

In conclusion, we recommend to our readers a careful consideration of the merits of the plans proposed by Trendelenburg and Passavant, for the relief of exstrophy of the bladder, and hope that American ingenuity may suggest some improvement on the apparatus of Passavant, or even of the operative procedures of Trendelenburg.

A NEW METHOD OF DILATING THE UTERINE CAVITY.

IN April, 1886, VULLIET, of Geneva, presented to the Academy of Medicine a paper in which he claimed that he was able so to dilate the uterine cavity as to bring into plain view all parts of it, even

the fundus, thus enabling the physician to inspect and treat morbid conditions of the endometrium, these objects being most desirable in chronic endometritis, fibroid tumors, and polypi, but especially where the mucous membrane of the uterus was the seat of a malignant growth. The dilatation was accomplished by means of small tampons of cotton previously dipped in an ethereal solution of iodoform and dried, to which were attached threads to facilitate their removal: one of these tampons, no larger perhaps than a good-sized pea, was pushed up to the fundus, with the aid of a sound, and this was followed by others until the uterine cavity was completely filled. The tampons remained in position for two days, and were then removed without difficulty, for at the end of that time the cavity was always found considerably enlarged, and the greater space thus obtained was at once filled out by fresh pledgets of cotton. Continuing in this way for about eight days the cavity of the womb and the cervical canal would be so well dilated that the endometrium could be inspected throughout its extent, the cavity could be easily explored by the finger, and both operative measures and therapeutic applications could be employed with great facility.

In order to determine its merits, the Academy appointed a commission composed of Charpentier, Cusco, and Tillaux, to investigate the practical application of this manner of dilating the womb. The report of the commission, published by Charpentier, in the *Nouvelles Archives d' Obstétrique et de Gynécologie* of December, 1886, endorses, in quite an enthusiastic manner, the claims advanced by Vulliet for the value of his method. It was found that chronic endometritis could be treated either by the curette, or by the local application of powerful remedies, with the most gratifying results, that the capsule of a fibro-myomata could be most conveniently incised, leaving the tumor to be afterward expelled from its bed by the contractions of the uterus, but that the greatest good was accomplished in cases of cancerous degeneration of the endometrium, for, with the morbid growth well exposed to view, the diseased tissue could be thoroughly scraped away and the raw surface well burned with the actual cautery. Several cases of this sort are described, in which, for the time at least, most satisfactory results were obtained.

The objection to this method of dilating the uterine cavity, and it is by no means a light one, is the great pain it gives the woman at first, although the uterus, it is claimed, soon becomes more tolerant of the foreign substances within it. The process of dilatation is, moreover, a slow one, but in spite of the length of time that the absorbent tampons remained within the uterus, they were free from odor when removed, and in no case was there the slightest rise of temperature or other manifestation of septic infection. That this method of Vulliet has some merit must be conceded, for circumstances can readily be conceived under which the accessibility of the interior of the uterus to the sense of sight and touch would be of the greatest assistance to the physician, by making the diagnosis of disease in that region more sure and its treatment more effective.

FALLACIES OF FILTRATION.

The average householder is sensitive upon the subject of his filter. He has paid a heavy price for the word "patented" stamped upon it, and the limpid stream which trickles from it is to him a sufficient refutation of all aspersions upon its efficiency. If he changes the filtering material once annually, the whole duty of man has been accomplished. It is only when the trickling stream dwindles down to an hourly drop that any doubts arise as to the fidelity of the trusted utensil.

What has preceded this clogging? A filter arrests a large proportion of the particulate matters in water, and in ways that are obvious. Among such matters are bacteria—chiefly represented by the ordinary almost omnipresent *water bacteria*, which are practically harmless as constituents of drinking water, unless they remain there under conditions favorable to the development of those products of decomposition intermediate between proteid matter and its ultimate dissolution. In addition, and held in the pores of the filter by some means not fully understood, there is present a portion of the soluble albuminoids of the water; here, then, we have congregated both the microörganisms and their culture-medium; and, given a reasonable degree of temperature, here are the conditions requisite for introducing into the filtered domestic water supply the complete series of soluble products of albuminoid decomposition. Not only is this the case, but, after the first few days of use, the completeness of the removal and retention of the bacteria is diminished, and the results of the proliferation of these organisms are manifest in their numerical increase in the filtered as compared with the unfiltered water. This is well shown in a series of experiments with different filters, by Dr. G. T. Swarts, reported to the Rhode Island Medical Society, and recorded in *The Boston Medical and Surgical Journal* of March 24, 1887.

His results show that some filters when first used successfully remove a certain proportion of organisms from the water. Other tests made seventeen days later showed in every case a marked increase in the number of colonies in the filtered as compared with unfiltered water. For instance, the unfiltered water contained thirty-six colonies of growth, while the filtered water showed the presence of colonies to the number of 2000, 9000, and 10,000.

An examination on the seventieth day showed an increase in case of one filter, of 117,000 colonies.

Another series of experiments was made to determine how far the consumer could cleanse his filter or sterilize it in some simple manner. The results showed, however, that even with every possible precaution, the number of organisms in filtered water exceeded the number in unfiltered by several thousands.

These investigations show conclusively that the organic matter retained in the meshes or interstices of the filtering media, contains organisms which increase rapidly while the filter is or is not in use, and especially if its position is in a warm kitchen or in proximity to a hot-water pipe.

The question of what would happen if a few stray germs of typhoid or cholera should enter this ready-made culture bed, and sojourn there until, reinforced by their progeny, they enter the organism of the unsuspecting prohibitionist, one hundred thousand strong, is unpleasantly suggestive.

We understand that there is no truth in the report that Dr. H. C. Wood intends to accept the Professorship of Medicine in the Johns Hopkins University.

Dr. Hunter McGuire, of Richmond, Va., is to deliver the annual address before the Alumni Association of Jefferson Medical College of Philadelphia, April 4, 1887. His subject will be "Progress and Development of Medical Science."

Professor Arlt, the eminent Professor of Ophthalmology in the University of Vienna, died March 7th. He was retired in 1883, having been well known and honored for his many writings and discoveries. He was the first to insist upon the necessity of having glasses prescribed and fitted by physicians instead of opticians.

A cablegram announces the death, in his seventy-seventh year, of Dr. Arthur Farre, Honorary President of the Obstetrical Society of London, and physician extraordinary to the Queen, and physician-accoucheur to the Princess of Wales.

During the recent festivities connected with the celebration of his ninetieth birthday the Emperor of Germany conferred the first class decoration of the Order of the Red Eagle upon Dr. Lauer, his physician in ordinary.

Dr. Lange is reported to have successfully extirpated a carcinomatous larynx from a woman at the German Hospital, New York, five weeks ago.

REVIEWS.

Skizzenbuch zur Einzeichnung Ophthalmoscopischer Beobachtungen. Von Dr. O. Haab. Zürich: Hofer & Burger. Philadelphia: James W. Queen & Co.

Sketch-book for Recording Ophthalmoscopic Observations. By Dr. O. Haab.

Dr. Haab's "Sketch-book" consists of three series of colored plates, with a few pages of explanatory text. The first series presents merely the plain general color of the normal fundus, in the second the optic disk is represented, while the third gives the retinal vessels also. The plates are designed to serve as the basis for sketches of cases encountered in practice; enabling one thus to record any lesion or anomaly of the fundus, without expending the time and labor required to fill in all the background and detail necessary for a complete colored sketch.

To make a sketch on one of these plates there are required only the double color-pencil which accompanies the book, with an eraser, the use of which gives yellowish or lighter areas; a common lead pencil or black ink to give gray or black, and a pen-knife, which by scraping away the ground color, gives spots or lines of pure white. But if it is preferred, the sketch may be completed by the use of water colors.

Dr. Haab directs attention to the benefits to be derived from the making of such sketches, both in the value of the records so obtained, and in the habit of close observation developed by endeavoring to reproduce the appearances presented to the eye. On the latter account the sketching of normal and pathological eye-grounds might well form an important part in the training of every ophthalmoscopist.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

The President, Charles McBurney, M.D., in the Chair.

Dr. Lewis A. Stimson read a paper on

THE TREATMENT OF OLD DISLOCATIONS OF THE ELBOW.

The great extension given in the last few years to the application of operative methods in the treatment of surgical diseases and injuries, has compelled a reopening of many questions which had been previously looked upon as settled, and has made it necessary again to collect and study the recorded experience for our guidance in the future.

Among these questions, that relating to the propriety of interference in old, unreduced dislocations is an important one, and one upon which experience is rapidly accumulating; and among these dislocations those of the elbow have an important place. The loss of mobility resulting from the injury, especially in the common dislocation of both bones backward, is usually so great that the disability is serious, the patient is unable to bring the hand to the head or chest, and is able to use it only in the arc of a circle whose radius is nearly

equal to the length of the extended limb, and he may, in addition, possess only such rotation as can be effected by movements at the shoulder. Moreover, the injury is most common in the young, and the disability, therefore, lifelong. I desire to present to the Society a brief record of a personal case, in which features of interest and importance appear, and a survey of the recent experience of others.

My case is as follows: Maggie F., a rather delicate-looking girl, eleven years old, was admitted to the Bellevue Hospital in April, 1886, with a backward dislocation of both bones of the right forearm, which had been produced five months previously by a fall from a sofa. The elbow was flexed at an angle of 150 degrees, and was immovable except for some rotation. The soft parts covering the joint were normal in appearance and to the touch, and it was possible to recognize by palpation the relations of the bones, and that the internal epicondyle was lacking, and that the external condyle was greatly thickened posteriorly, overlapping the upper surface of the head of the radius. The length of time that had elapsed since the injury was received, the extensive new formation of bone, and the degree of the disability led me to attempt to relieve the condition by an arthrotomy, Drs. McBurney and Halsted being present and assisting.

An incision was begun at the outer aspect of the arm, about two inches above the epicondyle, carried down to and a little beyond the latter, and continued for a short distance along the forearm parallel to and a little in front of the radius, and through this the mass of bone of new formation on the back of the external condyle was freely exposed and chiselled away. This mass grew backward and downward from the upper portion of the posterior aspect of the external condyle and the shaft above it, completely overlapping posteriorly the head of the radius in the form of a buttress against which the latter rested, and was continuous on its outer and inferior margins with the condensed soft parts which formed the new capsule.

The anterior part of the capsule, which was drawn snugly around the lower end of the humerus, was easily separated from it, and the articular cartilage of the latter appeared smooth and unaltered, but the dissection behind the humerus was made very difficult by the interposition of a mass of fibrous tissue between it and the greater sigmoid cavity, which entirely filled and was closely adherent to the latter. Dr. McBurney advised the making of a second incision upon the inner side of the elbow to facilitate this dissection, but unfortunately I preferred to meet the difficulty by dividing the olecranon, being encouraged so to do by the reports of some cases to be subsequently mentioned, and by personal experience of the method in operations for tubercular disease of the joint. So the incision was extended across the olecranon, and this process was divided obliquely at its thinnest part. The back of the condyles was then easily freed, and the epitrochlea was found to have been broken off and to have reunited with the humerus at some distance above its normal position. The attached internal lateral ligament was then separated from it, and the bones were then readily brought into place. The coronoid process of the ulna had not been broken.

The olecranon was sutured with silk-worm gut, a drainage-tube placed behind the condyle through the external incision, the wound closed, and the limb placed in a splint with the elbow at an angle of about 145 degrees. It was possible to flex it to a right angle, but in that position the strain exerted by the triceps upon the olecranon was so great as to endanger its reunion. As the history will show, in thus seeking to avoid failure of union, the occurrence of another and more serious accident which I did not anticipate—recurrence of the dislocation—was favored. Two days later the dressings were changed and the limb was enveloped in plaster-of-Paris bandages. A week later a fenestra was cut, and the tube removed; there was little or no suppuration. During the following month I was absent from the city; on my return the dressing was removed, and the wound was found to be solidly healed, but the dislocation had recurred.

A second operation was done three weeks later, two months after the first. A curved incision was made, its convexity upward, beginning just below the outer side of the head of the radius and crossing above the olecranon; the ulnar nerve was exposed and drawn aside, and the joint was opened by cutting through the triceps. The joint surfaces were found almost denuded of cartilage and much changed in shape by bony and fibrous outgrowths at their borders, so I excised the lower end of the humerus and the head of the radius; the bone was much softer than usual. I enlarged the sigmoid cavity by scraping and cut a notch in the lower edge of the humerus to receive the olecranon; catgut drains. Close fibrous union of the former division of the olecranon was found. The wound healed without incident in thirteen days; passive motion was made for several weeks, and the patient left the hospital with flexion to within a right angle and almost complete extension, but on looking her up in February, 1887, about seven months later, I found the joint completely ankylosed at a right angle. The only good result of the operation was an improvement in the attitude, and against that must be offset the loss of the slight amount of rotation which existed before the operation. There is still the possibility of restoring motion by another excision, but I advised the parents not to have that done at present.

The direct examination of the joint at the two operations disclosed several interesting features, of which some are new, and others have been before described, which bear directly upon the question of the best method of treatment. The extensive overgrowth of bone upon the back of the external condyle has not, I think, been observed, or at least reported, in any other case in which the dislocation had existed for only five months, and it is to be attributed, probably, to the stripping up of the periosteum. Although it may be remembered that a specimen of incomplete outward dislocation in a child eight years old, removed by excision, presented to the Society October 25, 1886, by Dr. Lange, showed a similar growth nearly half an inch broad on the outer aspect of the external condyle, one probably produced in the same manner. Taken in connection with the avulsion of the epitrochlea, which is common in lateral dislocations outward, but rare in the backward ones, and with the apparent integrity of at least the outer part of the anterior ligament, it suggests that the dislocation was produced not by the usual hyper-extension of the elbow,

but rather by a lateral outward flexion of the forearm which tore off the epitrochlea, and was then followed by a twist, which carried the coronoid process backward past the trochlea, and then by a direct impulsion of the bones backward and upward. Displaced in this manner, it is easy to understand that the head of the radius should have stripped the external lateral ligament from its attachment to the condyle, and have passed upward between the periosteum and the bone, leaving the former continuous more or less completely with the ligament, and itself remaining within the cavity thus formed. That the periosteum, thus stripped up, should have so promptly produced the mass of bone formed above and behind the head of the radius, is entirely in harmony with our experience. To this extent the case is exceptional, but other features are of more general occurrence, and may reasonably be looked for under like circumstances. The attitude of almost complete extension of the forearm is common, and the consequent overriding of the bones along the back of the humerus leads to the formation of new cicatricial bands between the olecranon and the humerus, and to the establishment of new attachments by the torn lateral ligaments so far above and behind the centre of motion that almost no flexion is possible without their rupture or elongation, and the return of the bones to their place can be effected only after a far more extensive rupture of these soft parts than that which accompanied the dislocation. In attempting to rupture these bands by forced flexion, the forearm is used as a lever, the fulcrum of which is situated on the ulna below the coronoid process, and the rupturing strain is exerted through the olecranon upon the ligaments and adhesions connected with it, and it is not to be wondered at that this process should so frequently have been broken in the manipulation. In the case which I have described the middle and posterior portions of the internal lateral ligament apparently had not been ruptured, but had been torn away at their upper attachment, remaining continuous with the fragment of the epitrochlea, and after this fragment had reunited with the humerus at a higher point, the ligament was as strong as it had ever been.

The filling of the greater sigmoid cavity by a mass of fibrous tissue, partly by new formation and partly furnished by the posterior portion of the capsule which slips in between it and the bone appears to be of frequent occurrence; it has been encountered in several operations, and the union between this mass and the cartilage of incrustation was so firm in my case, as also in others, as to require the application of the edge of the knife for its removal. When present it must be a serious, perhaps an insurmountable, obstacle to the restoration of the bones to their place by any method which does not directly provide for its removal. The adhesion of the anterior portion of the capsule to the cartilage covering the capitellum was but slight, and the cartilage itself was almost unaltered in appearance after the separation. The reason of this notable difference in the solidity of the adhesions contracted by the cartilage covering the greater sigmoid cavity and that covering the capitellum is not clear.

Another change, peculiar to the young, which was present in only a slight degree, if at all, in my case, is one which may so far alter the shape of the end of the humerus, and particularly of the capitellum, as to make it impossible to replace the radius and ulna even after the removal of all obstacles arising from changes in the soft parts. This change, which has rarely been noted at the elbow, is of common occurrence at the knee in the subluxations following prolonged flexion of that joint. It consists in an exaggerated growth of the epiphysis consequent upon the withdrawal of the pressure normally exerted upon it by the opposing articular surfaces, and as the conjugal cartilage of the capitellum runs obliquely from in front and above downward and backward, this growth takes place in a direction at right angles to that of this cartilage—that is, downward and forward—and the capitellum consequently forms an abnormally large hemispherical prominence on the anterior and lower part of the line. The epiphysis of the trochlea is smaller than that of the capitellum, forming only a comparatively thin scale upon the surface, and there are no observations to show any irregularity in its growth due to this cause. In the reported cases in which the capitellum was deformed, the ulna had remained more or less completely in contact with the trochlea, and consequently the factor of withdrawal of normal pressure did not exist for it. In Dr. Lange's specimen, above mentioned, the capitellum showed this enlargement very plainly, but the inner side of the trochlea was flattened.

Another change which has been observed only in cases of displacement of very long standing, is elongation of the neck of the radius, and this also I think must be attributed to the same cause. Reported specimens in which one or both changes have been observed are those of Humphrey, Allen, and R. W. Smith, but in none of them is it certain that the primary displacement was a traumatic dislocation, for they also presented evidences of defective development.

In Humphrey's[1] case the lower part of the left ulna was lacking, evidently the result of defective development; the right ulna was firmly ankylosed to the humerus nearly at a right angle, and was eight inches long, its lower end was well formed and was on the usual line with the radius; the radius was also eight inches long, and its head was displaced upward and rested against "the free part of the ridge that ascends from the outer condyle to the shaft;" it was somewhat irregular in shape, and its extra length was developed in its shaft and not in its neck as in other cases. The displacement upward was clearly the result of the elongation of the radius, whatever the cause of the original displacement from contact with the capitellum may have been, whether traumatic, pathological, or congenital.

Allen's[2] specimen was taken from the body of an elderly man without history. Both elbows were affected: flexion was normal, extension possible only to a right angle; rotation was entirely lost, the limbs being fixed in pronation. The radius crossed the front of the ulna and was united with it by bony union for a distance of about three inches at the upper part; below this part the shaft of the radius was much thickened. The neck of the radius was one and a half inches long, so that the head was carried well up behind the humerus

[1] Medical Times, vol. 4, pp. 286.
[2] Glasgow Med. Journal, 1880, vol. 14, p. 44.

on the inner side of the olecranon, and this over-riding was further increased by the abnormal growth of the external condyle downward and outward, the extent downward of the growth being estimated at half an inch. The trochlear surface was deformed, mainly by the loss of its inner lip. The olecranon fossa was so far filled up that the septum between it and the coronoid fossa was one-third of an inch thick.

In R. W. Smith's[1] specimen, which was taken from a woman about forty years old, the radius was displaced forward, and the external condyle was much larger than usual and bent forward, its anterior upper surface forming with the lesser sigmoid cavity of the ulna a deep hollow in which the head of the radius lay.

Finally, partial fractures of the head of the radius and of the coronoid process have been observed in dislocations backward, and the pressure of the fragment of the radius or the formation of bony union between the stump of the coronoid process and the humerus may interfere with reduction. In several cases the fracture of the head of the radius has caused so much disability that resort has been had to arthrotomy (Wagner in *Beilage zum Centralblatt für Chirurgie*, 1886, No. 24, p. 93), and in two cases of backward dislocation of both bones Annandale[2] found the coronoid process united to the back of the humerus "by a considerable amount of osseous material."

To recapitulate: In all cases of backward dislocation of both bones of the forearm of more than a month or six weeks' standing, it may be reasonably assumed that strong adhesions have formed between the olecranon and the stump of the external lateral ligament and the back and sides of the humerus, which must be ruptured or divided before the bones can be returned to their place, and that the greater sigmoid cavity is occupied by a closely adherent mass of fibrous tissue; and when the patient is under fifteen years of age it is probable that the lower end of the humerus has been altered in shape by the formation of new bone under the injured periosteum, on its back or sides, and by the exaggerated growth of the capitellum; and when the dislocation has lasted three months, or more, in a young patient, this deformity of the capitellum may be quite marked, and may be made still more important by an elongation of the neck of the radius.

It is possible also, though not probable, that there may be present a partial fracture of the head of the radius or of the coronoid process, which will seriously interfere with the restoration of the functions of the joint even after the reduction of the dislocation.

Turning now to the bearing of these changes upon the question of treatment, it appears that they are clearly incompatible with successful reduction by the means employed in fresh cases, even if the force employed be sufficient to rupture the adhesions and bring the bones down to the proper level. It is true that successes have been occasionally reported, but the reports rarely go beyond the statement that reduction was accomplished, and they leave the subsequent history of the case, and the degree of reëstablishment of the functions unrecorded. Until quite recently the only methods employed have been forcible attempts to reduce by traction and the breaking of adhesions, sometimes aided by subcutaneous division of the tendon of the triceps or of the adhesions on the sides and back of the joint, increase of the range of motion by the same means without reduction, reduction after fracture of the olecranon by forcible flexion, and excision of the joint.

Albert says that Liston, more than forty years ago, successfully reduced an old dislocation after having subcutaneously divided all tense bands, and that, in 1847, Blumhardt successfully practised arthrotomy in a similar case, making two lateral incisions, and dividing through them all the adhesions that opposed reduction. This case appears to have been entirely lost sight of, and it was not until thirty years later, in 1877, that Küster,[1] in reporting a case of fracture and dislocation of the astragalus, treated by excision, suggested that old dislocations of other joints might be successfully treated by arthrotomy. In the following year Trendelenburg,[2] in a paper recommending temporary division of the olecranon to facilitate operations upon the elbow-joint, reported a case of incomplete outward, or outward and backward, dislocation of both bones with avulsion of the epitrochlea, which he had treated by making an incision along the tendon of the biceps, and chiselling away enough bone from the lower end of the humerus in front of the coronoid process to allow flexion to a right angle; the result was good to that extent. A little later, Volker[3] reported a case of incomplete outward dislocation of the left elbow of six months' standing, in a boy thirteen years old, in which, after division of the olecranon, he had divided the adhesions, dissected away the new tissue adherent in the sigmoid fossa, and had then been able to reduce; as the change in the shape of the bones favored recurrence, he also removed the head of the radius. He then sutured the olecranon with two silk-worm gut sutures passed from side to side of the bone, closed the wound, and obtained a good result. His incision was V-shaped, its sides extending along the borders of the triceps, and the bottom of the V crossing the olecranon at the point where it was to be divided. The position of the limb (ankylosis in almost complete extension), and the evidences of serious pressure upon the ulnar nerve, were important factors in the determination to operate. He was so pleased with the result that he looked forward with confidence to the adoption of the method in all old dislocations with much disability.

Trendelenburg[4] promptly claimed priority in the suggestion of preliminary division of the olecranon, and reported a case of backward dislocation of both bones of eight weeks' standing, successfully treated in this manner. His incision was a curved transverse one, the convexity directed upward, crossing the median line well above the olecranon, and the flap of skin was then dissected and reflected downward to the point at which the olecranon was to be divided; this division was done with a chisel. Because of difficulty in bringing the olecranon down the limb was dressed in extension, but after the nineteenth day, when the wound was healed, the position was gradually changed, and four weeks after the operation the limb could be flexed to a right angle.

The olecranon reunited solidly in this case, and in Volker's.

In 1885 Nicoladoni[1] published a short paper on the application of arthrotomy to old dislocations of various joints, and included in it the reports of two cases in which he had practised it at the elbow. The first case was an almost complete outward dislocation of the left elbow in a lad sixteen years old, which had existed for eight months; the epitrochlea was broken off and drawn under the trochlea; the limb was in extension, flexion was almost entirely lost, but rotation was preserved. An incision eight centimetres long was made in front along the inner border of the trochlea, and through this the fractured epitrochlea was removed; a second incision of the same length was made on the outer side of the joint, through which, after removal of a small piece of bone which had been broken from the condyle, the soft parts were separated from the radius and the humerus; then, through a longitudinal cut made in the triceps, the adhesions between the olecranon and the back of the humerus were separated, and the bones were then easily restored to place. The wounds healed after slight suppuration; passive motion was begun after the third week, and the patient was dismissed after seven and a half weeks with the elbow flexed and movable through an arc of 35 or 40 degrees. Nine months later he wrote that he could flex and extend the joint freely, but that rotation was not quite so free.

The second patient was a large powerful man, forty-one years old, with a backward dislocation that had existed for six months. The limb was almost completely extended and immovable; there was some passive rotation. Two lateral incisions, each sixteen centimetres long, were made; through the first, over the outer condyle in front of the head of the radius, the soft parts were separated from the bone, leaving the periosteum undisturbed, into the trochlea, and above the fossa trochlearis in front and behind; the separation from the cartilage was easy in front, but very difficult behind; through the second incision, on the inner side of the elbow, the flexor muscles were cut away close in front of the epitrochlea, and the separation of the soft parts from the bone completed. The greater sigmoid cavity was found filled with hard cicatricial tissue, which was cut and scraped away after separation of the posterior attachment of the orbicular ligament. Reduction was then easily made. Two drains were placed on the flexor side of the joint, and one through the tendon of the triceps; the wound was closely sutured, Lister dressing applied, and the limb placed on a splint. Recovery took place without incident, and the patient was dismissed at the end of four weeks, the wounds being almost healed. There was good active rotation, but very little flexion; passively, there were complete extension and flexion to a right angle.

In drawing conclusions from this scanty record of only five cases we may be somewhat aided by the results of similar operations at other joints and in other forms of dislocation at the elbow. In several (five or six) cases of isolated dislocation of the head of the radius arthrotomy has been done with good results, both as regards the reduction of the dislocation and the restoration of function, although the latter has never been complete. I know of only one case (Burkhardt) in which a dislocation at the shoulder has been reduced by arthrotomy, and in this the functional result left much to be desired. In another (Albert) fracture of the surgical neck of the humerus took place during the operation, and the patient recovered with a pseudarthrosis, and in a third (Thiersch) the operation failed. At the ankle, the astragalus has been successfully replaced by arthrotomy by Dr. McBurney in a recent dislocation; and the operation has been done several times with success at the metacarpal joint of the thumb. In a case of thyroid dislocation of the hip, Polaillon[1] lost his patient by acute septicæmia.

In a case of dorsal dislocation of nine months standing, in a child seven years old, Dr. McBurney successfully reduced by arthrotomy, but the head of the femur subsequently became carious and was removed.

The success in Volker's and Trendelenburg's cases, in which the olecranon was divided, was fairly good, and the divided process reunited promptly and well; but in mine the union was only fibrous, and the position of the upper fragment was such that the limb had to be dressed in semi-extension, and to this I attribute the recurrence of the displacement. Probably the difficulty might have been avoided by a more free liberation of the upper fragment, from which I refrained because I did not think it necessary, and did not anticipate the consequences which followed. The method gave easy access to the joint, and a good view of the adhesions that needed to be divided, but in another case I should give the preference to the method by two lateral incisions without division of the olecranon.

The only facts in this brief record which may actually contraindicate resort to arthrotomy are the death of Polaillon's patient, and the change in the articular cartilage observed at the second operation in my case. Of the former it is sufficient to say that the case was of six weeks' standing, and had been subjected to several attempts to reduce under chloroform, the last one three weeks before the operation, and that the region of the hip was still tender and swollen; the patient was delicate and alcoholic. The incision was made in front, from the anterior inferior spine of the ilium downward, and during the operation the dislocation was transformed into a dorsal one. Apparently the operation was done with scrupulous attention to antiseptic details, and the occurrence of fatal acute septicæmia (with emphysematous gangrene) was probably due to extensive bruising and laceration of the soft parts; the record of the case indicates that the parallel between it and operations upon tissues that have recently been subjected to violent traumatism is close.

The change in the articular cartilage observed in my case could hardly have been caused by the inflammatory reaction following the operation, for that was not sensibly greater or more prolonged than after the original dislocation. I am inclined to attribute it rather to the keeping of the knife too close to the bone in the separation and freeing of the soft parts, and think, therefore, that in a similar case it would be better to divide the adhesions than to separate them from the humerus.

The reported cases are too few to justify much general-

[1] W[illegible] [illegible], 1885, p. 728.

[1] Bul[illegible] [illegible], 1881.

ization, but the large measure of success which they have furnished is an encouragement to further trial. In the meantime, the rules of conduct in the presence of old backward dislocations of the elbow formulated by Albert appear to be judicious. He says that in elderly patients he limits interference to rupture or subcutaneous division of the adhesions, and that if reduction then fails he forcibly flexes the elbow to a right angle, with or without fracture of the olecranon, and allows it to become ankylosed in that position.

In younger patients he makes the attempt to reduce, sometimes dividing the tendon of the triceps so as to avoid fracturing the olecranon; reduction failing, he does an arthrotomy with two lateral incisions, and if this also fails he proceeds to resection.

To this I should wish to add the caution that an arthrotomy should not be undertaken until after the tissues have entirely recovered from the inflammatory reaction and the fresh lacerations of the original injury or of attempts to reduce; and that the longer the dislocation has lasted, and the younger the patient under fifteen years, the less is the probability that arthrotomy will be sufficient, and the greater the probability that excision will be required.

In old incomplete outward dislocations little good is to be hoped for from anything but arthrotomy, for the common interposition of the fractured epitrochlea cannot otherwise be overcome, or the cicatricial obstacles on the inner side removed. The choice will probably lie between improving the attitude by forcible flexion, if the limb is extended, and arthrotomy, the internal incision being made in front of the trochlea rather than upon its side.

Dr. Pilcher thought that the case described by Dr. Stimson must have been the same as one he had had under observation during the previous winter. If so, he thought that he might be able to clear up some of the obscure points in it. When he first saw the patient she was under the care of a skilful surgeon, who had made a diagnosis of fracture of the lower end of the humerus into the joint; crepitus under manipulation having been distinct. At the outset of the case there was no indication of a dislocation, as stated by that surgeon, although the conditions were so obscured by great inflammatory swelling, when first seen by Dr. Pilcher, that a satisfactory examination was then difficult. It was said that there had been threatening gangrene in consequence of previous too tight bandaging. In the course of time, after union had taken place and the swelling had subsided, he again examined the case. It was now apparent that a fragment involving more or less of the external condyle had been displaced forward and downward and in its new position, where it had become fixed, encroached upon the articular surface for the radius, limiting the power of flexion at the elbow. There was also a partial backward dislocation of the ulna existing. Along the inner margin of the muscular mass of the forearm which has its origin from the external condyle, there was a depression occupied by dense, fibrous, cord-like tissue. He believed that by the gradual degeneration and contraction of this tissue the displacements had been produced that resulted in the final deformity and loss of function, these being consecutive and remote results of the original injury, which had been a fracture. The limb had been dressed in a position midway between flexion and extension. He had never questioned the correctness of the diagnosis of fracture, although when he examined the patient the condition of the joint was such as to render prolonged manipulation unjustifiable. The inflammatory swelling, and the anterior mass would have been explained perfectly well by a fracture. The patient had been under his observation for some time and a day had been set for an arthrotomy for her relief, when she disappeared. He learned subsequently that the patient had entered Bellevue Hospital.

Dr. Stimson replied that in his case there was certainly no fracture of the lower end of the humerus, but only an outgrowth on its outer side. When he excised the end of the humerus he found that it was perfect, with the exception of the epitrochlea.

Dr. Weir remarked that the good results which had been obtained in cases of old dislocations of the elbow-joint, as time went on, had led surgeons to leave these cases to some extent to nature. It was only of late that he had adopted such means as forcible flexion, division of the triceps tendon, etc., for the purpose of correcting the deformity. But he had come to the conclusion that more could be done in the way of radical treatment. Two German observers, Sprengel, of Dresden, and Schüssel, of Berlin, had shown that we could safely interfere at an earlier period after the accident than was generally supposed, and that failure to reduce the dislocation should be followed by operation, and that the rent in the capsule produced by the original injury should also be sewn up. The prognosis is better the earlier the surgical interference.

Dr. Gerster said that his experience with old dislocations of the elbow embraced four cases, in two of which operations were performed. In one instance (last December), the patient was a child two years of age, having a deformity similar to that described by the reader; the case was first seen three months after the accident. Arthrotomy and excision of the joint were resorted to; a peculiar callus was found over the external condyle, which was shown on section to be due to a fracture of the condyle. After having sawed off the surface it appeared necessary to detach this fragment, as it was so loosely attached to the humerus that it would probably have become necrosed. In all the cases, in addition to backward dislocation of the forearm, the so-called "gun-stock" deformity was marked. He believed that it was possible that the periosteum might be stripped off, and that the interval between it and the bone might become filled with blood-clot, which would organize to form connective tissue, and ultimately bone, although this had never been proved anatomically. In all the cases that had come under his observation, there had been no doubt concerning the occurrence of fracture. In a case under the care of Dr. Daniel Simpson, at the Mt. Sinai Hospital (two years before), a young man sustained a fracture of the external condyle and the capitellum, with dislocation forward, a callus being subsequently formed on the flexor side of the elbow, which prevented flexion; the bony deposit was removed, and the condition of the joint, as regarded flexion, was much improved. The two other cases which presented the same deformity are still under observation. The accident must be more common in young subjects than is generally supposed. In the men-

tioned cases in which he had operated, the speaker had made a large incision, with the express purpose of obtaining a good view of the interior of the joint, and ascertaining the exact pathological condition. He found that the fragment consisting of one-third of the trochlea, and the external epicondyle, together with the capitellum, were twisted around at right angles to the direction of the articular surface of the humerus, so that the capitellum looked into the bend of the elbow. The diagnosis, he admitted, was not easy, especially for the reason that in many cases the patient could not be examined until several hours after the accident, when there was such an effusion of blood that the condition was obscured, and crepitus could not be obtained. The latter was the only positive sign of fracture obtainable. Most of these cases were not examples of simple dislocation, but of fracture complicated with dislocation backward and inward. As regarded the results of treatment, in his own case they had been quite satisfactory, flexion and extension being almost completely restored. He had performed arthrotomy in several other cases of dislocation, especially of the thumb; in one instance the flexor tendon had slipped over the head of the metacarpal bone; it was necessary to lift it out of its false position with a strabismus hook. In another case (that of a boy of twelve), the dislocation was not seen until seven weeks after the accident, although reduction would have been easy if it had been practised early. The third case was one of dislocation of the index finger of a boy; reduction was readily effected by means of arthrotomy, and division of the capsule. He also performed arthrotomy in a case of old habitual dislocation of the shoulder-joint in a young girl. Two months after the accident she entered Mt. Sinai Hospital; reduction was easily effected, but the bone would not stay in place, whereupon the speaker incised the joint, removed a portion of the lax capsule from the mesial side of the capsule, closed the latter with catgut sutures, and the patient did perfectly well.

In answer to a question by Dr. Briddon, he admitted that dislocation was generally secondary to fracture. He called attention again to the frequency of "gunstock" deformity in these cases, which Dr. Stimson had not noted.

THE PRESIDENT said that since Dr. Stimson had referred to a case in which he himself had operated, he thought it was proper that the result of the operation should be clearly stated. The patient was a child between six and seven years of age, with old dislocation of the hip, of nine months' standing, resulting from a fall; there was great deformity and disability. Some of the surgeons who examined the patient were in doubt as to whether the condition was dislocation or separation of the epiphysis. A free incision was made over the head of the femur; the latter presented a normal appearance, but a piece of the articular cartilage was easily detached. The head was movable within an artificial sac which contained about a drachm of serous fluid. The acetabulum was filled with a semi-gelatinous material. Reduction was easy after the division of a few adhesions; the wound was closed, and a hip-splint was applied. Neither fever nor other bad symptoms followed, although a sinus persisted for seven or eight months. The speaker had examined the patient about a month before. He found the child well; on manipulating the limb there was neither pain nor crepitus, and motion was fairly free. On introducing a probe, bare bone was discovered at the edge of the acetabulum. A free incision was made, and it was found that the whole head of the femur was carious, so that it was necessary to excise both the head and the neck, and to scrape out the acetabulum. The patient made a good recovery.

In reply to a question from Dr. Weir, the President said that the patient had been kept in bed after the first operation. He thought that the propriety of operating in cases of old dislocation was clear, but that an operation was more likely to be successful if it was undertaken early—that is, not later than two or three months after the accident.

DR. GERSTER said that as far as the propriety of arthrotomy was concerned there was no question about it at the present day. Under the modern antiseptic system a surgeon would do wrong not to interfere if he could not reduce a dislocation, whether he saw the case early or not. In reference to the fatal case of Polaillon's in which complete antiseptic precautions were said to have been observed, the speaker believed that the occurrence of phlegmon constituted in itself sufficient evidence that there was septic infection. The natural inference was that no one ought to undertake arthrotomy who was not thoroughly versed in antiseptics, since he risked not only the patient's limb, but even his life.

DR. STIMSON repeated that in his own case there was no fracture of either condyle of the humerus. At the first operation the articular surface was found entirely unbroken, the outline of the front of the bone was normal, and the mass of new bone on the back of the external condyle was not at all like the callus of a fracture. In reply to the objection, that an effusion of blood would occur between the detached periosteum and the bone, and that this blood would prevent subsequent formation of bone by the periosteum, it may be said the same effusion must take place under the periosteum in cases of fracture, and yet it is well known that bone is abundantly formed there.

Dr. Gerster said that whenever pus was formed it indicated some failure in the technique. In one of his cases the catgut that was used had been placed in an open vessel at an operation that took place two days before, had been left exposed all night, and had then been put into a bottle. This gut was used to tie the vessels at his operation. The patient had a violent chill the same night, with evident signs of septicæmia. Dr. Gerster opened the wound and found three ligatures surrounded by pus; the wound was subsequently treated by the open method and healed quite well. There was no trouble in the joint itself, and the patient now had perfect motion.

TUMOR OF THE BRAIN REMOVED BY OPERATION.

DR. R. F. WEIR presented a tumor which he had removed from the posterior occipital region of the brain. It was, he stated, the largest cerebral tumor that had been removed surgically. A full report of the case was promised later.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 4, 1887.

THE PRESIDENT, A. JACOBI, M.D., IN THE CHAIR.

(Concluded from page 361.)

DR. J. LEWIS SMITH said that at the present time the greater part of the profession coincided with Dr. Billing-

ton in the opinion that diphtheria is a local disease primarily; and yet for himself he could not see how this can always be the case. He had met with a number of instances in which the disease had a period of incubation lasting as long as six or eight days, and it, therefore, seemed to him to be from the first a constitutional affection. At the same time, he was thoroughly in accord with the reader of the paper as to the great importance of local treatment. As time went on, he said, he became more and more impressed with the fact that all irritating substances should be avoided in this connection, and hence, he is in the habit of making use of very mild applications. Muriate of pilocarpine had been very highly recommended, and even lauded by some as a specific, but he felt compelled to warn those who heard him against the employment of this agent. It is extremely dangerous, and in one case in which he had used it the patient died with all the symptoms of œdema of the lungs; the fatal result in this instance being clearly due in his opinion to the effect of the drug.

As to nasal diphtheria, the nasal passages are, in his experience, not an infrequent location of the primary exudation. It is, he believed, quite a common occurrence for the diagnosis not to be made until the membranes had become very extensive, and the patient is very apt to die if local treatment is not resorted to at a comparatively early period. As to the medication to be applied through the nostrils, common salt, which had been recommended by Dr. Billington, was, he thought, hardly antiseptic enough, and he preferred to use salicylic or boracic acid. A very good combination is the following:

R.—Acid. boracic.	3j.
Sodii borat.	3ij.
Sodii chloridi	3j.
Aquæ	Oj.

In his practice he is in the habit of making applications to the nasal passages by means of an ordinary medicine dropper.

Dr. Smith thought highly of alkaline inhalations, but the amount of lime in lime water, which is still used to a large extent, is very small. Its alkalinity and solvent action can be materially increased, however, by adding a drachm of bicarbonate of soda to each pint of lime water. As regards trypsin, its expensiveness is an objection among the poor, but it can be used in comparatively small quantities as an addition to the ordinary alkaline solutions. It is, probably, of considerable benefit. Physicians err, he thought, in not carefully noticing at each visit whether the child is becoming hoarse or not. Hoarseness being the first indication of the implication of the larynx and trachea in the membranous exudation, its appearance should be constantly looked for.

Dr. Francke H. Bosworth said that one point of great importance had not been referred to, and this was the fact that glandular tumors of the pharynx offer one of the most favorable evidences possible for the lodgement of the diphtheritic poison; while if the nasal passages and fauces are perfectly normal, the individual is much more likely to escape the disease. The clinical significance of this point was self-evident. Dr. Billington's paper only afforded additional proof of the fact that there are no specifics for diphtheria. It is, therefore, to the faithful carrying out of the two or three indications to which he had referred that we are to look for success in the treatment of this disease. In regard to nasal injections, he thought that placing the use of the syringe in the hands of even a trained nurse, involved considerable danger, and he greatly preferred to employ the spray. Delano's atomizer, to which Dr. Billington had alluded, is a good instrument as long as it will work, but the trouble with it is that it is constantly getting out of order. Hence, it is better to use one constructed on a different principle, and the "Magic" atomizer, which can now be obtained at any druggists for a dollar, is as efficient as any for the throat. For the nose Millard's atomizer, No. 5, costing $1.25, is probably the best instrument. It has a large nozzle, and by means of it fluid can be made to pass in one nostril and out of the other by the force of the current of air generated. Of all cumbrous and useless appliances that have been put into the hands of the medical profession, he thought the galvano-cautery is the worst. The effect produced with it is simply that of heated platinum wire, without any electrical action whatever, and precisely the same results can be obtained by other agents, and in a much more convenient manner.

Dr. D. Bryson Delavan spoke particularly of the value of bichloride of mercury in the treatment, and expressed the opinion that it has scarcely received as much attention in the present discussion as its merits entitle it to. This agent has been constantly shown to have much greater germicide power than carbolic acid; and, therefore, he thought it ought to be preferred to the latter. In his own hands it has proved more productive of good than any other remedy. While in nasal diphtheria the efficiency of the antiseptic spray is unquestionable, he thought it a good plan to spray the nasal passages, even in the pharyngeal form of the disease, as it assists in freeing the pharynx of obstructions, and also enables the patient to breathe through the nose. He preferred the spray very much to the use of the syringe.

The Chair stated that Dr. J. T. Hutton, of Minnesota having reported unusually good results with the topical use of lunar caustic, Dr. Billington wrote for some further particulars of the method of treatment, when Dr. Hutton replied that he would be present in person on this occasion, and it now gave him great pleasure to introduce that gentleman to the Academy.

Dr. Hutton said that there are probably fifty remedies that will cure diphtheria if we only knew how to use them. While the disease is local in the pharynx he believed that he can arrest it in every instance. His statistics showed a mortality of only 12 in 209 cases, notwithstanding the fact that in several of these he did not give continuous treatment. His experience was confined entirely to Minnesota; although he presumed the disease is essentially the same in its general characteristics everywhere. He had gone to Minnesota to practise nine years ago, but did not meet with any diphtheria until seven years ago. In the neighborhood in which he resided five families had lost twenty children, and thirteen families, thirty-six children from the disease before he moved there. The first time he was called upon to treat diphtheria his experience was very

unfortunate. When he arrived at the house, which was twenty miles from his own home, he found that three children had already died of the disease, and three others were very low with it. He was sorry to say that two of the latter also succumbed afterward. In the next family that he visited he first made use of the plan of treatment to which he has ever since rigidly adhered. In this household no less than five children were dead from diphtheria, and three others were very low with it. All three of the latter, however, recovered under the treatment which he then instituted, and which he believed to be infallible for the first stage of diphtheria in the region of country in which he lived, however it might be elsewhere. He did not make use of it in the stage of stenosis.

The two great indications in diphtheria, he believed, are, *first*, as the disease is local at first, to destroy the false membranes; and, *second*, as the disease is attended with marked vital depression, to support the patient. For destroying the membranes he employs a solution of nitrate of silver of the strength of from twenty to fifty grains to the ounce applied by means of a camel's hair pencil, and he said the application is no more painful than that of syrup or water. These applications should be repeated until all the membrane is completely destroyed, and he had known of violent cases to be sometimes controlled by a single application. Chlorate of potash is also directed to be used as a gargle or swallowed. In carrying out the second indication, an abundant supply of fresh air is a necessity, and if it can be obtained in no other way, the patient should be taken out of doors, unless the weather is intensely cold. As the heart is liable to fail, it is desirable to have the patient as quiet as possible, with the body kept in the recumbent position and sufficiently warm. Milk, eggs, beef-extract, and alcoholic stimulus are to be given freely, and he generally employs quinine in doses of one grain about every hour. With this plan of treatment most of the cases were gotten under control within twenty-four hours, and there was no subsequent paralysis, or other disagreeable sequela. In nasal diphtheria he used a five per cent. solution of carbolic acid by means of the syringe.

Dr. Joseph E. Winters said that local treatment is impracticable in cases of diphtheria limited to the throat in young children, though this is not the case when the disease affects the nose. If diphtheria is primarily local, the first object in the treatment should be to destroy the membranes by means of strong caustics. Yet all who had taken part in the present discussion, except Dr. Hutton, had condemned this course of action. All, however, agreed that local treatment should be directed against the membranes; but for himself, he could not see why so much stress was laid upon the membranes, as long as they were confined to the fauces. If they are removed forcibly, or by means of caustics, they will only reform. The one thing that promotes secretion more than anything else is heat; and it should be applied both internally and externally. Hot applications should be made, and these should be kept continuously hot. The primary indication in the treatment of diphtheria, he thought, is to prevent the extension of the membrane into the larynx, and this is also accomplished by the persevering use of heat. The patient is to be kept absolutely still, and no change from the recumbent posture is to be allowed for any purpose whatever. If heat were properly applied externally and internally, he did not think it worth while to fatigue the patient with the frequent or continued use of the spray. The croup bottle giving off the vapor of turpentine he had found very useful, and he is also in the habit of employing the remedies mentioned by Dr. Billington. In nasal diphtheria local treatment can be satisfactorily carried out if sufficient tact be used. In the treatment of swollen glands in connection with nasal diphtheria, Dr. Winters said that he could not subscribe to the use of ice, as recommended by the author of the paper, as he believed it to be injurious by promoting the spread of inflammation.

Dr. H. D. Chapin said that he greatly preferred the spray to the syringe for local treatment in the throat, and spoke particularly of the liability of the use of the syringe to excite vomiting.

Dr. Beverley Robinson said that he should be very much opposed to any form of douche which caused vomiting, and that he also was decidedly in favor of the spray. He did not believe, however, that the ordinary spray-producer is of any use practically. The only atomizer which he employed is that of Dr. Lefferts, and he thought that spraying with an efficient apparatus is the only thorough way of washing out the nasal cavity. The plan referred to by Dr. Smith, of using a medicine dropper, was simply a delusion and a snare. As to Dr. Hutton's method of treating diphtheria, it was pretty nearly as old as the history of the disease itself, and the use of lunar caustic, which had formerly been employed by a large number of physicians, had been abandoned over and over again by one after another. Cubeb, he thought, is more useful in its action upon the throat than the chlorate of potash. He had at one time supposed that it had some specific effect, but he now believed that it is simply a very efficient agent in combating the catarrhal element of the trouble. In his opinion there is no one remedy which will cure a very toxic case of diphtheria invariably, and death will occasionally result whatever means may be employed against the disease.

Dr. Andrew H. Smith said that while he agreed in the main with the practice of those who had spoken this evening, he did not agree with the majority of them in the matter of theory. As to the nature of diphtheria, he was glad to hear it stated that the membranes do not constitute the disease, and personally he believed it is as much a constitutional affection as scarlatina, for instance, and that the membranes are not even an essential element. We are told that the membranes are precisely the same as those met with in old-fashioned membranous croup, and also in those cases in which patients from time to time bring up complete casts of the trachea and ramifications of the bronchi. But if this be so, the latter class of patients must be affected with chronic diphtheria, and this he believed could not possibly be the case. The membranes, therefore, are not so important as had been represented; but still there is apt to be a necrotic process going on underneath them, and the absorption of septic material rendered it necessary to resort to local treatment. Local treatment is more important in the nose than in the throat, and as the hard-rubber syringe is apt to

cause suffering and do injury, he is in the habit of using a soft-rubber nipple, which is attached to an ordinary hand-bulb. When this is applied in one nostril, the fluid can be made to come out at the other. It is important that the fluid employed shall be of the same density as the serum of the blood, and the preparation which he prefers is a weak solution of bichloride of mercury (1 to 4000 or 6000) with a drachm of salt to the pint of fluid, in order to give it the proper density.

Dr. Thomson said that twenty-five years' experience has convinced him of the advantages of local treatment. He related the following case. A young man whose bed-fellow was taken with diphtheria was separated from his companion and carefully watched. On the ninth day afterward he had a very severe chill; his throat and nostrils then showed nothing but a little diffuse redness. In an hour, however, there was extreme congestion of the fauces, with grave constitutional symptoms; but it was not until the sixth day that any membranes made their appearance. On the sixth day afterward all the membrane disappeared, and the temperature was found to be normal. On the morning of the ninth day, however, he had another chill. The urine was now found to be loaded with albumen, and in two days he died from cardiac paralysis. This was a case, he thought, which clearly demonstrated that diphtheria is a purely constitutional disease. His own treatment, therefore, was based on internal support. His inquiry had always been, What antiseptics can be given in the largest quantity? and he had found the chlorine group could. Bromine is a useful remedy locally, and there is one agent which had not been referred to to-night which is an admirable antiseptic, particularly when any necrotic process is going on. This was the persistent use of oxygen gas.

Dr. Alfred L. Loomis remarked that it seemed to him that Dr. Billington had arrived at the conclusion which every sensible physician would come to who carefully watched his cases. While in a certain proportion of cases the disease might be local primarily, he believed that in the great majority of cases diphtheria is primarily a constitutional affection. In former years he had seen a great deal of diphtheria, and he had travelled over pretty much all the ground that was known, however, as regards local treatment. He had employed, in the first place, mechanical agents; second, escharotics, and, third, astringents, including the nitrate of silver. The conclusion that he had at last arrived at, was that nothing but cleanliness, with local antiseptics, and constitutional support is required. There are no specifics in this disease, and it is always best to treat the case and not the diphtheria.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, March 11, 1887.

Vice-President George Wilkins, M.D., in the Chair.

Dr. George H. Fox, of New York, read a paper on

common errors in the treatment of skin diseases.

He said that the great error made by practitioners in treating skin diseases, is failure to treat the patient; the disease is treated, but not the patient. It is most important that the patient should have better food, fresher air, and, in fact, everything that tends to improve the general health. Special treatment of the disease is of no avail without first improving the condition of the patient. He thought attention to diet is most important, and said there should be a radical change both in the quantity and quality of the food; a dietary should be given the patient; the majority of patients improve on starvation diet. He advised his patients to increase the quantity of fluids, and decrease the solids; to eat less and exercise more. A change of diet is useful, the more radical the better; he gets the best therapeutical results from a vegetable diet in the treatment of inflammatory skin diseases; a meat diet congests the skin, a vegetable diet lessens congestion. He is in the habit of restricting the meat in winter, and forbidding it in summer. In giving directions to patients, it is better to tell them exactly what to eat instead of what to avoid. Water should be taken sparingly with meals, and in quantity after meals.

In speaking of local applications, he said that very few are needed. If the disease be acute, soothing applications should be prescribed; if chronic, stimulating ones. Infantile eczema is, as a rule, too much stimulated, and chronic eczema, with infiltration, too little stimulated.

In treating psoriasis, chrysophanic acid is the best remedy, but even this remedy should not be used in every case, for it does harm when there are congestion and inflammation; but later, when the eruption becomes dry, it does good. In acne a tonic treatment is the best. In speaking of local applications, the reader of the paper said that if a substance is needed to be absorbed by the skin, then the animal fats should be used; if mere protection is wanted, vegetable fats do very well. Vaseline has little power of penetrating the skin.

He then went on to speak of arsenic, which, he said, is used too much by general practitioners in the treatment of skin diseases, and which, as regards skin diseases, would not be missed if abolished from the pharmacopœia; he now rarely uses it. It is a much overrated remedy.

Dr. Shepherd said he was not prepared to go the length that Dr. Fox did in attributing such a vast influence to diet in the treatment of skin diseases. No doubt it often is important, but he thought that, like many others, Dr. Fox was riding his special hobby too hard. Many individuals with an eczematous diathesis contract eczema from their occupation—change of diet will not benefit such cases. No doubt, people, as a rule, eat too much, and in the higher ranks of society this is especially the case. In such patients diet is of the utmost importance. In this country people eat too much meat, and he is in the habit, when treating skin cases, of limiting it to one meal a day. In regard to local applications, he was thoroughly in accord with Dr. Fox. Most physicians in inflammatory skin diseases stimulate too much; it is a common thing for physicians to prescribe zinc ointment in every case, and to give no directions as to the use of water and soap. He had found many skins in the acute stage of eczema unable to bear ointments at all, and to be much relieved by a mild lead lotion. He also agreed partly with Dr. Fox concerning the misuse of arsenic. It, like zinc

ointment, is prescribed as a routine practice in every skin case by many physicians. Still, he thought, he had given it with benefit in psoriasis and bullous eruptions. He had no hesitation in saying also that it is a most valuable tonic, and would be sorry to do without it. In treating eczema he had long ago discarded it.

Dr. R. P. Howard said that it had been long recognized that diseases of the skin are local manifestations of a general condition. He thought that treatment by alteratives is the best. He was not prepared to hear that so much attention is now given to diet, but it seemed to him to be rational. He agreed with the last speaker in thinking that arsenic is valuable as a tonic, and useful in psoriasis and bullous affections.

Dr. Hingston said that local treatment of skin diseases is very generally useless. He trusted to constitutional treatment by properly regulated diet. He did not agree with Dr. Fox in what he said about meat diet. The French-Canadians are great meat-eaters, yet have few skin diseases; some visit the United States and come back with affections of the skin; this he attributed to the diet, which is generally composed of pies, doughnuts, bread, and but little meat. Bread and meat he considered a good diet for skin diseases; they should, however, be taken separately. He believed in taking large quantities of water between meals.

Dr. Phelps, of Chateaugay, N. Y., as a general practitioner in the country, thoroughly endorsed every word Dr. Fox said. He believed most thoroughly in a complete change of diet in the treatment of skin diseases. He mentioned a case of infantile eczema which was cured by changing the diet from fresh cow's to condensed milk. Acne in females is, he thought, most generally caused by uterine disease, and until this is relieved the acne cannot be cured.

Dr. A. L. Smith said that he had long held that all skin diseases, not specific or parasitic, are due to errors of diet. He had little faith in local treatment, and considered that it is most important to attend to the stomach. He thought that the good old mixture of rhubarb and soda is too much neglected in the treatment of skin diseases.

Dr. Wilkins asked Dr. Fox if inmates of penitentiaries are more free from skin diseases than other people. Also, if in Germany, where little meat is eaten, there is a less amount of diseases of the skin.

Dr. Fox, in answer to Dr. Wilkins, stated that although they eat little meat in Germany, they drink much beer.

CORRESPONDENCE.

DEATH-RATE IN AMERICAN LYING-IN HOSPITALS.

To the Editor of The Medical News,

Sir: I would like to have an opportunity to explain some points in my article on "The Death-rate of Lying-in Hospitals in the United States," which are criticised by Dr. Garrigues in his letter to The Medical News of March 26. The original form of the article contained a detailed account of the number of women delivered and the number of deaths for each year, in the thirty-four hospitals, but this statistical table was found to occupy such an unconscionable amount of space in a journal devoted to general medical topics that the greater part of it was stricken out and only the total results for the six years 1880 to 1885 were allowed to remain. It would have been more courteous, I confess, to have referred specifically to the great improvement that Dr. Garrigues had effected in the Maternity Hospital, but the aim of the paper was to show the condition of the country as a whole in regard to lying-in hospitals, and, moreover, I thought at the time, and still hold the opinion, that Dr. Garrigues's pamphlet on Antiseptic Midwifery had been so widely read that it would surely be familiar to any one who might take the trouble to read my paper carefully.

As to the means, the use of antiseptic measures, by which this improvement was effected in the Maternity Hospital and afterward elsewhere, I regarded it as a fact so well known, so generally accepted, as to make a special reference to it, on my part, superfluous.

The reform instituted by Dr. Garrigues, in 1883, while it, or some modification of it, has been adopted in many of the foremost lying-in hospitals of the country, and has in them accomplished much good, has not, or had not in 1885, spread so widely or as rapidly as it should have done: Of the 3704 women who were delivered in 1885, in the thirty-four hospitals already mentioned, 2.02 per cent. died, and the following table speaks for itself:

The death-rate, from all causes, in five hospitals, 1885:

Louisville, City Hospital,	.	3.75	per ct. of women confined.
[illegible]	[illegible]	[illegible]	[illegible]
King's Co. Hospital, L. I.,	.	4.76	"
[illegible]	[illegible]	1.11	[illegible]
New Orleans, Charity Hospital, 10.22 (!)			" "

This last record reminds one of the days when Semmelweiss was struggling for reform in the Vienna Hospital or when Tarnier first took charge of the Maternité.

As to the injustice done the country by the publication of such statistics, no one could, more earnestly than I, desire to see this country as preëminent in scientific achievements as it is in material resources or political advancement, and if my original article, with the discussion it has provoked, should contribute in the smallest degree to the attainment of a higher level in this subdivision of scientific work, the management of parturient and puerperal women in hospitals, I shall feel well repaid, not only for the labor expended in the collection of the statistics, but also for the rather unfavorable criticism that their publication has excited.

Barton Cooke Hirst.

Philadelphia, March 26.

DISLOCATION OF THE FEMUR IN A YOUNG CHILD.

To the Editor of The Medical News,

Sir: Our apology for reporting the following case is because of its rarity in children of such tender years, as otherwise the case presented nothing of especial interest worthy of note, except that it had a remarkable getting up only two days after the injury.

On August 24, 1885, Laura M. G., aged three years, seven months, and eighteen days, in waltzing and whirling around the room to the music of a piano, on which the nurse was drumming, fell, and in attempting to rise found she could not, commenced to cry, and complained

of pain in the hip. The child was placed in bed, and Dr. Deppen called in. He at a glance noticed that, to all outward appearance, there was an iliac dislocation of the hip-joint. Examining the case closely, he found the usual symptoms of such an injury present.

A careful examination, Dr. Wenrich in consultation, revealed a very typical case of iliac dislocation, with absence of all symptoms indicating fracture of the neck of the bone, or separation of the epiphysis. The child was thoroughly etherized, and the dislocation reduced, without any difficulty, by manipulation, the head of the bone slipping into the socket with a very audible snap, heard by all present. The child made a remarkable recovery, feeling so well at the end of two days that she got out of bed unobserved and walked across the room. No evil followed this, and she soon followed with similar excursions. Drs. Wenrich and Deppen.

Wernersville, Pa.

NEWS ITEMS.

CINCINNATI.

From our Special Correspondent.

The Commencement of the Medical College of Ohio was held March 8th. The degree was conferred upon over seventy. A more than ordinarily large Spring Course began at this institution March 15th.

The Alumni Association held its annual meeting on the afternoon of commencement. Fully three hundred members were present. Interesting addresses were delivered by the President, J. H. Tate, M.D., of the class of 1840; W. H. Kelly, M.D., 1881; and T. P. Hart, M.D., 1887. Dr. Robert Boal, of the class of 1828, and the oldest living alumnus, was elected president for the ensuing year.

The Miami Medical College held its Commencement March 9th. Twenty-nine young men received the degree of M.D. With the close of this session the Miami becomes the Medical Department of the University of Cincinnati.

The Academy of Medicine has elected the following officers for the ensuing year:

President.—Joseph Ransohoff, M.D.
First Vice-President.—W. E. Keely, M.D.
Second Vice-President.—F. Forchheimer, M.D.
Recording Secretary.—G. A. Fackler, M.D.
Treasurer.—George E. Jones, M.D.
Corresponding Secretary.—James M. French, M.D.

The Hamilton County Medical Society has recently been formed. Its aim is the regulation of the practice of medicine in the State of Ohio. It has not as yet received the universal support which its object deserves, yet its membership is increasing. Dr. C. G. Comegys is President; Dr. J. A. Thompson, Secretary.

The Regulation of the Practice of Medicine in Minnesota.—A new law has just been enacted in Minnesota by the provisions of which the Governor shall appoint a board of medical examiners consisting of nine members, who shall hold office for three years. No member of this board shall be appointed to serve for more than two terms in succession, and no member of any college or university having a medical department shall be appointed to serve as a member of the board, two of which shall be homœopathic physicians.

The third section provides that all persons hereafter commencing the practice of medicine and surgery, in any of its branches, in this State, shall apply to said board for a license so to do, and such applicant, at the time and place designated by said board or at the regular meeting of said board, shall submit to an examination in the following branches, to-wit: Anatomy, physiology, chemistry, histology, materia medica, therapeutics, preventive medicine, practice of medicine, surgery, obstetrics, diseases of women and children, diseases of the nervous system, diseases of the eye and ear, medical jurisprudence and such other branches as the board shall deem advisable, and present evidence of having attended three courses of lectures of at least six months each; said board shall cause such examination to be both scientific and practical, but of sufficient severity to test the candidate's fitness to practise medicine and surgery. When desired, said examination may be conducted in the presence of the dean of any medical school, or the president of any medical society of this State. After examination, said board shall grant a license to such applicant to practise medicine and surgery in the State of Minnesota; which said license can only be granted by consent of not less than seven members of said board.

The board may refuse or revoke a license for unprofessional, dishonorable, or immoral conduct. In all cases of refusal or revocation the applicant may appeal to appointing power of said board.

This act does not apply to commissioned surgeons of the United States army or navy, to physicians or surgeons in actual consultation from other States or territories, or to actual medical students practising medicine under the direct supervision of a preceptor.

According to section six, any person practising medicine or surgery within the State without having first obtained a license, or contrary to the provisions of this act, shall be deemed guilty of a misdemeanor, and upon conviction shall be fined not less than fifty nor more than one hundred dollars, or by imprisonment in the county jail not less than ten nor more than ninety days, or both fine and imprisonment. Any person shall be regarded as practising within the meaning of this act who shall append the letters "M.D." or "M.B." to his or her name, or for a fee prescribe, recommend for the use of any person any drug or medicine, or other agency for the treatment, cure or relief of any wound, fracture or bodily injury, infirmity or disease; provided, however, this act shall not apply to dentists.

This act takes effect on July 1, next.

In Memory of Dr. Flint.—There has just been erected at Bellevue Hospital a tablet in memory of the late Dr. Austin Flint, by the Commissioners of Public Charities and Correction. It is of massive size and very handsome as well as novel workmanship. It is a plate of brass set on a panel of antique oak. The inscription, which is imprinted on the shining brass in Roman letters of black enamel, with initials in red enamel, is surrounded by a band of conventional palm

leaves, relieved at intervals with mat scrollwork. The inscription reads as follows:

In Memory of

AUSTIN FLINT, M.D., LL.D.

Entering the profession with broad culture and thorough education he remained an active physician to the last day of his life. As a medical writer he added to the knowledge of the American profession and to medical science. As a teacher he was loved and respected by thousands of his pupils in all parts of the country. As physician to Bellevue Hospital for twenty-five years, he contributed largely to its reputation by his character, acquirements, labors, and wise counsels.

UNIVERSITY OF NEW YORK.—The Medical Department of this institution graduated 151 candidates on March 8th.

COLLEGE OF PHYSICIANS AND SURGEONS OF BALTIMORE.—The fifteenth Annual Commencement of this institution was held on March 15th. The degree of Doctor of Medicine was conferred upon 88 graduates.

AMERICAN DERMATOLOGICAL SOCIETY.—The next annual meeting of this Society will be held in Baltimore, August 31st and September 1st and 2d.

PROFESSOR GUSSEROW.—This well-known physician has been proposed as the successor of the late Professor Schröder.

BERLIN HOSPITAL PRACTICE. — During the year which closed in January, 1887, in the nine large hospitals of Berlin 43,479 patients were treated, of whom 6347 died.

MEETINGS OF FRENCH SOCIETIES. — The French Society for Otology and Laryngology will meet in Paris on April 13th, and on the 17th and 18th of April next the yearly meeting of the Association of French Physicians will be held.

RESIGNATIONS FROM A HOMŒOPATHIC HOSPITAL.—Eight of the women physicians connected with the "Medical, Surgical, and Maternity Hospitals of the Women's Homœopathic Association of Pennsylvania," have resigned because the managers have made a rule that "no medicines, except strictly homœopathic potentized remedies, shall be allowed for use in the dispensaries or in any department of the hospital."

NOTES AND QUERIES.

MR. W. F. GRAYOT, of Smithland, Ky., writes us that he has been requested to prepare the salicylic acid and iron solution used in the treatment of rheumatism at the New York Hospital, according to the formula given in THE MEDICAL NEWS of December 11, 1886. He has tried it several times, but has not been able to make a perfect solution. He says: "The salicyl acid will not dissolve. Is there any special way of preparing it? If so, will you please be kind enough to send me the *modus operandi*. I have tried it every way I can think of, and have concluded that there must be some mistake in the recipe."

DR. GEORGE L. PEABODY, Physician to the New York Hospital, writes us concerning the formula, as follows:

"Upon the receipt of your note regarding the iron salicylic solution, I turned it over to my house physician, Dr. Vought, and asked him to go to the apothecary shop and put me up one ounce of the solution, exactly according to the printed formula in THE NEWS. The result is a perfectly clear solution.

"Dr. Vought tells me that the only details that are essential are to use crystalline phosphate of soda. If the water of crystallization has been driven off, you get *too much* of the phosphate. The water in the solution is warm water, not necessarily hot, but not

[illegible] to correct one error (probably typographical) in the otherwise accurate abstract which you [illegible] on Practice of the New York Academy of Medicine, on March 15th. What I did say was that the nozzle of the atomizer should not be thrust far into the *mouth*—not into the nostril. I said—and believe the point to be of much practical importance—that spraying should never be made, in the treatment of diphtheria, a substitute in the nasal passages for syringing.

Yours, very respectfully, C. E. BILLINGTON, M.D.

[illegible] repeatedly meet with much annoyance in endeavoring to [illegible] my hypodermatic syringe needles pervious by the introduction [illegible] small wire furnished by the instrument dealer. Finding that [illegible] I [illegible] corrosive substance to take its place; I substituted therefor [illegible] hair or fine shoemaker's bristles. PROCIDENTIA UTERI.

A Clinical Lecture delivered at the Good Samaritan Hospital.

BY THAD. A. REAMY, M.D.,
PROFESSOR OF OBSTETRICS AND CLINICAL GYNECOLOGY IN THE MEDICAL COLLEGE OF OHIO

(Reported by John M. Withrow, M.D., Assistant to Chair of Obstetrics.)

THE patient for to-day's clinic is suffering from procidentia uteri. When the entire uterus is external to the body and enveloped in the inverted vagina, it has been called by various names. By some it is called prolapsus uteri, and others, who see in this condition a close resemblance to the pathological protrusion of other organs, call it a hernia. I think procidentia appropriate to designate complete prolapsus.

The name of the condition, however, is of only secondary importance to us to-day, and we shall at once consider briefly the causes and methods of treatment. You have been taught to consider the uterus as a freely movable organ, suspended by ligaments and soft parts within the pelvis. Every pathological change in the position of the uterus indicates some pathological condition of these supports. It has been the custom to divide the causes of uterine descent into: 1. Those which press the uterus down from the abdominal cavity. 2. Those which drag the uterus down from below. 3. Those conditions which so increase the size of the uterus that its own weight leads it gradually to assume a lower position in the pelvis. Now, while it is very clear that such classification is quite rational, it is of little importance from a clinical standpoint, and a correct conception of the character and sequence of the several events which combine to create procidentia is of much greater value. This uterine displacement is usually the result of parturition, although not immediately following it, and, consequently, as in the case before you to-day, it is almost always a disease of middle life or old age. Some rare instances of procidentia have been reported in young unmarried women as a result of violent straining efforts, or sometimes it occurs from the attempts of the uterus to extrude a polypus. Except these cases, which are very rare, procidentia is either a direct or indirect result of the lacerations occurring during parturition or diseases incident to the puerperal state.

Of these puerperal diseases, probably the most important is the subinvolution of the uterus, with or without subinvolution of the vagina. Subinvolution of the uterus acts as a cause by increasing the weight of the organ, thus tending to the gradual weakening of its supports. When subinvolution of the vagina also exists, the disease comes on more rapidly, since the normal resistance of the vaginal walls to the descending uterus is impaired.

You may confidently expect uterine descent in those cases in which you find after the puerperal period a large boggy uterus, with flabby non-resistant vaginal walls, unless proper steps are taken to cure the subinvolution in both organs. Here the uterus, sinking by its own weight, wedges apart the vaginal walls, thus increasing both its own and their congestion, until it forces itself through the feebly resisting vulvar cleft. If, in addition to this increased weight, subinvolution, there also exists such an injury to the vagina as impairs its ability to sustain the uterus in the beginning and to resist its descent afterward, procidentia is all the more likely to occur.

This injury to the vagina not only conduces to the disease in this way, but it also leads directly to vaginal subinvolution and remotely to uterine subinvolution. One form of such vaginal injury as is productive of procidentia is sometimes observed in the absence of either perineal or vaginal laceration, where the descending head pushes the vaginal mucous membrane in advance of it during labor. In these cases the mucous membrane is torn loose and glided upon the deeper vaginal structures, and pouts at the vulva very much as a loose sleeve lining is pushed ahead of the hand in putting on a coat. This is all the more likely to occur because of the œdema of the submucous connective tissue of the vagina which ensues during the latter part of gestation. It is in such cases that we are apt to have uncomplicated vaginal subinvolution, and later on this flabby, congested organ dragging upon the uterus at the cervico-vaginal junction may induce uterine descent. You can also readily understand that this descent is likewise promoted by the absence of support which would occur in such an organ.

We now come to those more patent lacerations of the vagina and perineum which are the most frequent causes of the disease we are studying. Simple lacerations of the perineum in the median line, even when quite extensive, are not as active in the induction of procidentia as was formerly supposed, and many women with marked perineal loss go through life without suffering from descent of the uterus. The vagina and pelvic floor are not of so much service as supporting agents to the uterus as might be inferred from a casual study of their relations. The uterus does not bear its weight through the cervix upon the posterior vaginal wall. It is swung to the pelvic walls by means of ligaments, but you must remember that these ligaments approach the uterus intimately connected with the vagina and are attached to it at about the same place; that is, the cervico-vaginal junction. This is especially true of the sacro-uterine or posterior, and the vesico-uterine or anterior ligaments. The broad ligaments, spreading out laterally from the uterus, serve more to stay it, and keep its fundus in the proper direction than as actual supports.

Bearing in mind, then, that these anterior and pos-

terior ligaments closely blended with the vaginal walls at their mutual points of attachment are, with their fat and connective-tissue packing about them, the chief supports of the uterus, you will readily conceive that when the vaginal walls drag downward they pull these ligaments with the uterus in the same direction. Consequently, when any disease or injury destroys the tonicity, stiffness, or support of the vaginal walls, in the lower part of the canal, they are left in some degree suspended to the uterine ligaments, and thus act as mechanical force drawing the uterus down by their own weight.

Now let us consider briefly the agencies supporting the vagina. The lateral walls are rather firmly attached to the pelvic fascia, which suspends them to the pelvic walls, in an upward and forward direction, above the origin of the levator ani muscles. The posterior wall is supported and held upward and forward by the levator ani muscles, between whose lateral halves the vaginal canal emerges at the vulva. These muscles, with the fascia covering them, are the chief supports to the posterior vaginal wall and the perineal body. They meet in this body after encircling the mouth of the vagina, between it and the anus. Their direction from their origin on the anterior and lateral interior walls of the pelvis is downward, backward, and inward toward the perineal body, thus forming, with the median portion of the same muscles, called the pubo-coccygeus, a sort of sphincter to the vagina. By this arrangement the posterior wall is literally slung up against the anterior wall, which is thus supported. In front of and above the anterior wall lies the bladder, which derives some of its support from the vagina. The rectum lying behind the posterior wall, does not serve to sustain the vagina, except in so far as it is itself held up by the levator ani, coccygeus, and other structures of the pelvic floor.

The sequence of events following perineal and vaginal injuries varies in different cases, and depends upon the character of the laceration and the position of the uterine axis. If there is such injury to the mouth of the vagina that the levators are divided laterally, or torn away from the fascia at the side near the mouth of the canal, without any or extensive perineal injury, the anterior wall at the lower part being thus unsupported, will probably pout at the vulva first, forming a cystocele. Following this, traction will first be made on the anterior ligaments by the sinking bladder and anterior vaginal wall, and the uterus will be anteverted. As the uterus descends the posterior wall comes down until prolapsus is complete and procidentia exists. In such a case, however, the cystocele will always be more prominent than the rectocele. Indeed, if there has been no injury to the perineum, there may never be a rectocele, and you may be able to introduce the finger between the uterus and posterior vaginal wall to a limited extent even with the entire uterus external to the vulva.

If, on the other hand, there should be extensive laceration of the perineum extending up the posterior vaginal wall, the sequence of events is changed. In this case the levators are separated from each other at their point of union in the perineal body and the muscles in contracting draw the sides of the vagina forward by means of their intimate union with the fascia, from which, in this injury, they are not necessarily torn. Thus the posterior vaginal wall, deprived of their support, and by the same injury losing the foundation normally given by the perineal body, sags down and out, producing rectocele. As the rectocele increases by the gravity of congestion and the straining efforts of defecation, it ultimately drags down upon the posterior ligaments of the uterus, first causing a retroversion, and gradually leading to descent and procidentia. Cystocele in such instances will usually appear before a condition of entire procidentia takes place, but since it mostly ensues after some descent of the uterus has occurred, we are justified in assigning the cystocele to the third place in the general displacement. You must remember, however, that in these cases there is always more or less cystocele, and that it is not absent in some cases of this class, as rectocele sometimes is in the class of cases previously mentioned, where cystocele was the first step in the displacement.

Let me now call your attention to the order of occurrence of these deformities in a third class of cases, in which there has been no laceration anywhere in the parturient tract. I have already referred to these cases as instances of general subinvolution of the uterus and vagina, and those cases where there has been a separation of the vaginal mucous membrane from the deeper structures.

In these the order depends upon the direction of the uterine axis when the heavy, congested uterus begins to descend. If the uterus is retroverted, the posterior vaginal wall is first lowered by the sagging posterior ligaments; and then, acting as a further cause by its own weight, it sinks lower, drawing the uterus downward, and, consequently, rectocele is the first event in the displacement followed by prolapsus of the uterus and cystocele until procidentia occurs.

The first deformity noted in this instance is not properly a rectocele, but a prolapsus of the posterior wall. I mean by this, that if you were to introduce your finger into the rectum you would not find that the anterior rectal wall was depressed or sacculated forward into the prolapsed vaginal wall as in a rectocele. Here the rectum is not affected, but remains normal in direction supported by the perineal body, and only the vaginal wall loosed from the rectum and perineal body, has come down in advance of the descending uterus. If, on the other hand, the subinvoluted uterus becomes anteverted preceding descent, and its heavy fundus lies upon the bladder, the depressed anterior ligaments will let down both the anterior vaginal wall and the superjacent bladder. Thus, as the anterior wall descends, a cystocele becomes the first of the three important events which will later characterize the displacement—cystocele, uterine prolapsus, and rectocele, or prolapsus of the posterior vaginal wall.

We now come to the important subject of treatment. What can we do to alleviate the suffering and remove the inconvenience of patients who are the subjects of this dreadful condition?

In the third class of cases where there is no laceration, and where the exciting cause is to be found in defective involution, we can usually cure the affection by postural and therapeutic treatment, followed by the use of suitable pessaries. In such cases you should put your patient in bed, replace the uterus, use at first copious vaginal irrigations of hot water, and, later, the

depleting influence of glycerine and astringent tampons, at the same time administering judicious constitutional tonics. When in this way the uterus is greatly reduced in size, and the tonicity of the vaginal walls is improved, a suitable pessary may be introduced, and the patient allowed to go about.

It is not usually necessary to have recourse to surgery in such cases, and the use of a pessary without first treating the subinvolution, would be unwise, since the presence of a pessary would only increase the congestion in the vaginal walls, besides stretching an already too greatly distended canal, although at times the early introduction of a pessary will so straighten the vagina that the circulation will really be improved. When, however, proper treatment has so reduced the venous congestion of the vagina, and its canal is constricted by astringents, and toned up by tonics, a pessary is well borne and decidedly indicated. It will prevent the very beginning of uterine descent, and maintain the parts in such a position that the circulation is not impeded, and venous stasis improbable.

Notwithstanding these facts, you will every now and then hear of a physician who denounces pessaries *in toto*, boasts to his patients that he don't believe in them, removes them whenever he finds them, making the removal the occasion for adverse criticism. It is sufficient to say that, as a rule, such physicians have not informed themselves as to the conditions demanding the use of the pessary, nor have they any clear or scientific conception as to the *modus operandi* of support.

In the first two classes of procidentia, where lacerations of the vagina or pelvic floor are the underlying cause, surgery offers the best prospect of cure. All operations looking to the relief of procidentia propose, as nearly as possible, to restore the injured parts to their normal integrity in the first place, and in the second place, so to narrow the vagina as to prevent the descent of the uterus. Of course, this narrowing must not be so extensive as to destroy the function of the vagina.

While there has been a general unanimity among gynecologists as to the requirement of some narrowing operation, they do not agree as to the proper site and method of the repair. Some constrict the canal by operating upon the anterior wall, others confine their efforts to the posterior wall, and still others operate upon both; while all agree in restoring the parts damaged by the original injury. I regret to be obliged to say to you that no one method yet performed has been uniformly successful.

Sims, one of the pioneers in this field of surgery, was quite successful in correcting this affection by making a V-shaped denudation upon the anterior wall, as I here show you upon the board. The difficulty which sometimes arose after this procedure by the cervix getting into the pocket left behind this fold, was quite a formidable objection. Consequently, Emmet modified the operation by making three points of denudation here upon the anterior wall just below the cervix, as you see in the diagram. He drew these three points together by sutures, indicated by these lines. In this way a fold was made upon the anterior wall and no pocket left. This method, however, was not uniformly successful, and has the objection of leaving a strip of undenuded tissue between the two sides of the folds, thus weakening the repair line.

Hegar operates upon the posterior wall by denuding a large triangular space, whose base is the integument of the perineum and the apex is upon the posterior wall well up toward the cervix. The width of this triangle depends upon the amount of perineal laceration and the height upon the extent of the rectocele. The sutures are introduced transversely at the upper part of the triangle near the apex, while the sides of the lower part of the denuded triangle are brought together by perineal sutures as in the ordinary operation for perineal laceration. These lines, here in the figure on the board, indicate the direction taken by the sutures both above and below.

Simon's operation is performed in the same place, and differs only in the shape of the denudation, which in this case is roughly shield-shaped, as I here show you. Since the denudation here is wider upon the posterior wall, it accomplishes a more extensive narrowing of the vagina than Hegar's method. The sutures are introduced in much the same way as I have just demonstrated in Hegar's operation.

Martin, of Berlin, has devised an operation which presumes to restore the longitudinal columns on the posterior wall, at the same time narrowing the vagina and repairing the perineum. This drawing illustrates the shape of denudation, and these lines indicate the position and direction of the sutures. By drawing together the sides of these two parallel tracts of denuded surface upon the posterior wall, two cicatricial columns are formed, one on each side of the median line, which not only narrow the vagina but likewise stiffen its posterior wall. The coaptation of the two sides of this somewhat crescent-shaped denudation, at the lower end of these parallel tracts, repairs the perineum.

Martin also insists upon the amputation of the cervix as essential to the success of his operation, believing that there is always more or less hypertrophic elongation of the supra-vaginal portion of the cervix. I cannot consent to such universal necessity for cervical amputation, although I have often practised removal of the cervix where its hypertrophy was excessive, and in such cases I believe the amputation a most important adjuvant to the operation.

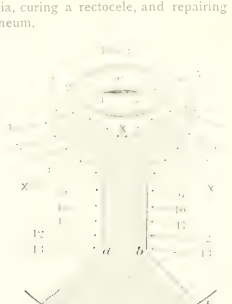
When in cases of prolapsus there is much subinvolution of the uterus which does not improve markedly during the treatment preparatory to the operation, and the cervix remains large and boggy without being specially elongated, I prefer the excision of a wedge-shaped piece of tissue. I have found such practice eminently satisfactory, both in diminishing the size of the cervix and in curing the general subinvolution of the uterus, for I believe that no operation will be permanently successful in curing prolapsus if the uterus remains in an excessive state of subinvolution.

Alexander's operation has lately come into fashion as one of the surgical procedures for curing prolapsus. It consists in shortening the round ligaments of the uterus at their points of insertion at the inguinal rings. It sometimes fails, is always difficult and frequently dangerous, and inasmuch as it is yet only on trial, and other safer operations are quite satisfactory, it is not to be recommended.

Dr. Paul F. Mundé advises both a modified Simon operation upon the posterior wall, and Stoltz's method upon the anterior wall for cystocele, in cases of procidentia.

Stoltz makes an elliptical denudation upon the vaginal wall between the meatus and the cervix after the manner of Dieffenbach as is here represented, and then brings the freshened edges together by a single suture in a drawstring fashion, as is illustrated by this dotted line. In cases of long standing, where the cystocele is especially prominent, the necessity of narrowing both vaginal walls cannot be obviated, although generally a skilful repair of the posterior wall will be sufficient. Various other operations upon the posterior wall are performed, but those just mentioned give an idea of the object generally sought and the methods employed for its attainment. Notwithstanding all these ingenious plans, however, as I said a little while ago, none has been uniformly successful.

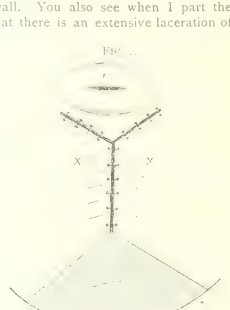
I, therefore, propose to-day to perform and illustrate an operation for this condition, which I have been practising for several years, and as yet with very satisfactory success. It is somewhat similar to an operation which I performed in your presence last year for cystocele; but, as you shall see, this is performed upon the posterior wall with the threefold object of correcting a procidentia, curing a rectocele, and repairing a lacerated perineum.



The patient will now be brought in. This patient is forty-five years of age, the mother of four children, the youngest five years old, and she is still menstruating. As you see, she is strong and well nourished. She has been a hard-working woman, and her vigor is even yet only impaired by the inconvenience and suffering caused by a procident uterus.

She first consulted me about three months ago, at which time the entire uterus was external to the body, and there was an extensive erosion of the cervix extending fully an inch from the external os in all directions. After touching this with lunar caustic I replaced the uterus and introduced a very large elastic ring pessary, the watch spring, covered with rubber; I also directed copious daily vaginal irrigations of hot water. The pessary kept the uterus up for as long as four weeks, during which time the erosion entirely disappeared and the organ was greatly reduced in size, but every now and then since, the poor woman came with pessary out and uterus down. Of course, I did not hope to cure entirely such a case as this by such treatment. I only desired to put the uterus in the best possible condition, preparatory to an operation. But please note the good effects of keeping the uterus in position even for a short period.

The patient is now thoroughly anæsthetized, and I remove the pessary. You observe the uterus is not visible at the vulva. But when I part the vulvar walls you can see the external os, and with this vulsellum I easily draw the entire organ completely outside the body. With the uterus in this position you can plainly note the greater prominence of the rectocele as compared with the cystocele. Now that I have pushed the uterus back into position, this greater prominence of the rectocele is more perceptible. When I introduce my finger into the rectum, you can plainly see, from your seats, that it enters into this pouting tumor here at the posterior commissure, demonstrating that we have to deal with a rectocele and not a simple prolapsus of the posterior wall. You also see when I part these vulvar walls that there is an extensive laceration of the peri-



neum extending clear back to the sphincter, but not involving it.

In this case I think we are justified in assuming that the rectocele was the first in the sequence of events leading to the procidentia. We now make the operation.

Now that the operation is completed and the patient out of our presence, let me, with the assistance of these diagrams on the board, explain its steps more in detail.

Fig. 1 represents the shape of the denuded surface on the posterior vaginal wall. The arms at the upper part extend well up to the sides of the cervix in the lateral culs-de-sac of the vagina. These are denuded as deeply as is possible without entering the peritoneal cavity just below and behind the cervix, and without interfering with the ureters at the upper lateral extremities.

It is very important that this denudation be deep, since in the first place it will give greater supporting strength by the thickness of the line of union obtained, and in the second place a deep denudation of these lateral arms will unite the vaginal walls more intimately with the underlying fascia. This increases the supporting power of this fascia to the vaginal culs-de-sac, and thus to the uterus, by giving it a "shorter hold" to the vaginal walls, if you will permit the expression.

The width of the denudation upon the posterior wall depends upon the amount of vaginal constriction required. You must be governed in the amount of divergence between the lines *aa* and *bb* by the extent of perineal injury. The greater the injury the wider the divergence.

If there should be no laceration of the integumentary perineum, these lines should converge to a point on the posterior vaginal wall at or just behind the fourchette. I use catgut for the sutures inside the vagina, those numbered in the figure 1 to 13 inclusive, and also for the suture marked ×, because of the difficulty in removing either silk or wire over the freshly united perineum.[1] These should all be tied before the perineal sutures are introduced, indeed, it is best to secure them before the perineal denudation is made.

The suture marked × is of great importance and I wish to call special attention to it. It should be introduced about one-quarter of an inch from the border of the denudation in the angle made between the denuded tract on the posterior wall and one of the denuded arms. From this point it is carried across the denudation in the direction indicated by the dotted line and brought out in the undenuded apex between the two arms behind the cervix, it is then reintroduced in this apex about one-quarter of an inch from its point of emergence and carried across the other denuded arm in the direction of the other dotted line and brought out at a point in the opposite angle between the lateral arm and the posterior tract corresponding to the point of entrance. In tying this suture across the upper part of the posterior denuded tract the three angles are brought together.

Fig. 2 shows the field of operation after all the vaginal sutures are tied. For the perineum silver wire is used in the usual way, as shown here in the diagram, but the upper sutures should be carried across high up, about on a level with the lowest suture inside the vagina, so as to secure perfect coaptation of the line *aa* to the line *bb*.

Finally, as to our patient; sexual intercourse must be forbidden for three months after the sutures are removed. During this time she must not do hard work, but must spend part of each day on the couch. These precautions are necessary in order that the modified vagina may become firm, and that the uterus in its restored position may undergo involution. For, unless the weight of the uterus be reduced, it is only a question of time when prolapse will again occur, no matter what operation has been done upon the vagina.

[1] The great objection to catgut, heretofore, has been the danger of its speedy absorption before union had occurred, but this difficulty has been surmounted by the method of Veit, of Berlin. He places the gut in pure oil of juniper wood for twenty-four to forty-eight hours, and then preserves it in a mixture of pure alcohol and glycerine, ten per cent. of the latter, till used. Water should never touch the gut. In this way it lasts in the tissues for ten or twelve days. See letter by Paul F. Mundé, Amer. Journ. Obst., page 914, 1886.

ANEURISMS TREATED BY THE INTRODUCTION OF CATGUT, OR OF WIRE, WITH ELECTRICITY.[1]

BY ROBERT ABBE, M.D.,
ATTENDING SURGEON TO ST. LUKE'S HOSPITAL

The domain of cases upon which the surgeon may operate, owing to newly adopted principles, is enlarging year by year, and just in that proportion the number of "hopeless" cases diminishes. The most superficial observer will see a growing disposition to interfere with many varieties of infirmities for which in the past active treatment has been discouraged by all surgical authorities. One is led from time to time to review such maladies, and to ask whether advanced methods will yet allow us to touch them. As the miner has often found a fortune in the discarded ores of silver mines when worked over by a new process, so now some of the forbidden cases of twenty years ago are fairly met by justifiable new procedures.

In this spirit of inquiry I venture to open the question of the value of interference with a small class of aneurisms, the treatment of which has heretofore been considered useless. This class is that of aneurisms springing from the aorta or its greater branches, and not amenable to the ligature or relieved by medicine, diet, or rest. These are so common that we all see them from time to time. They run a steady downward course, interrupted, happily, in some cases by a temporary clotting, but soon advancing again, leaping the barriers of bone and cartilage until the thinned walls give fatal pressure effects on veins, nerves, or the trachea, or sudden rupture ends the patient's misery.

Taking our guide from nature's attempt at repair by the two methods of deposition of firm clot, or by thickening the sac through hypertrophic, or inflammatory, changes, we find the most promising to be that of inducing clot within the sac.

Practically, accumulated experience shows that coagulation *will* take place upon certain foreign substances introduced into the current. Wire is especially favorable, either silver, iron, or steel. This can be sterilized by preliminary boiling in carbolic solution. Thirteen cases of the use of wire have now been reported, to which I am able to add two more. The first attempt was made by Mr. C. H. Moore, of Middlesex Hospital, in 1864, of which I will speak later. Moore's method consists merely in the introduction of wire. Of the cases now on record, the most brilliant results were obtained last year by Loreta, of Bologna, and Morse, of San Francisco. The outcome of the others has not been curative, though seeming to look in the right direction.

[1] Read before the New York Surgical Society, March 23, 1887.

Last year Mr. Richard Barwell practised a modification of Moore's method, by introducing ten feet of steel wire into an aneurismal sac and passing a current of electricity through it, sufficiently strong to obtain an electrolytic action and to induce the formation of a coagulum by quick deposit. Thus, he substituted a long wire, coiled in the blood-current, for the short needle-point of so-called electro-puncture, which latter alone has in many hands been of unquestionable service in ameliorating the condition of aneurisms in the last stage.

Mr. Barwell's patient was a man with large aneurism of the aortic arch, apparently a hopeless case, and associated with serious lung trouble. A fine, insulated trocar served to allow the steel wire to pass. The positive pole was attached to this, while a negative pole of spongiopiline was spread over the back. A current of ten milliampères was passed for an hour and ten minutes. The man had no pain or inconvenience. The tumor gave no sign of immediate improvement, but in twelve hours "the man appeared much better, the tumor was more solid, and the pulsation more distant." Four days later a tumor appeared at the other side of the neck, which had been observed two years before, and then disappeared—evidently an extension of the sac in that direction. One week later he died of his pulmonary trouble. A post-mortem was obtained, and of the clot that was formed in the aneurism he says: "The wide coils of wire are surrounded by thick, firm, colorless clot, which in many places binds the wire to the sac-walls, thus strengthening them and rendering rupture hardly possible where the wire had penetrated. In the secondary sac this had not formed." Barwell commends the method for large internal aneurisms.

Soon after the publication of Barwell's case, Dr. J. West Roosevelt, of this city, had an opportunity to try the method on a case of aggravated aortic aneurism threatening death. He has kindly offered me the case to report in this connection.

The patient was a man of twenty-five years, with a syphilitic history. In November, 1885, he began to notice a dry cough; some weeks later dyspnœa and dysphagia ensued, and pain was present in the right pectoral region and axilla, occasionally extending down the right arm, or into the back near the scapula. At that time also he noticed a pulsating tumor in front of the chest at the right of the sternum. His dyspnœa was great when he lay on the left side or back. He had been prevented from working for four months, yet he was in fair flesh. The pulsating tumor involved the four upper ribs near the sternum and gave a double bruit. He was given iodide of potash, was kept at rest, and somewhat under the influence of anodynes for two weeks with slight ease from pain, but the tumor continued to enlarge.

On the 4th of August, Dr. Roosevelt placed the man on his back, and inserted a short, insulated aspirator-needle into the tumor; when the blood trickled out, he passed about seventy-five yards of fine steel piano-wire (No. 00). The patient experienced some feeling of weakness, became pale, and had pain, from the position on the back, to which he was unaccustomed. The wire was connected with one pole of a constant battery, and a large wet reophore was placed under the right shoulder. From four to eight cells of an ordinary galvanic battery were used, measuring about twenty-five milliampères. It gave him no pain, and was continued for a half hour. The tumor still pulsated. The patient was kept quiet another half hour and then was put to bed. He had no pain subsequently from the operation. On the following night he required morphia for insomnia.

Next day the tumor did not pulsate so strongly, and he had some pain and vertigo. On the third day the tumor was less painful, but still pulsated. His breathing was not so comfortable, and in the evening his temperature rose to 100°, but fell to normal in the morning, and remained so afterward. On the fourth day dyspnœa and slight cyanosis appeared. On the seventh day he was better than before the operation, and had less pain and dyspnœa. By the tenth day the tumor was much less painful, the pulsation visibly diminished, and he could breathe easily lying on his back or left side, which he formerly could not do. During the third week he could swallow and breathe with greater ease, and the tumor felt harder. At the beginning of the fourth week he began to vomit, and to complain of headache. His iodide of potassium was, therefore, stopped. On the twenty-second day a painful, dark-colored spot appeared on one toe, and the man appeared badly. On the twenty third day he died. No autopsy could be obtained.

In October last, I had an opportunity to repeat this operation in the following case: A man, forty-six years of age, free from specific history, was referred to me by Dr. Naughton, for treatment of a large pulsating tumor at the root of the neck, on the right side. It had been observed as a very small swelling above the clavicle, not more than a year before, and had steadily enlarged until now it filled the supra-clavicular space, extending backward to the scapula. The greater growth of late had been back of the middle plane of the neck. A loud bruit could be heard over its entire surface. Its pulsation lifted the shoulder at every beat. Neuralgic pain of the right shoulder and arm had been coming on for several weeks, and pressure on the brachial plexus caused paralysis of the deltoid and triceps muscles. The right arm and right half of the face remained dry, while the opposite side was covered with profuse perspiration. There was slight hoarseness. The right pupil was smaller than the left, and ptosis of this eye had developed. The axillary, brachial, and radial pulses were small. A diagnosis of dissecting aneurism of the subclavian was made.

After consultation (Drs. Sands, Weir, Peters, McBurney, Bangs, Lange, and Bull) it was decided that the condition would not be checked even by ligature of the carotid, with shoulder amputation, and being left with a patient whose pain was only eased by frequent hypodermatics of morphine, while the growth of the aneurism could be seen to advance every day, I decided to resort to Barwell's method, to lengthen his life, and, perhaps, to lessen the

pain. The oval cavity of the tumor was estimated to measure four by five inches.

After three weeks' observation, under iodide of potassium, I decided to use catgut before employing wire. I operated on November 19, no anæsthetic being given. With a No. 2 aspirator-needle, I pierced the front of the sac, and the blood spirted out to a distance of two or three inches. No. 1 catgut, taken fresh from juniper-oil, and drawn through a damp sublimated towel, was easily, though slowly, pushed into the sac. It was best fed by short grasps of the thumb forceps. One hundred feet of it were thus introduced, occupying an hour. The patient lost two or three ounces of blood only, and had no pain, or discomfort, whatever. There was a slight rise of temperature (to 101° F.), on the following day, the pulse remaining unchanged. The tumor was a little warmer than before. On the second day the patient continued to feel well. The outer third of the sac had very decidedly hardened; the remainder pulsated as before. An ice-bag was ordered to be applied. The radial and brachial pulses could not be felt. The hand continued warm. On the third day his temperature rose to 102°, though he felt otherwise as well as he did before the operation. After that his temperature declined rapidly to normal. The tumor, however, grew decidedly backward and upward during the week, and lifted the scapula. On the eighth day the dissection seemed much more rapid, and the hoarseness amounted to aphonia.

On the ninth day Dr. Roosevelt very kindly assisted me, and I introduced through an insulated aspirator-needle one hundred and fifty feet of fine steel wire, sterilized by boiling in carbolic acid solution; a copper plate a foot square, covered with wet cotton, was placed over his back and was connected with the negative pole, and the positive was attached to the end of the wire. A current was measured by Dr. Roosevelt up to fifty milliampères, which was the limit of the register. This required but fifteen cells; the entire thirty-six cells of the galvano-faradic battery were subsequently applied. The patient experienced no pain or discomfort. His pulse which had been 110, rose only ten beats during the process. The current was continued for an hour—the latter part of the time reversed so as to bring the negative pole within. He was rather exhiliarated than otherwise, and when removed to bed would not have known that any operation had been done.

The tumor still pulsated when we concluded. On the following day I could perceive an increased firmness in the walls, though the pulsation continued. Subjectively the patient felt rather better, and I had some hopes of the outcome, when, on the second evening, he suddenly had a rupture of the sac into the trachea and expired. It was impossible to obtain an autopsy.

Although it is to be regretted that these cases could not be followed to the post-mortem table, there are yet some points of value in each that may be added to the study of the subject. It will be seen that both were utterly hopeless cases, and, while we cannot assert that life was prolonged, it was not shortened by the operation. In my own case the man was approaching his end, and it was his only hope.

The question may be asked, whether the rupture of the sac into the trachea was hastened by the pressure of the wire inside. I judge not, for the tracheal pressure that preceded the rupture had been progressively getting worse, as evidenced by the hoarseness increasing for a month—showing that it was making its way toward the trachea. I find three other cases of rupture following active treatment. One of Churton's last year, in which he had used electro-puncture without wire, and in twenty minutes fatal hemorrhage from the trachea ensued; the other was Domville's case of aortic aneurism, in which he put fourteen inches of iron wire into a sac, and when four weeks later the man died of sudden rupture into the pleura, it was found that no wire was near the perforation. The same occurred in Dr. Ransohoff's case, reported at the last meeting of the American Medical Association; over ten feet of silver wire were introduced into the sac, in two sittings, three weeks apart. Death suddenly occurred one week after the last, from rupture into the pleura, but the autopsy showed that there was no wire near the place of rupture. (The Medical News, May 29, 1886, page 597.)

Whether the duration of life was longer or shorter owing to the treatment by wire insertion, is pure speculation. My own impression is, from studying all the cases, that without exception every one was in a desperate state before operation. Some even threatened dissolution. My own patients lived thirty-six hours only, before rupture occurred. Most of them lived several weeks, and Loreta's, ninety-two days, having apparently been restored to health, while Morse's still survives. In one case reported by Mr. W. Cayley, the large aneurism at the root of the neck became solid and the patient lived eighty-six days after some forty feet of steel wire were introduced. The thoracic portion of the aneurism extended, and Mr. Gould subsequently put in thirty-five feet more to solidify if possible the portion that was causing serious dyspnœa. No disturbance followed nor was he relieved.

As regards the chances of emboli from the wire giving trouble, I find but two of the fifteen cases in which wire was introduced, that caused such an accident. Mr. Moore's case, the first on record, showed at the post-mortem suppurating foci in the kidneys, with death on the fifth day. As the case occurred in 1864, it is quite as probable these were septic as that they were embolic. No case that has since been done has shown septic infection, due to the care now exercised in sterilizing the wire.

In a note in the *British Medical Journal* of May, 1885, Dr. Maclean, who witnessed Mr. Moore's operation twenty-three years ago, and who saw the organs and aneurism after the autopsy, says that the immediate cause of death was inflammation of the sac and the pericardium, and also he recalls the innumerable clots in the fresh preparation, of varying consistence, hanging from the wires, ready to drop into the blood, and emboli exactly like them were found in the arteries of the organs dissected to

show them." In Dr. Roosevelt's case a dark colored, painful spot appeared on one toe on the twenty-sixth day. The absence of other reported accidents by emboli, shows that it is no more to be feared from wires than from the untreated walls of an aneurism.

Having shown that nature will tolerate considerable quantities of wire for periods of eighty-six and ninety-two days, and even indefinitely in favorable cases, as in Dr. Morse's, and that it has never been known to induce suppuration when aseptic, it is now of importance to see how much solidification is really brought about by the foreign substance. Of the sixteen cases of wire-insertion, eight were followed to an autopsy. Bacelli's third case, in which seven watch-springs, each about twenty inches long, were inserted, was the only one which failed to show coagulation. The patient lived only two days. His second case, in which three springs were introduced, lived ten days, and excellent clots were found around the metal. His first case, in which only one spring was used, lived two months, was improved, and presumably the wire was imbedded. In Donville's case fourteen inches of iron wire were found imbedded in firm clot, two weeks after its introduction into an aortic aneurism, the patient dying of ruptured sac. Dr. Ransohoff reported last year a case of large aneurism at the root of the neck, into which he put at two sittings ninety-eight and ninety-six inches of silver wire. The case was hopeless from the first; however, the patient survived over four weeks. Autopsy showed the "coils of wire imbedded in recent and old clot." In Mr. Cayley's case of large sacculated aneurism of the aortic arch, the patient survived the introduction of seventy-five feet of steel wire eighty-six days, and the "entire upper portion of the sac was filled with clot, in which the wire was imbedded." In Barwell's case (already quoted) the electricity and wire combined had caused the latter to become "surrounded by thick, firm, colorless clot, which in many places bound the wire to the sac-walls, thus strengthening them." In Prof. Loreta's famous case (reported last summer) the post-mortem revelations were very gratifying. The patient was a sailor, who had an aneurism of the abdominal aorta, the size of a small fœtal head. Laparotomy showed it to be matted to the viscera, stomach, etc., from which it was separated. Six and a half feet of silvered copper-wire were introduced through a fine canula, the point of perforation was touched with pure carbolic acid, and the wound was closed. He made an excellent recovery. Twenty days later the pulsation had ceased, and by the seventieth day he resumed his work. On the ninety-second day the aorta ruptured at the point at which the sac sprang from it. Autopsy showed that the latter had shrunk to the size of a walnut, and was completely filled with coagula of organized fibrin. The wire was found unaltered, and rolled into a globular mass within the sac.

Dr. Morse's patient, in San Francisco, a man of thirty-two years, received a blow from a coal bucket which resulted in an aneurism of the abdominal aorta, which grew for eight months, accompanied with much suffering. Loreta's operation was done, and four and a half feet of silvered copper wire introduced into the sac through the laparotomy wound. The tumor was the size of two fists.

The patient's subsequent temperature remained below 101°.

On the ninth day the left femoral artery became plugged, whether from embolism or endarteritis cannot be said. Pulsation returned in it, however, in the fourth week. The tumor shrank to a small nodule, and so remained without bruit. The patient left the hospital less than eight weeks after the operation—apparently cured.

Dr. Lange reported a case to our Society quite recently, in which he obtained an autopsy. He had inserted thirty feet of wire into an abdominal aneurism. The patient survived twelve days. The specimen showed the wire imbedded, to a large extent, in firm clots against the wall, but free in some places in the current. It is reasonable to believe that it would always be buried in laminated clot, if left for a while.

As bearing upon this point, I would note that Schrötter, of Vienna, two years ago inserted twenty inches of Florence-silk into a large aneurism, and four days afterward thirty inches more. The patient died in the third week, of pulmonary œdema, and the autopsy showed the silk in coils entirely enclosed in laminated clot. In Bryant's case of popliteal aneurism, the horse-hair was enveloped (to use his words) in "huge laminated clots." The inflammation of the sac-wall probably plays no small part in aiding solidification. I feel convinced that it is desirable to provoke some inflammation. In my patient there was a decided increase of local temperature in the outer part of the sac, with slight œdema of the subcutaneous tissue, and hardening of the sac. This followed on the second day, after one hundred feet of catgut had been introduced. The continuous application of an ice-bag entirely controlled the inflammatory action. In Schrötter's case of silk introduction, it is reported that "intense œdema appeared in the vicinity of the sac from its inflammation," the virtue of which was apparent, in the imbedding of the silk, as was found three weeks later at autopsy.

Finally, I would review the part that electricity may play in the combined treatment. We have but three cases in which the sac was subjected to electrolytic action through an extensive wire coil within it. Barwell used a current of ten milliampères, Dr. Roosevelt about twenty-five, and I one hundred. The patients experienced no pain or discomfort whatever. The current was passed for a period of from half an hour to an hour and ten minutes. In my case the current was reversed during the latter half hour, so as to bring the negative pole within. No change in the patient's condition could be perceived, and no gas could be discovered in the sac, as in some cases of electro-puncture, where it became tympanitic for a short time, without harm.

The promising statements of Cinicelli and others about the value of electrolysis in aneurisms have seemed to many delusive. The small amount of coagulation that takes place around a fine needle, is

perhaps of less value than the irritation of the sac. Therefore, it seems reasonable to my mind that if we tangle a mass of fine wire so that it will reach every part of the sac, and then cause a deposition of clot on it by electrolysis, we do more justice to the method. Cinicelli claims that no cure of aneurisms takes place after electrolysis without inflammation of the sac.

Occasionally a case succeeds, as one reported by Dr. Simpson, of Manchester, in 1881; an aortic aneurism that had eroded the rib and threatened to rupture, continued well five years after repeated electro-puncture.

As regards the strength of the current to be applied, experience only will say. De Watteville thinks that twenty or thirty milliampères for each needle are sufficient, others five or ten. But, when a large wire surface transmits the current, it is probable that fifty or one hundred are not too strong.

Conclusions.—It is evident that we need many accurate scientific observations before we can speak definitely of the value of Barwell's method. One may say that Moore's treatment, by simply placing wire in the sac, has not yet been tried in any case that was not already hopeless and in the last days of life. The same may be said of Barwell's; yet the evidence warrants a continuance of its trial. It is not a coincidence that cases show a decided amelioration of symptoms.

It has been proved that there is a deposition of clot; sometimes so abundant as to cure, as in the cases of Loreta and Morse. The fine wire is so yielding that it may be compressed by the aneurismal contraction into a small fraction of its bulk, without exerting much expansile reaction against the wall; and it is probable that an hour's electrolysis so far weakens it, as well as roughens its surface, that it is quite prepared for the deposition of the clot and the shrinkage of the sac.

The operation is not in itself perilous; no deaths have occurred from its performance. The subsequent much-desired inflammation of the sac was easily kept under control by ice-bags in every case.

The principle does not seem faulty, and its application should not be abandoned or condemned, until much more extended trial has been given to it.

EXCISION OF THE LARYNX AND PHARYNX.

By D. Hayes Agnew, M.D.,

Emeritus Professor of Surgery in the University of Pennsylvania.

D. L. White, male, aged fifty-eight years, was brought to me by Dr. Eisenberg, of Norristown. The patient complained of impaired or feeble voice, with some hoarseness. He had previously been under the care of Dr. J. Solis-Cohen and quite recently had consulted Dr. Seiler, both of whom had recognized the presence of a growth involving the upper portion of the larynx, and believed to be a sarcoma. At the time the man visited me the neoplasm could be distinctly seen extending down to, but not below the vocal cords. As the growth appeared to be very vascular, it was not deemed proper to pinch off a fragment for microscopical examination. Believing the tumor to be a sarcoma, and in view of its steady encroachment upon the glottis, excision of the larynx was advised. The patient was admitted to the University Hospital on January 31, 1887, and the operation was performed February 2.

An incision was carried from the hyoid bone to the middle of the suprasternal fossa, over the median line of the neck. The isthmus of the thyroid body being large, was tied on each side and divided between the ligatures, after which the sterno-hyoid, sterno-thyroid and thryo-hyoid muscles were detached from their insertions and dissected away on each side, thus exposing the larynx, and two or three of the upper rings of the trachea, anteriorly and laterally. A number of vessels were tied, branches of the superior and of the inferior thyroid arteries. The trachea was now separated sufficiently from the œsophagus to admit the passage of a grooved director, when the former was severed by a probe-pointed bistoury carried between the cricoid cartilage, and its first ring. A rubber cork, through which was passed a siphon tube, was next introduced into the trachea, filling up accurately the lumen of the air passage, and was secured in place by a stout thread. The work of separating the larynx from the pharynx was next effected, chiefly by the handle of the scalpel, and taking along with the perichondrium the origin of the two constrictor muscles. A transverse cut through the thyro-hyoid membrane completed the work of excision so far as the larynx was concerned.

Unfortunately, at this stage of the operation it was found that the growth had invaded the pharynx, and to such an extent as to require its entire removal, saving a very narrow strip of its posterior wall. The vessels divided in this last stage of the operation being secured, the wound was well washed with a solution of bichloride of mercury (1 to 1000), covered with carbolized gauze and a pledget of salicylized cotton. Before the last of the dressing was made, it was observed that the secretions from the mouth and fauces ran down in a continuous stream, through the wound. Fearing that these secretions might find their way through the loose tracheal fascia into the mediastinum, a sponge, rendered thoroughly aseptic, with a cord attached, was passed through the upper part of the wound into the fauces, in order to receive the discharge. This was removed and replaced by others from time to time, fulfilling somewhat imperfectly the object in view.

The patient was now carried to his room, apparently suffering very little from the effects of the operation. The canula was covered with antiseptic

gauze, and the temperature of the apartment maintained as nearly as possible at 70°. Directions were also given to the nurse to keep the tube cleared of all accumulations of mucus, and to administer at proper intervals through the œsophageal tube, from half a pint to a pint of peptonized milk. The patient passed a fairly comfortable night, sleeping at intervals from twelve to six A.M.; temperature, 99°.

Feb. 3. Patient comfortable, pulse 100, respiration 24. Some trouble experienced from irritability of stomach, the milk regurgitating through the tube, in consequence of which rectal alimentation was directed. In the course of the evening an accident occurred which came well nigh proving fatal. A quantity of fluid was suddenly rejected by the stomach, a portion of which ran into the canula causing asphyxia. Fortunately the surgical resident, Dr. Westcott, was near at hand and promptly rendered the necessary relief.

4th. Patient exhibiting some signs of exhaustion, considerable restlessness, respiration 34, temperature 104°. Suppositories of quinia ordered and one ounce of whiskey every three or four hours.

5th. Increasing exhaustion, pulse 150 and feeble, temperature 106°, respiration increasingly frequent and shallow; died quietly shortly after nine o'clock.

REMARKS.—As the friends would not allow an autopsy, it was impossible to determine satisfactorily the cause of death, whether due simply to exhaustion from heart failure, the man having been, it was said, addicted to great excess in the use of stimulants; or what is equally probable, from pulmonary congestion, an occurrence which in frequency stands at the head of the list of causes giving rise to death after excision of the larynx. Just what the relation between the operation and the succeeding pneumonia, so common, is, has not been definitely settled in my mind. It may be septic, or it may be, as alleged by some, attributable to the unavoidable injury done to the branches of the recurrent laryngeal nerves. The danger from septic causes must be greatly increased when it becomes necessary to remove the pharynx along with the larynx, as the discharges from above, instead of being conducted into the stomach will accumulate in the sulcus at the top of the chest in spite of every precaution to the contrary.

Were the operation to be repeated, I should certainly perform a preliminary tracheotomy, allowing some time to elapse before attempting the excision.

The tumor removed proved to be a tubular epithelioma, and not a sarcoma, as it was thought to be at the time of the operation.

THE LOCAL TREATMENT OF DIPHTHERIA.[1]

BY J. LEWIS SMITH, M.D.,

THE opinion seems to be gaining ground in this country that diphtheria is primarily a local disease, in most instances; this is the belief of Wood and Formad in their able report made to the National Board of Health, in 1882. The authors of this report, aided by the previous investigations and experiments of Curtis and Satterthwaite, in this city, made many original microscopic examinations. They state that they did not find bacteria in the blood and tissues of mild cases, but only in cases that reached a certain degree of intensity, and the inference which they seem to draw is that in these mild cases the disease may remain local. But I believe, whether diphtheria be primarily local or not, that when the physician is summoned, he ordinarily has a constitutional malady to treat. The exudate upon the faucial surface, containing the bacteria in countless numbers, and in great activity, is deeply seated, and is in immediate relation with the blood-vessels, so that these organisms must enter the circulation in abundance. We know, too, that in severe diphtheritic attacks nephritis frequently begins within twenty-four hours, showing that the blood is already contaminated. Moreover, when there is an incubative period of six or seven days, it is very improbable that the specific principle remains that time upon the surface where it is received, in a state of quietude. It must be in the blood, and be gradually poisoning the blood, during this period of incubation.

But whether diphtheria be primarily local or constitutional, we all acknowledge the importance of local treatment. In selecting the local remedies, I believe it should be a principle to guide us, that nothing should be used which irritates, for if we employ irritating measures, and increase the redness and inflammation, we are liable to increase the severity of the local ailment, and, I think, the amount of exudation. Modern physicians, who have a better knowledge of the nature of diphtheria, now perceive that the older physicians, as Bretonneau and Trousseau, were misguided in their judgment, and that they did harm when they applied powerful acid and other agents to the faucial surface in the belief that they burnt away the disease, nor should we, in my opinion, attempt to remove the pseudo-membrane by forcible means, since we are able to destroy by local treatment, which is not severe, all the micro-organisms in it, and render it inert. The application to the fauces should be made either by the hand-atomizer, a camel-hair pencil, or a small syringe. The sponge of the probang is too rough and is likely to cause forcible detachment of the pseudo-membrane, irritate the surface, and, perhaps, produce more or less hemorrhage.

Many antiseptic and disinfecting mixtures which fulfil the indications mentioned above, have been recommended for treatment of the fauces. For many years I have used the following, which, though unpleasant to the child, does not irritate, and it readily penetrates the diphtheritic exudate, disinfecting it and rendering it an inert mass; it immediately destroys the life, and puts a stop therefore to the movements of the microörganisms, not only in the pseudo-membrane, but in the muco-pus which bathes the pharyngeal surface. This effect I have ascertained by microscopic examinations.

[1] [illegible] Academy of Medicine, March 15, 1887.

R.—Acidi carbolici . . . . . gtt. x.
Liq. ferri subsulphat. . . . . ʒij.
Glycerinæ . . . . . ʒij.—M.

It is conveniently applied by a large camel-hair pencil, two or three times daily, or in malignant cases oftener. It is a powerful astringent, and always after its application a considerable quantity of pseudo-membrane and congealed muco-pus is brought away, and it therefore gives greater satisfaction to the parents than almost any other application. Diluted by an equal quantity of water, it may be used in the atomizer. Perhaps the following formula is as beneficial as any for more frequent use:

R.—Aquæ chlorinæ . . . . . ʒj.
Sodii bicarbonat. . . . . ℈ss.
Mellis } . . . . . ad ʒss.
Glycerinæ }
Aquæ calcis. . . . . ʒiv.—M.

This should be used in the hand-atomizer every hour or second hour, and if the instrument work well, I have found three or four compressions of the bulb sufficient. As alkaline solutions dissolve pseudo-membrane, the solvent action of the lime-water is, of course, increased by adding the sodium bicarbonate. Trypsin may be employed in the mixture, since its solvent action, unlike pepsin, is not impaired by the alkaline medium, but it is expensive, is not soluble, and must be added sparingly so as not to clog the atomizer. In the declining stage, when the amount of pseudo-membrane is diminishing, the atomizer need not be used so frequently.

Nasal diphtheria is properly receiving more attention than was bestowed upon it a few years ago. In not a few instances the first manifestation of diphtheria is in the nostrils, and I have noticed that in many instances it is not diagnosticated, and is supposed to be a simple coryza until three or more days have elapsed, so that the proper treatment is not employed until the pseudo-membrane begins to appear on the faucial surface, or around the entrance of the nostrils, which may not be until four or five days have elapsed.

Nasal diphtheria is a dangerous form of the disease, because septic absorption is very liable to occur from the nature of the tissues involved, so that early and frequent local treatment is important. The Schneiderian membrane is midway in sensitiveness, as it is in position between the conjunctiva and pharynx, so that a wash which is proper for the fauces, might be too irritating for the nostrils. I do not employ the potassium chlorate for the nostrils, because it is in my opinion too irritating. We must prescribe a wash that does not possess irritating properties, and is at the same time actively antiseptic and disinfectant. The following is the formula which I employ:

R.—Acidi borici . . . . . ʒij.
Sodii borat. . . . . ʒj.
Sodii chloridi . . . . . ʒi.
Aquæ . . . . . Oj.—M.

Any wash prescribed for the nostrils should always be used tepid, and it is important that it be made with the proper instrument. If the child lies upon its back, the application may be made with a small glass or gutta-percha syringe, a bulb with a stem, or even a large straight medicine-dropper. With the use of such an instrument the patient must lie on the back, for if he do not the upper nasal cavity will not be reached. If the point of the instrument be too sharp and liable to injure the Schneiderian surface by the movement of the head, this result may be prevented by drawing India-rubber tubing over the tip. The preferable instrument, however, seems to be the hand atomizer, with a bulbous tip, and six or eight forcible compressions should be made at each sitting.

I am convinced that much of the success in treating the different forms of diphtheritic inflammation —nasal, pharyngeal, and laryngeal—by the spray depends on the instrument used. Some of the instruments have too weak a bulb, some become quickly clogged and are soon out of order. Many young children resist their use, and when the fauces are treated most of the spray is received upon the tongue. The shops sell one instrument having a bulbous gutta-percha tip, half an inch in diameter, which serves as a tongue depressor, and which throws a heavy spray. It has the name Millard's, and if it continues to be made with a strong firm bulb, the pharynx, nostrils, and larynx can be satisfactorily treated by it. The tongue being depressed by it does not intercept the spray. In spraying the larynx, of course, compression should be made at each inspiration.

The following is probably as safe and useful a prescription as any for the treatment of the nostrils, and it should be used in ordinary and severe cases as often as every second hour. Perhaps, salicylic acid might be profitably substituted for the boracic.

R.—Acidi borici . . . . . ʒi.
Sodii borat. . . . . ʒij.
Sodii chloridi . . . . . ʒi.
Aquæ . . . . . Oj.—M.

The local treatment of laryngeal diphtheria or diphtheritic croup is so important, and so much is to be said in reference to it, that it cannot be expected to be a subject for discussion this evening, but I may call attention to the importance of observing at each visit whether there be the least change in the voice of the patient, for I am certain that if the proper alkaline inhalations be employed as soon as the least hoarseness is apparent, when there is only redness of the laryngeal surface, or, perhaps, a thin pseudo-membranous film, croup may, in many instances, be prevented.

Before closing, I wish to caution members of the Academy in regard to the employment of pilocarpine in the local treatment of diphtheria. In some of the medical journals pilocarpine administered internally is recommended for its supposed local action, in producing an abundant mucous secretion, which aids in detaching the pseudo-membrane. I have witnessed its employment for this purpose, with the most disastrous consequences. The action of the heart became feeble, the bronchial tubes and the alveoli were soon filled by the secretion or serous exudation, extreme dyspnœa suddenly occurred, and

the patient, who a few hours before was in a comfortable state, perished with such symptoms as occur in extreme œdema of the lungs. Useful as is pilocarpine in nephritis, it does not appear to be the proper remedy in the active period of diphtheria, and it use seems to be extremely hazardous.

AUTOMATIC PISTOLSHOT AFTER SUICIDAL WOUND OF BRAIN, AND ITS POSSIBLE MEDICO-LEGAL RELATIONS.

By ALFRED A. WOODHULL, M.D.

P. C. was found in bed about 9.30 A. M., January 27, 1887, unconscious, with a penetrating pistol-wound near the right parietal protuberance, from which there had been profuse hemorrhage. He was lying on his back with all his limbs perfectly extended, and his right hand tightly grasped a self-cocking revolver (calibre 32) with the finger on the trigger. This was so firmly held as to require some force and patience to disengage it. Two chambers of the pistol were discharged, the empty shells remaining. At the autopsy the fatal bullet was found to have passed transversely and slightly upward, perforating both lobes of the cerebrum and contusing the inner table of the opposite parietal bone. The hair near the wound was singed. The other bullet had passed through the ceiling at a point about two feet to the left and twelve feet beyond the head as the body lay. The ceiling was seven or eight feet higher than the bed, and it had been struck at an angle of about twenty-five degrees with its plane.

The question arises, Which shot was fired first? Upon one hypothesis, that in the ceiling would be a trial shot to determine whether the weapon was in good working order. Upon the other, it was due to the unconscious and automatic pressure of the finger upon the trigger, as the arm, by its own muscular action, was straightened along the body. I believe this latter to have been the case; and if it were so, it is conceivable that another person present might have been fatally wounded by this second shot. In that event the discovery of two bodies might have led to the suspicion of murder followed by suicide, while in fact there would have been suicide followed by involuntary manslaughter.

The mechanism of the self-cocking pistol, by which continuous pressure upon the trigger both cocks and discharges the weapon, must be borne in mind in discussing the case.

QUANTITATIVE VARIATIONS IN THE GERM LIFE OF POTOMAC WATER DURING THE YEAR 1886.

The value of the so-called biological analysis of drinking water—the quantitative and qualitative determination of bacteria present—is still very unsettled. Recent investigations certainly have not contributed toward a clearer understanding of the problem, but have made it more complex. Meanwhile, statistical determinations cannot be amiss in aiding investigators in interpreting their own results. It is from this point of view that the following statistics are published without any attempt at estimating the quality of the water therefrom.

The water was drawn from a faucet in the basement of the Agricultural Department building, which was constantly in use, so that there could have been no stagnation of water in the smaller pipes. It was immediately examined according to the method of Koch—two gelatine plates being always made from the same sample of water. This was measured with flamed glass pipettes, without being diluted. The pipettes[1] were graduated by determining accurately how many drops of distilled water were required to make 1 c. c. If 51 drops were necessary and only 8 added to the gelatine, $\frac{8}{51}$ c. c. was considered taken. This method is far simpler than the one which insists upon dilution, unless the number of bacteria be very large.

From 0.1 to 0.5 c. c. of water was added, according to the probable number of bacteria present. The culture medium was the well-known beef infusion peptone gelatine containing 10 per cent. gelatine. There was always a close agreement between the two parallel plate cultures made from the same sample.

As to the results of the year's observation we first observe from a glance at the table that the number is highest in winter, in spite of the fact that heat greatly favors and cold checks multiplication.

TABLE GIVING THE MONTHLY AVERAGE NUMBER OF BACTERIA FOUND IN ONE CUBIC CENTIMETRE OF POTOMAC DRINKING WATER DURING 1886.

March	1	2
April	1	1

This anomalous condition is not so difficult of explanation. In the winter the water as it reaches the city is more or less turbid, and, when shaken, clouds, composed of very minute particles, are seen. These

[1] The pipettes are made by drawing out, in the flame, the middle point of a piece of glass tubing about 15 cm. long and 0.7 mm. in diameter, until a narrow tube is formed ¼ to 1 mm. in diameter and about 30 cm. long. This is broken in the middle to make two pipettes. If the capillary tube be drawn out the exact size being determined for each pipette. Into the other the necessary aspirating force. Immediately before use the pipette is held with the bulb between the fingers. Care must be taken lest the heat be too great and change the form and size of the orifice. If any doubt exists as to this point, it is best to graduate the pipette again *after* use, and with the sample of water to be examined if the latter should vary much in its specific gravity from distilled water.

will pass through ordinary filter paper, and when gathered together as in distilling water, the residue is made up of reddish earth. This turbidity, most pronounced in winter, gradually disappears toward summer when the water becomes very clear and limpid. The number of bacteria varied with the change in turbidity, being highest when the suspended matter was most abundant. This fact impressed me so strongly after a number of observations that it became possible to anticipate quite accurately the number of bacteria present by looking at the water in the tube with transmitted light.

It seemed reasonable to conclude that whatever agency brought the suspended earth also brought the bacteria, and that the earth contained the bacteria. Throughout the winter of 1886 I noticed that after heavy rains the turbidity increased quite suddenly, this fluctuation, of course, producing a corresponding rise and fall in the number of bacteria. The rain, washing down the soil from the surface drained by the tributaries of the river was thus the cause of the turbidity. But was there any relation between rainfall and the number of bacteria? Through the kindness of the Signal Office I obtained the data given in the third column of the table. Comparing the second and third columns, the relation is certainly not on the surface. The heaviest rains occurred in July, but the number of bacteria did not rise perceptibly and no turbidity appeared. The only explanation which suggests itself is that which must be sought in the changed condition of the surface of the soil in winter and summer as regards vegetation. The precipitated water is caught by the foliage of trees, by the grass and herbage, which clothes the soil everywhere. The soil itself is at the same time more firmly bound together by the vegetation itself. In winter all this is changed. The absence of vegetation leaves the loose soil ready to be washed into streams by rain and melting snow, carrying with it the bacterial vegetation.

The majority of bacteria carried into the river are, no doubt, harmless, but what is to prevent the infectious microörganisms of typhoid and other diseases from being washed down and carried into our houses with the suspended matter? The danger is thus not constant but only occasional. The number of bacteria may have no direct significance, but it is certainly an index of the possible danger. It is safe to assume that Potomac water free from suspended matters contains from 50 to 200 bacteria in 1 cc. This will, no doubt, be found a low average for unfiltered river water when more statistics have been collected of other streams, whose water is used to supply towns and larger cities.

No qualitative examination of the different kinds of bacteria was made for want of time. Liquefying bacteria were constantly present, when the bacteria were few in number, as in summer, as many as 50 per cent. were liquefying; so that counting was somewhat difficult and many plates were lost by the confluence of the large colonies and the total liquefaction of the gelatine layer. When the number was very high, as in winter, the liquefying forms did not increase in the same proportion, but formed only 5 to 10 per. cent. of the whole. These observations led to the inference that they are constant inhabitants of the water, and that attention must be directed to them, first of all, if individual forms are to be more closely examined.

MEDICAL PROGRESS.

A New Treatment for Incised Wounds of the Throat Penetrating the Air-passages. — Dr. D. S. Young, surgeon to the Cincinnati Hospital, describes his method of treatment as follows in the *Lancet-Clinic* of March 5, 1887.

The method we have adopted to secure a safe and speedy relief in these cases, after the hemorrhage is controlled and the injuries to the internal appendages attended to, is to proceed and close the wound both internally and externally, so as to render it impervious to air and fluids. This is accomplished by uniting the incision in the windpipe with catgut sutures passed through the cartilage, including the mucous membrane; they should be placed one-eighth of an inch apart and firmly tied, and the ligature cut close to the knot.

When the air-passage is completely or extensively divided, two or three silk sutures might be placed one on each side and one in front, to sustain better the parts in position, as they will not be affected by moisture and become relaxed as the gut is liable to be. The external wound is cleansed, its margins brought together and secured with pins, or wire sutures. The head is brought slightly forward, and held by a cap with tapes fastened to a band around the chest. In cases of violent delirium, Christopher's plaster-of-Paris dressing is invaluable, as it secures perfect rest to the parts, and leaves the throat freely exposed. No especial dressing is required further than occasionally sponging the surface. The patient speaks and swallows immediately after the wound is closed, but should be restrained as much as possible. The external sutures can be removed after five or ten days. The internal catgut and silk are left undisturbed and are absorbed, or thrown off into the windpipe. No irritation or spasmodic coughing has been excited by their presence.

Xylol in Variola.—Oetvös, of Budapesth, has selected from 465 cases of smallpox 315 of severity, with whom he used xylol and obtained excellent results. The general anæsthetic effect of xylol was especially noticeable. The contents of the pustules coagulated in three or four days in masses which showed, when incised, a fibrinous base, with proliferation of the Malpighian layer. The pustules were rarely confluent, and only in the most severe and fatal cases. The drying of the pustules was without complications; scars formed very rarely; digestion was but little disturbed. The expired air had an odor of xylol, which produced an agreeable deodorization. An antipyretic or antiseptic effect was not observed. Fever generally ceased on the twelfth day; recovery was accomplished in thirty-two days; death, when it occurred, was on the eighth day.

The remedy was given in wine (added *guttatim*), 6 times daily, for 12 days. Adults took from 30 to 45 minims in 24 hours, the total amount taken reaching 6 drachms. Children took the drug readily in wine;

adults used fruit essences and aërated waters. The following is a useful formula:

℞.—Xyloli puri . . . . . grs. 45.
Aq. menth. pip.,
. . . . . ℥ij.
Syrup. cinnamoni,
M. . . . . ℥ss.
M. D. S.

Sig.—Tablespoonful every two hours.

The . . . . . smallpox, was 22 per cent.; which the writer considers a . . . . . M. . . . .

Xyloi is obtained from the oily liquid separating from diluted crude wood-spirit, and from the light oil of wood tar or coal tar. It is a thin, colorless, oily liquid, resembling benzol in odor, has a burning taste, and is insoluble in water, but dissolves readily in alcohol.—*N. . . . .*

THE TREATMENT OF COLDS.—DR. WHELAN, in *The Practitioner* of March, 1887, writes as follows:

The usual "coddling" treatment of colds, except in the very old, very young, or very delicate, is a mistake. A person suffering from a catarrh should certainly be warmly clothed and avoid draughts; but by shutting himself up in a warm room, by taking warm air baths, and lowering medicines, he only promotes the development of the exciting cause of the affection.

"Feed a cold, starve a fever." There is a deal of wisdom in the first part of this advice. A person with a catarrh should take an abundance of light nutritious food, and some light wine, but avoid spirits, and, above all, tobacco.

Now as to medicines. All depressants should be avoided. For some time I was in the habit of taking a mixture recommended by Dr. Jukes Styrap, composed of minute doses of morphine, antimonial wine, and potassium citrate. This, beyond doubt, always subdued the acute inflammatory stage, but I have no hesitation in saying I was depressed by its action, and rendered liable to relapses and renewals. Personally I have found the large dose of an opiate in the early stages, as extolled by Sir Thomas Watson and Dr. George Johnson, very unpleasant, and of but little use.

Trying to avert an attack by a large dose of potassium iodide failed in my hands. The bromides were useless through all stages. Antiseptic inhalations and spraying afforded temporary relief from the distressing symptoms, but failed to cure.

Belladonna, quinine, and arsenic I have found useful when given separately—not so much in large as in small doses. When combined I believe them to be nearly specific—prophylactically and therapeutically, if I may so speak.

The formula I invariably use is as follows:

℞.—. . . . . .
. . . . . .
. . . . . .
. . . . . .
Pulveris gummi acaciæ, q. s. ut fiant pilulæ xii.

Sig.—One every three, four, or six hours, according to circumstances.

If these pills be commenced in the early stage of a common cold—*i. e.*, when the affection is as yet confined to the nose and pharynx—the affection will be nipped in the bud. At starting one pill should be taken every three or four hours, and later on every six. If a catarrhal subject has a box of these pills always at hand, he has, I believe, a weapon wherewith to meet and defeat his enemy. The longest time I have seen a cold last whilst the patient was fairly taking these pills was three days. How the remedy acts I do not know, except it be as a powerful nervine and general tonic, bracing the patient's tissues up to resist the attacks of the exciting cause of the affection.

TINCTURE OF IODOFORM.—PROS gives the following formula for this tincture, which is convenient for use and may be readily preserved:

Iodoform	1 part.
Potassium iodide and glycerine (each)	70 parts.
Alcohol at	2 "

The iodoform and iodide are finely powdered, the glycerine is added, and the whole mixed in a homogeneous mass; the addition of the alcohol makes a complete solution.—*Journal de Médecine*, March 6, 1887.

STATISTICS OF CASES OF EXTRACTION OF CATARACT BEFORE AND SINCE THE INTRODUCTION OF COCAINE.—DR. E. T. COLLINS, of the London Ophthalmic Hospital, writes as follows in the *Hospital Reports* of that Institution for January, 1887:

So much has been said and written of late on the evil effects of cocaine, that I think it may be interesting to make a comparison between the cases of cataract extraction occurring in the hospital during the year 1883, before the introduction of cocaine, and those treated in 1885, when cocaine made up with a saturated solution of boracic acid was used in almost all cases. In making this comparison, I have counted the number of cases of panophthalmitis, the number of cases of loss of vitreous, and the number of cases of severe iritis, with the following results:

In 1883 there were 225 cases of extraction of senile cataract: 14 suppurated, or 6.2 per. cent.; 32 cases lost vitreous, or 14.2 per. cent.; and 16 cases had severe iritis, or 7.1 per. cent. In 1885 there were 264 cases; only 3 suppurated, or 1.13 per cent.; 22 cases lost vitreous, or 8.3 per cent.; and 9 cases had severe iritis, or 3.49 per. cent.

Mr. Morton, in the *Royal London Ophthalmic Hospital Reports for 1879*, vol. ix., published the results of 146 cases of extraction of cataract occurring in 1875 and 1876; of these 8 suppurated, or 5.47 per cent.; 6 lost vitreous, or 4.1 per cent.; and 18 had severe iritis, or 12.3 per cent. These figures speak for themselves.

TOTAL EXTIRPATION OF THE UTERUS AND NEPHRECTOMY.—DR. SCHMIDT, of Cologne, relates a case in which these formidable operations were successfully performed at one sitting. The patient was forty-nine years old, and had given birth to four children, all stillborn; and the menopause had occurred two years previously. For a year she had suffered from severe,

irregular uterine hemorrhage. Carcinoma of the cervix, involving the vault of the vagina, was detected. The uterus was removed, but the operation was rendered very difficult by abundant, cord-like adhesions between the fundus and the pelvic walls. The peritoneal cavity had to be very widely opened. On careful examination of the extirpated uterus, it was found that an inch of the right ureter had been cut away with that organ. The vagina was plugged with iodoform gauze, and the right kidney was removed through a lumbar incision. The patient made a good recovery. Dr. Schmidt states that total extirpation of the uterus is quite inadmissible, when it appears at all probable that a ureter is likely to be injured, not that the necessary nephrectomy would greatly increase the risk, but rather because the extirpation of the uterus would be of little service in such a case, as the cancerous infiltration would be extensive, and rapid recurrence would be certain. Yet, when the ureter has been injured, he thinks that nephrectomy is preferable to sewing the proximal end of the ureter to the vaginal walls, as this leads to inflammation and sloughing, and renders nephrectomy necessary later on. In Dr. Schmidt's case, it must be noted that the disease had distinctly involved the cellular tissue to the right of the cervix.—*British Medical Journal*, March 12, 1887.

The Treatment of Gastro-intestinal Atony.—Germain Sée prescribes as follows in *L'Union Médicale* of March 10, 1887:

℞.—Magnesiæ calcinatæ,
Cretæ præparatæ . . . . aa ʒiv.
Colombo pulv. . . . . gr. xv.
Vanillæ pulv. . . . . gr. viij.—M.

Sig.—Half teaspoonful to coffeespoonful before each meal for persons troubled with gastro-intestinal atony with tympanism. In some cases it is well to prescribe in addition 5 or 10 drops of the tincture of nux vomica in black coffee after meals.

A saline purgative should be taken from time to time as required.

A "Specific for Diabetes."—At a recent meeting of the Société de Thérapeutique, M. Martineau stated that he had been treating diabetes for the last ten years, with almost invariable success, by a method which he had borrowed from a practitioner now dead. He had hitherto made no communication upon the subject, because he had wished to be perfectly certain that his conclusions were not premature. The treatment consists in the administration of a solution of carbonate of lithia and arseniate of soda in aërated water, to the exclusion of all other drinks. Besides taking this with his meals, the patient uses the same as a beverage when thirsty at other times. M. Martineau affirms that this regimen has cured sixty-seven of seventy diebetic patients he has had occasion to treat.—*Lancet*, March 19, 1887.

Preparations of Terebene.—Terebene is a derivative of turpentine produced by distillation in the presence of sulphuric acid. It is a colorless, volatile oil having a rather agreeable, thyme-like odor and acquires with iodine a dark green appearance.

It has been extensively used in chronic bronchitis, attended by fetid expectoration.

Vigier, in the *Revue de Thérapeutique* of February 15, 1887, gives the following formulæ for useful combinations of this substance:

℞.—Terebene . . . . . ℈xj.
Gummi acaciæ . . . . . ʒij.
Aquæ . . . . . ʒxv.
Sacch. pulv. . . . . ʒiijss.
Gummi tragacanth. pulv. . . . ʒj.

An emulsion of the terebene, gum acacia, and water is to be made, to which should be added the sugar and gum tragacanth previously mixed. A homogeneous mass should be made of the whole, which is to be divided into 100 troches or capsules.

The emulsion of terebene is a preparation whose decided taste is masked with great difficulty. The following disguises the sharpness of its flavor with fair success:

℞.—Terebene . . . . . ʒiv.
Gum. acaciæ pulv. . . . . ʒiij.
Aquæ . . . . . ʒxv.
Syrupi zingiberis . . . . . ʒvijss.

Which may also be prepared in 100 troches or capsules.

Comparison of the Methods of Removal of Cataract with and without Iridectomy.—Dr. H. Knapp, of New York, writes as follows on this subject in the *Archives of Ophthalmology* for March, 1887:

If we compare the simple extraction with the extraction combined with iridectomy, we find as *advantages* of the former the following:

1. It preserves the natural appearance of the eye.

2. The acuteness of vision, other things being equal, is greater.

3. Eccentric vision and "orientation" (correct localization of objects in the visual field) are much better, adding a great deal to the comfort and safety of the patient.

4. Parts in direct connection with the ciliary body, such as shreds of the capsule and iris, are not so liable to be locked up in the wound and thus transmit morbid conditions to the most vulnerable part of the eye, the ciliary body.

5. It may not necessitate so many after-operations.

As *disadvantages* may be mentioned:

1. The technique of the operation is more difficult in all its parts: (*a*) The section must be larger, to let the lens pass through an aperture, the size of which is diminished by the iris lying in it; it must be more accurate to secure coaptation, and it must be more rapidly performed in order to prevent the iris from falling before the knife. (*b*) The opening of the capsule requires a deeper introduction of the cystitome into the anterior chamber. (*c*) The expulsion of the lens is more difficult, and (*d*) the cleansing of the pupillary area is much more troublesome than in the combined extraction.

2. Prolapse of iris and posterior synechiæ are more numerous.

3. It requires a quieter and more manageable patient during and after the operation than is needed in the combined extraction.

4. It is not applicable to all patients, whereas combined extraction can be used as a general method.

The Use of Uncooked Milk.—The question of the habitual use of uncooked milk which prevails is

one which demands serious attention. Again and again have milk epidemics of typhoid fever, scarlet fever, and diphtheria shown conclusively how severely the incidence of the disease in question has been felt upon those using uncooked milk, as opposed to those taking milk only after it has been boiled or otherwise cooked. At one time it was thought that the matter involved only the question of the cleanliness of the dairy, and the freedom of those engaged in the management from communicable disease; and the mere fact of milk coming from country dairies has been held to be sufficient guarantee of its wholesomeness. As a matter of fact, our experience goes to show that the danger is at its greatest according as dairies are situated in the more remote and rural localities; for it is precisely in scattered rural areas that first cases of ill-defined sore throat and other affections in the families of those having to do with cows and milk are most likely to pass unnoticed. But recent experience has shown that disease in the human subject, whether unrecognized or concealed, is not the only—perhaps not the greatest—danger that has to be contended with in connection with our milk services. It has now been shown that the cow herself may suffer from a disease which at present is rarely, if ever, regarded as of any importance by dairymen, and which may give to the milk, at the actual moment of entering the pail, the power of producing scarlet fever in those who consume it in its raw state. Just as the excellent arrangements which have been made for the medical supervision of dairies must at times fail to detect certain cases of disease in the human subject, so must any veterinary or other inspection of cows fail in certain cases to prevent scarlatina-producing milk from being despatched from the dairy. We would, therefore, once again urge the importance of using milk only after it has been boiled or otherwise cooked. And for those who have not habituated themselves to the somewhat altered taste of boiled milk as a beverage, we may note that if milk be boiled immediately after its delivery by the milkman and then be set aside in a cool place for some six hours, the taste which is sometimes objected to will be found to be almost entirely removed; and not only so, but milk so treated keeps good and wholesome for a longer period than does unboiled milk.—*Lancet*, March 19, 1887.

SCHEDE'S METHOD OF DRESSING WOUNDS.—PROF. MIKULICZ communicates to the *Przeglad Lekarski* an account of fifty cases of surgical operations which were treated by the method recommended by Dr. Schede at the last surgical congress in Berlin—viz., to allow blood to fill the wound and to lie between the lips after they are brought together, any deficiency in the quantity of blood being remedied by the use of the knife, the idea being that the blood either actually becomes organized or serves as a protection for the granulations as they are formed. The wound is covered with protective, to prevent evaporation. Professor Mikulicz's observations included six resections of joints, four amputations, six dissections, two ligatures of arteries, seven extirpations of large tumors, etc. In thirty-six of the fifty cases union took place without suppuration, in four there was extensive formation of pus, in five superficial suppuration starting from the points of the suture, and in the remaining cases pus had existed previously to the operation, and the disinfection at the time not having been complete, it continued subsequently. The general condition of the patients was highly satisfactory, even in those cases where suppuration occurred, the temperature in no case rising much above normal. The dressings were not removed or changed for at least a fortnight, sometimes not for a month. This appears to be of great advantage in the case of bone and joint operations, where complete immobility of the parts is a desideratum. Other specified advantages attributed to this plan are that wounds attended with a loss of substance rapidly fill up, and the cicatrices that form are peculiarly soft and smooth. Professor Mikulicz does not find, as Schede did, that the existence of silver sutures in osseous lesions has any unfavorable influence on the cicatrization of the wound. He remarks that it is important not to bind the external dressings too tightly to the wound. —*Lancet*, March 19, 1887.

ANTI-ASTHMATIC CIGARETTES.—HIRTZ, in *L'Union Médicale*, of February 24, 1887, gives the following prescription for cigarettes to be smoked to relieve the dyspnœa of asthma:

℞ [illegible] . . . . . gr. 75.
[illegible] . . . . . ʒij.
Tabaci foliarum . . . . . ʒij.
Potass. iodid.,
Potass. nitrat. . . . . ãã gr. 75.

100 cigarettes are to be made from the above.

THE INTRA-TRACHEAL INJECTION OF FLUIDS.—SEHRWALD, of Jena, summarizes his experiments as follows:

1. The perforation of the trachea of a dog with a Pravaz syringe is not dangerous, is easy, and not painful.

2. The reaction of the entry of fluids is cough. This can be diminished by warming the fluids, by narcosis, and by custom.

3. The volume of the introduced fluid may be, for a dog, 750 grains.

4. Efficient fluids are sublimate, 1:5000; acid bor., 5:100; acid salicyl., 1:100.

5. By varying the position, the fluid can be introduced into every part of the lung.

6. The fluid pervades the alveoli, the peribronchial region, the bronchial glands, and the kidneys.

7. The absorption by the lung is quicker than that by the tractus intestinalis, or by the subcutaneous tissues.

8. The lung can absorb in five days four times its own weight.

9. The effect of drugs is, therefore, quicker if they are introduced by the lungs than by any other way.

10. Injecting into the lung is like injecting directly into the circulation.

The author hopes that it will be possible to use this method for the treament of lung diseases.—*Journal of Laryngology*, March, 1887.

PRESCRIPTION FOR ASTHMA.—DR. CAZENAVE DE LA ROCHE has found iodide of potassium combined with cow's milk a very efficient remedy for asthma. It should be given as follows: distilled water, four and three-quarter ounces; iodide of potassium, two drachms. One tablespoonful of the solution in a cup of milk twice a day.—*British Medical Journal*, March 12, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SATURDAY, APRIL 9, 1887.

THE TREATMENT OF INCOMPLETE ABORTION.

THE treatment of cases of abortion when, after the expulsion of the embryo, or fœtus, the rest of the ovum, or a considerable portion of it remains in the uterus, is by no means uniform. Some practitioners employ immediate intervention, endeavoring at once to empty the uterus, using, if necessary, instruments for the purpose. Others advocate an expectant plan, content with daily antiseptic vaginal injections, waiting until signal for action is given either by hemorrhage or by offensive discharge; in either of the latter conditions delay is no longer permitted, but removal of the offending material from the uterus must be effected, and followed in some cases by intrauterine antiseptic injections.

Of course, the nearer the time of miscarriage is to that of fœtal viability, the more the phenomena are similar to, or identical with those of premature delivery, and the discharge of the placenta is effected by the same means, should interference be necessary, that are employed when delay occurs in the third stage of labor. But it is the cases of abortion occurring earlier in pregnancy, for example, from six weeks to three or four months, and which are incomplete, that furnish a sort of debatable ground as to practice. It is well to know what nature does in the large majority of these cases. Where rest and proper precautions are taken, the offending body is expelled usually within a few days, the interval rarely being a week or two, and no injurious consequences are observed. In quite exceptional cases there is no history of any expulsion, either spontaneous or artificial. Thus, in conversing with one of the most eminent obstetricians as to the treatment of incomplete abortion, he stated that he neither advised nor practised active intervention, and then, as illustrative of his views upon the subject, stated that several years before his wife had such an abortion at three months, and there was no interference; the retained placenta and membranes never made their appearance, and yet her convalescence was prompt, and her health had remained subsequently perfect. Further, occasional cases of either severe hemorrhage, or of offensive flow and elevation of temperature, sometimes preceded by a chill, though this is most frequently absent, do occur, and, as we have previously said, demand prompt and active intervention. These are the cases which are adduced by the advocates of immediately emptying the uterus, if the abortion be incomplete, as an argument for their practice, and against expectation. But they forget the much larger number of incomplete abortions treated by the expectant plan where no such accidents occurred; and they forget, too, that the advocates of expectation would be just as active in intervention as they, in such small minority of cases presenting the symptoms just mentioned, and that the results are almost invariably favorable.

In further considering this subject, we desire to call attention to the method pursued by CHÉRON, as given in the February number of the *Revue Medico-Chirurgicale des Maladies des Femmes*, and to the practice of TARNIER as presented in his work upon obstetrics, the second part of which has recently been issued. Chéron advises, in case the placenta be retained, that the patient be placed upon her back, the legs flexed upon the thighs, and the latter strongly flexed upon the abdomen, for he claims that this position causes the neck of the uterus to lie in the axis of the vagina and thus in part remove obstacles to the expulsion of the placenta. The position alone often determines the discharge of the fœtal appendages. He states that it is useless to pull upon the cord, for this readily breaks, and dangerous to attempt artificial delivery with the hand or with the curette. But if at the end of twenty-four hours the expulsion fails, the patient should be put in the obstetric position, the speculum introduced, and hot water thrown upon the cervix, through which the uterus almost always contracts, and the placenta is expelled. But if this method fails, intrauterine galvanization is employed, the negative pole being introduced into the cervical canal, and the positive pole connected with a large metallic plate, covered with chamois, placed upon the hypogastrium, and a current of fifteen to twenty milliampères employed, the current being made regularly intermittent. The uterus very soon contracts, and complete expulsion of the fœtal appendages results. It is asserted that the employment of these means, which are inoffensive and which every practitioner can use, never fails.

Tarnier does not advocate immediate interven-

tion, and he sustains his position by the results of cases treated according to the expectant plan at the Charité and the Maternité. Twenty-two cases were under observation at the former, the placenta being retained after the fœtus was expelled, and hemorrhage did not occur when the former was discharged; and in three women who had incompletely aborted and been brought to the hospital with fever, the fever soon disappeared after the employment of antiseptic injections. At the Maternité there were twenty-four cases of retention, two of the women, one of whom was brought to the hospital sick, suffered from infection; all recovered except one, who died from pneumonia fourteen days after abortion. He asserts that if all untimely intervention be abstained from, incomplete abortion rarely gives rise to the complications which to-day are so much feared, especially when antiseptic injections are employed.

He next considers the treatment by forceps and curettes, and regards it as often inefficient, and sometimes dangerous; the curette, for example, acts blindly, so that the sound mucous membrane of the uterus is liable to be injured, and thus entrance of septic germs may occur. In some cases where dilatation of the cervical canal was required for the use of ipstruments within the uterus, very serious rents of the cervix have been made. He advises then, in incomplete abortion, simply "antiseptic toilets and vaginal injections," two or three times a day, resorting to intervention only when some complication occurs.

The expectant plan of treatment of incomplete abortion is, we believe, that which is followed by most practitioners.

OPERATION FOR EXTRAVASATION OF BLOOD WITHIN THE CRANIUM.

In The Medical News for December 25, 1885, and May 8, 1886, we discussed the subject of the proper treatment of injuries of the head followed by intracranial hemorrhage, and called especial attention to the valuable papers on this subject by Wiesmann, Krönlein, and Ceccherelli.

The opinions expressed by these surgeons, which have commended themselves to our judgment, have recently had a striking confirmation in the experience of Schneider, of Königsberg, who, in the *Archiv für klinische Chirurgie*, Bd. xxxiv. Heft 3, publishes an account of a case of punctured wound of the skull, followed by aphasia and hemiplegia, in which he trephined and removed an intradural blood-clot from an opening in the middle cerebral artery, and effected a cure.

The patient was a young man eighteen years old, who was stabbed with a knife in his left temple, and who had, almost immediately, paralysis of the right side of the face and of the right arm and leg. Four days afterward he was brought into the hospital in Königsberg. He then had a small, almost healed wound over the third frontal convolution. He was perfectly conscious, and could answer by signs, although he could not speak a word. He could and did write with his left hand, with increasing facility for several days, although he had been right-handed before. As the hemiplegia increased without febrile symptoms, Schneider attributed it to an accumulating extravasation of blood, and operated for its relief on the ninth day after the injury. He trephined the skull at the seat of the wound, opened the dura, removed a small clot, found the first branch of the middle cerebral artery spurting in the substance of the brain, seized it with forceps and ligated it with catgut. The wound was then cleansed, the opening in the dura was sutured with fine catgut, the soft parts covering the skull were also sutured, a drainage tube was inserted, and a Lister bandage was applied. The wound healed by first intention. On the third day after the operation the patient began to articulate, and in four weeks he spoke perfectly. Part of the hemiplegia disappeared more rapidly, the leg and arm recovering in eight days; but the facial paralysis was not wholly gone after a lapse of six months.

It will no doubt strike those who observe the points of this case in the light of what is known concerning the phenomena of extravasation of blood within the skull, that the suddenness of the appearance of aphasia and paralysis might have led Schneider to diagnosticate an injury to the brain beside a hemorrhage above or below the dura.

In intracranial hemorrhages, uncomplicated by an immediate injury to the brain substance, the onset of the symptoms is gradual; on the other hand, a sudden aphasia or paralysis indicates that the brain substance itself has been injured. This might have been recognized at once in the case just described, and the fact that it was not is the only error we note in connection with it. The diagnosis of a persistent bleeding was in accord with our present knowledge of injuries of the cranium, and was abundantly corroborated by the disclosures and the results of Schneider's brilliant operation.

UNTOWARD EFFECTS OF COCAINE.

The varied and constant use of the hydrochlorate of cocaine by almost every practitioner of medicine renders imperative attention to the fact that this drug may act as a poison, since a very large number of well-authenticated cases of this character are now on record. While almost every reader of the current medical journals can recall the report of some case in which serious symptoms asserted themselves, the literature of the subject is so scat-

tered that little attention has been given to it. Within the last few weeks, however, quite a large number of cases have been recorded in various medical periodicals, especially in Great Britain.

One of the first things which strikes the reader of these reports is the fact that no particular line of symptoms appears to be characteristic, and that the doses reported as producing toxic symptoms vary even more than the unlooked-for results themselves.

In England, where the practice of using cocaine hypodermatically for the purpose of producing local anæsthesia seems to be carried on much more fully than in this country, surgeons have reached the most varied conclusions as to the dose which may be safely given in this manner. Some insist that as much as four grains may be given under the skin, while others report very serious poisonings from the use of one grain. Thus, Magill records the case of a strong, healthy man to whom he gave, previous to an operation for phimosis, a hypodermatic injection of one grain. In fifteen minutes the man was extremely pale, and suffered from severe præcordial pain. The pulse was very slow and intermittent, but did not resemble that present when syncope is impending; complete recovery took place in twenty minutes. More remarkable even than this is the record of seventeen cases gathered by Ziem, of Dantzig, in 1885, in which decided toxic effects occurred simply through instillations of the drug into the eye, and in which the amount of cocaine reaching the general system must have been very small indeed.

The symptoms which assert themselves are, as has just been stated, remarkable for their variety, and they range in severity from slight systemic depression to temporary blindness, or even syncope and collapse. Robson records a case in which aphasia followed its use in the removal of a nasal polypus, while Littlewood has seen great loquacity, and finally syncope, follow the hypodermatic administration of sixty minims of a six per cent. solution.

The interesting question in regard to this matter is the cause of the production of these symptoms and the best method for their avoidance. Unfortunately, there seems to be no fixed rule on which we can depend, since the causes themselves are as yet not by any means understood. Naturally idiosyncrasy occurs to the mind of every one as the most likely explanation, and this idea is somewhat strengthened perhaps by the various effects produced.

Again, it may be that the sudden and enormous demand has led to the placing on the market of adulterated or carelessly prepared samples of the drug, and if this be the case the reports of toxic effects should be constantly on the decrease, since at present the supply and demand are so nearly balanced. Whatever may be the explanation, it certainly seems of the greatest importance that the profession in general be reminded that cocaine is not to be used recklessly and without proper care.

TOTAL EXTIRPATION OF THE UTERUS THROUGH THE VAGINA.

Although the extirpation of the uterus through the vagina for the removal of carcinoma, is a comparatively new operation, it has, in the short term of its existence, shared the advance experienced by those other operations of gynecology which have been converted, of recent years, from desperate measures to perfectly legitimate and not particularly dangerous therapeutic procedures. This point is well illustrated by the statistics of 60 operations for the removal of the uterus through the vagina, published by Fritsch in the *Archiv für Gynäkologie*, Bd. xxix. Heft 3. The mortality of the operation itself was only 10.1 per cent. and two of the deaths were hardly to be ascribed to the operation. A still more gratifying feature of the statistics is the number of women who were much benefited, some of them perhaps cured, by the removal of the cancerous womb. Of the 53 women who survived the operation, 20 remained healthy, 2 after three years, 7 after two years, 8 after one year, and 3 after ten months. This is a most satisfactory result to have achieved in dealing with a disease which of itself is necessarily fatal, even should the relief afforded be but temporary, and unfortunately this may prove to be the case, for v. Hofmeier's statistics show that three years and more of apparent health may be followed by the return of the disease.

Such a low mortality associated with a rather formidable operation must attract attention to Fritsch's method of operating, which may be thus described: The lateral vaginal vault is first incised and the lateral attachments of the uterus severed, the tissues being transfixed by a needle and thread and securely ligated before being cut. As soon as the uterus is free to descend about two and a half inches, the anterior vaginal vault is incised, the bladder is detached from the uterus and then, for the first time, the peritoneal cavity is opened, the uterus is tilted far forward, and the broad ligaments are secured by ligatures from above and then cut through. Finally, as the last step of the operation, the posterior vaginal wall is separated from the uterus, which is then removed, usually without difficulty. Should the uterus, however, be as large as a child's head, as it was in two of the cases recorded, considerable, but not insuperable, difficulty might be experienced in its extraction.

In view of these results, Fritsch expresses the hope that the knowledge that cancer of the womb can no longer be called an altogether incurable disease may be more widely disseminated among both the laity

and general practitioners. With such information women afflicted with this disease may seek surgical aid as soon as its existence has been discovered, before the morbid process has reached such a stage that an operation can only be undertaken as a last resort when it is merely a forlorn hope.

ETIOLOGY OF GASTRIC ULCER

In [illegible] 1887, a novel explanation of the production of ulcer of the stomach is suggested by Rasmussen, who found in a very large number of cases furrows or grooves on the surface of the stomach caused by the pressure of the costal edge. These pressure grooves usually run obliquely from the middle of the lesser curve toward the pylorus. The serosa is often thickened, and he has seen adhesions to the diaphragm. At these points the mucosa sometimes is atrophied. In one of the Copenhagen hospitals scars of gastric ulcer occur in the bodies of 7 per cent. of the men, and from 32 to 36 per cent. of the women, and in the great majority of these cases the cicatrices have been about the middle of the lesser curve, or a little nearer the pylorus; the very situation in which the pressure furrows occur. The author thinks that the theory of a pressure necrosis much more satisfactory than the one usually adopted of thrombosis or embolism of the small arteries. The suggestion is an interesting one, and would account for the much greater frequency of gastric ulcer in women, but, like the older views, it is not free from difficulties.

At the annual meeting of the Alumni of the Jefferson Medical College held on Monday, Dr. S. W. Gross was elected President, and Dr. Austin Flint, Orator for the ensuing year. In the evening the Alumni gave a reception to Dr. Hunter McGuire, the Orator for 1886, which was largely attended.

The sixty-second annual commencement of the Jefferson Medical College was held on Tuesday, and the degree of M.D. was conferred on 187 graduates.

The South Carolina Medical Association meets at Aiken on Tuesday next, the 12th inst., and the Medical Association of Georgia, at Atlanta, on Wednesday, the 20th of April.

The Southern Medical College, of Atlanta, at its commencement, held March 3d, conferred the degree of M.D. on thirty graduates, and the Atlanta Medical College, on the following day, graduated forty-five of its one hundred and twenty-one students.

REVIEWS.

The Principles and Practice of Operative Surgery. By Stephen Smith, M.D., Professor of Clinical Surgery in the University of the City of New York, Surgeon to Bellevue and St. Vincent Hospitals, New York, etc. New and thoroughly revised edition. 8vo. pp. 877. Illustrated with one thousand and five woodcuts. Philadelphia: Lea Brothers & Co., 1887.

This work of Dr. Stephen Smith's has been a long time before the profession, and its merits have been proven by its exceptionally large sale, eight large editions having been exhausted in less than eight years. The present edition has been thoroughly revised and it will be found to represent fully the views in regard to surgical practice as held at this time.

Time and space do not permit more than a brief notice of this valuable and almost encyclopedic volume, and we shall not attempt an analysis of its contents, but shall briefly note our impressions as derived from a careful examination of its pages. As has been stated, the work is fully abreast of the times, but whilst taking cognizance of the various new procedures which have been advocated with earnestness by different surgeons, there is a tone of judicious conservatism pervading the book which is highly gratifying to those who do not rush to extremes at every new move of doctrine. This is seen especially in regard to operations upon the stomach, intestine, and fractured patella. The author also speaks with no uncertain voice in regard to the use of antiseptics, and we think his earnest but dignified advocacy of the use of these agents will go far toward furthering their general adoption.

The general practitioner will find this work fill a place in his library or upon his desk which but few other works can, for within its covers will be found many subjects discussed which he would look in vain for in most manuals of operative surgery; in fact, this is not a manual but a comprehensive treatise. The first 120 pages are devoted to the principles of operative surgery, preparations for operation, antiseptic directions, treatment of wounds, wound fevers, etc., and the rest of the work is divided into sections corresponding to the various anatomical systems of the body, as the osseous and muscular, with a short section devoted to "Orthopædia." The whole work is up to the times, easy to read, with good type and illustrations, and is a book which will be useful to any one who may be fortunate enough to procure it.

SOCIETY PROCEEDINGS.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

[illegible]

The Vice-President, John H. Packard, M.D., in the Chair.

Dr. N. A. Randolph read the following note on

THE IRRADIATION OF MOTOR IMPULSES.

About two years ago this question arose in my mind, If a man performs work with the muscles of (*e. g.*) his right hand exclusively, and to the point of fatigue, can

he thereafter perform as much work, of the same nature, with the left hand as he could if the right had not been previously exercised?

It will be seen that this question relates in nowise to a comparison of the work of the two hands, but to an examination of the work which may be accomplished by one hand as conditioned by the previous exercise or non-exercise of its fellow of the opposite side.

It is evident that the answer to this query is dependent on intracranial processes solely, and that such answer would throw some light upon the functional independence or interdependence of the two halves of the brain.

In order to answer the question just stated, certain conditions are prerequisite. The subject of experiment must have no conception of the object of the investigation, or he will unconsciously become a partisan of one or the other hand. He must, also, have a very strong inducement to exercise his volition to the utmost.

These conditions were fulfilled in the persons of some intelligent and vigorous convicts in the Eastern Penitentiary in this city. The stimulus was a money prize to the man who accomplished the most work in a given time. In the prosecution of these experiments I am under obligation to the courtesy and assistance of Dr. W. D. Robinson, physician to the penitentiary.

In the first series of experiments, rubber bulb syringes, identical in all their measurements, were used, and the amount of water which the men could transfer from one vessel to another in a given time was accurately measured and taken as proportionate to the work performed. Some forty observations were made by this method, with the uniform result that either hand could do more work when its exercise preceded than when it succeeded the similar exercise of its fellow of the opposite side. It was found, however, that the muscular effort could not be entirely restricted to one side of the body in this method, as great fatigue was always accompanied by a grimacing and writhing which implicated the muscles of both sides of the face and trunk.

A Morse telegraph was next used, the muscular movements in this case being restricted to an up-and-down motion of one finger of each hand, the number of such movements made in a given time being recorded on the usual long and narrow strip of paper as dots or dashes, in accordance with the celerity of contraction and relaxation of the flexors of the finger. The results of this series of experiments were uniformly confirmatory of those before obtained, but the method had to be abandoned as productive of great eye-strain in counting.

I then had made the instrument which is here shown. It consists simply in the clockwork and dial of an ordinary gas metre, to which a lever is adapted in such wise that each flexion of the finger is recorded by an appropriate motion of the index on the unit dial. The apparatus is fixed in a box, upon which the hand and forearm may conveniently rest. The lever projects through an aperture in the lid, and a glass plate in the side permits the records on the dial to be easily read off and noted. Six healthy prisoners, supplied with the incentives of cash and competition, were repeatedly examined by this means. To each, fifteen minutes was given to make the best record he could with (*e. g.*) the right forefinger, and thereafter the left forefinger was similarly exercised for the same time. On the following day the same process was repeated, always commencing, however, with the finger of the hand which had been used second on the previous occasion. No man was ever thus employed twice on the same day.

The results were practically uniform. The man who for fifteen minutes flexed and relaxed his right forefinger with the greatest speed possible to him would, on the following day, accomplish, on an average, nearly ten per cent. less work with that finger when its exercise was consecutive to a similar exercise of the forefinger of the opposite side, than when its work was initial.

Usually more work could be accomplished by the simultaneous exercise of the two forefingers, than by their exercise one after the other. In such exercise of both hands at once, and apparently from some unconscious effect at rhythm on the part of the subject, it was noted that the movements of the left forefinger were generally more active and rapid than when used alone, although in both instances the greatest effort at speed was evidently made. I am told that some pianists have a similar experience, inasmuch as they find it possible to exercise the fingers of the left hand more rapidly when the right is similarly engaged than when the right is inactive.

The relation of these facts to the observations of Dr. S. Weir Mitchell and Dr. Morris Lewis is supplemental in its nature. These observers, as is well known, showed that the knee-jerk is reinforced by any voluntary movement in any part of the body, and that this reinforcement was apparently due to such an irradiation of motor impulse from the active centres to other similar centres as placed them and their related muscles in a condition of heightened responsiveness to external stimuli. My studies not only tend to confirm these observations, but to show that the fatigue of one centre may induce a sympathetic fatigue in other centres.

These observations are of interest, inasmuch as they suggest—that the centres for volition, attention, and coördination (or one or more of these) are not, in their functional activity, bilaterally symmetrical and independent—that is, that these functions have not attained complete differentiation into right and left will, attention, or coördination; that, probably, the first effect of the voluntary activity of a portion of one cortical motor area is a stimulation of the corresponding portion of the other hemisphere—a stimulation that may result in its slightly premature fatigue; that apparently more work can be effected through the voluntary simultaneous exercise of two such portions of the motor apparatus than by their independent exercise one after the other.

Dr. Weir Mitchell said that the remark that with fatigue comes an increasing tendency to convulsive or useless acts of facial or other muscles, is interesting. It seems to show that with feebleness comes increasing waste by overflow of motor energy on to distant ganglia. Perhaps in all states of weakness there is more or less increase in regard to this tendency. The explanation of Dr. Randolph's facts is difficult. It may be that the overflow of energy on to symmetrically related centres, or on to others, may be competent to weaken them without being strong enough to cause motion; and whether this occurs as regards the opposite hemisphere, or only as regards opposite spinal centres, is hard to say.[1]

[illegible] motion a mechanism.

We are also free to speculate as to the relative failure of one hand, the last in use, as due to there being but one centre originative of will signals to the lower ganglia, and itself capable of fatigue. If, however, we entertain any such view, it might be in a measure tested by exacting work from a non-symmetrical pair of limbs, as a foot and hand. He inclined toward the use of the overflow theory to explain the lowered capacity for work by one hand after exhaustion of the other. It would explain why in consentaneous use of two symmetrical parts more work is done than when they follow one the other.

The overflow would be in this case valuable, and not damaging or wasteful. This led him to relate an experiment which Dr. M. Lewis and he left out of their paper on knee-jerk, but of which now he is sure enough to speak. When we use the maximum power of one hand on a dynamometer, the coincident use of the other hand adds nothing to the result; and this form of experiment has been commonly used as a test of the reinforcing capacity of the opposite member. If, however, using two fingers, or the grip of the thigh adductors, on the bulb of a mercurial dynamometer until great exhaustion occurs, and then making a new effort coincidently with violent use of another member, the mercury leaps quite to the level attained during the first effort by unfatigued muscles. It does not seem easy to explain this fact, except by assuming that the overflow of energy usually wasted is in this case made efficient.

The question of muscular, and indeed ganglionic, tone is brought forward in an interesting way by this experiment. When we strike the patellar tendon, a sudden, distant, voluntary act, adds reinforcement. What is it that happens to the muscle or ganglion so influenced? Is it made more sensitive to impressions, or with this is there a slight flow upon it of motor energy? And if so, can we measure the effect, and thus influence what we conceive of as muscular tone?

For some time he has been engaged in discovering if these reinforcements do cause motion—*i. e.*, a slight preparatory muscular contraction making the subsequent volition, or other excitatory activity, more potent in its results.

He has been able, so far, to prove that in spastic cases distant muscular effort, such as a grimace, really causes distinct and measurable movement in the extensors of the thigh and presumably elsewhere. This interesting discovery has been confirmed in New York and at Harvard. Whether in *normal* man remote motion is thus capable of causing slight shortening of all other muscles does not as yet seem clear. In his own experiments he obtained what seemed to be the same but slighter results than such as were seen in spastic paralysis. He hopes very soon to solve his doubts, and to be able to state his conclusions in more decisive shape. Upon what these may be will depend much of our hope as to realizing clearly the true nature of muscular tone.

We often speak of nerve power as if there were a common stock from which are drawn the supplies needed by every active organ, and reason that it is unwise to try to carry on at once two functions which exact large expenditures—as digestion and intense thought, or digestion and exercise. Practically the difficulty may be one chiefly of blood supply. This is illustrated in the not rare fact that some feeble people cannot digest except when at rest. These facts suggest to him the idea that he would like to see if Dr. Randolph's cases would lose ten per cent. of mechanical capacity after a period of exhausting mental labor or during digestion.

DR. H. C. WOOD said that the old theory which was used to explain the principle of counter-irritation, was that there is a certain amount of nerve force in the system, and that when by means of counter-irritation the nerve force is drawn to a distant point, it is removed from the inflamed part. Modern science does not recognize the truth of this theory, but it looks to him as though there is a certain amount of truth in it.

DR. H. R. WHARTON reported a case of

INNOMINATE ANEURISM TREATED BY SIMULTANEOUS DISTAL LIGATION OF THE RIGHT COMMON CAROTID AND SUBCLAVIAN ARTERIES; RECOVERY.

Andrew C., aged forty-two years, was admitted to the University Hospital, suffering from an aneurism of the innominate artery.

On Nov. 13th he was etherized, and Dr. Ashhurst cut down upon and ligated the right common carotid artery just above the omohyoid muscle with a catgut ligature; the right subclavian artery was next exposed and ligated in its third part just outside the anterior scalene muscle with a ligature of the same material. The wounds were closed with silver sutures, drainage tubes being introduced, and were dressed with oiled lint, the whole right arm being wrapped in cotton. No immediate effect was noticed in the aneurism from the application of the ligature, nor were there any cerebral symptoms. The patient did well after the operation, and upon the succeeding day the temperature and color of the right arm were good. The wounds did well, and in the course of a few days it was noticed that the tumor at the root of the neck had become smaller and firmer, and that its pulsations had diminished in force; the dyspnœa and dysphagia had also diminished very markedly, and the patient was able to sleep comfortably in the recumbent posture. Up to the time of his discharge from the hospital repeated examination failed to discover any pulsation in the radial artery. After this time the patient's improvement was continuous, and he was discharged from the hospital on January 13th, just two months after the operation.

Consecutive double distal ligation of the right carotid and subclavian arteries has been practised for innominate aneurism (as diagnosticated) in eight cases, with three recoveries and five deaths, although there was temporary relief in one of the fatal cases.

Dr. Wharton has found the records of thirty-two cases of simultaneous double distal ligation of the right carotid and subclavian arteries for innominate aneurism (as diagnosticated), in which the operation was followed by recovery in twelve cases, death in sixteen cases, and by temporary improvement in four cases. The results of both methods of treatment as regards the number of recoveries is nearly equal, but it must be remembered

Resistances on the one circuit, A, so interfere as to lessen the flow of energy below what will move the mechanism. Meanwhile the other battery, B, runs to exhaustion. At last we call on battery A for a repetition of the full work done by B, and find A unable to effect the same work as that done by B, on account of having been partially disabled by its previous ineffectual waste of energy.

that the number of cases in which consecutive ligation was resorted to is very small in comparison with that in which simultaneous ligation was employed. He thinks, therefore, that at the present time the weight of surgical opinion is in favor of the views of Mr. Barwell, that, in innominate aneurism, the simultaneous double distal ligation of the right carotid and subclavian arteries is both a more efficient and safer procedure than the consecutive ligation of the vessels.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, March 23, 1887.

THE PRESIDENT, CHARLES McBURNEY, M.D., IN THE CHAIR.

CASE OF EXCISION OF THE ELBOW.

DR. WYETH presented a boy, fourteen years old, whose elbow he had excised a few weeks before. He entered Mt. Sinai Hospital in January, having but slight power of motion in the left elbow. Exsection was performed, one inch of the humerus being removed, together with the articular surface of the radius and ulna. The olecranon was partially preserved, in order to maintain the attachment of the triceps. A movable splint was applied, and at the expiration of ten days passive motion was practised daily. A rapid recovery followed. The patient was presented in order to show the fair degree of mobility obtained at this early stage of the after-treatment.

DR. GERSTER said that he had repeatedly used the apparatus in a case of excision, but had not been entirely satisfied with the result, since flexion could be carried only to 90 degrees, because the posterior part of the capsule was too short. In reply to a question from Dr. Wyeth, as to whether the new capsule was not rendered more lax, he said that, on the contrary, he employed this method of treatment in order to correct too great laxity. By reason of the movable hinge, the bones were compelled to move backward upon the sawn surface of the humerus; otherwise they would tend to be attached near to its anterior edge.

DR. BRIDDON asked if the object aimed at was not to restore the fulcrum as it originally existed.

DR. GERSTER said that it was. The apparatus, he explained, was not originally devised by Dr. Lange, but by Madelung some time before; Dr. Lange had only added the sliding fulcrum.

DR. SANDS remarked that, theoretically, all excised joints should heal without suppuration, but that such results were certainly exceptional. The result in the present instance seemed to be fairly good. Where there was no suppuration healing occurred promptly, as in a case which he had exhibited before the Society, and in which he had performed excision for the relief of ankylosis; healing was complete at the end of two weeks. It would be useful, the speaker thought, to note in the case presented just how much had been gained by the treatment. While rotation appeared to be good, flexion and extension were both limited, the angle between the arm and the forearm being 90 degrees in the position of extreme flexion, and about 130 degrees in that of extreme extension. It seemed also to him that the impediments to free motion were of a bony character, which would not be removed by passive motion.

DR. WYETH admitted that Dr. Sands's observation with regard to the limitation of motion was just as it applied to extension of the forearm. He had purposely left a little of the sigmoid surface in this case, in order to preserve the insertion of the triceps muscle; the arrest of extension was undoubtedly due to this bony projection. He added that the boy had passed from under his observation three weeks after the operation, although he did not leave the hospital until three weeks later), so that he (Dr. Wyeth) did not have an opportunity to practise passive motion of the joint; he intended to see the patient at frequent intervals, in order to manipulate it. If he could gain no more of extension than that at present enjoyed he would be satisfied. The object of further treatment would be to improve flexion.

DR. POORE said that he had excised an elbow more than a year before, and the patient returned with complete ankylosis. He repeated the operation, and healing occurred without suppuration, although pus had been present on the first occasion. He thought that there was always more or less suppuration after the first operation.

DR. WYETH remarked that there was very little suppuration in the case under consideration. Strips of tin were applied at first, but these were removed, and the movable splint worn after ten days.

DR. BRIDDON thought that the restricted motion observed in these cases was often due to the surgeon's anxiety to save as much of the bone as he could. He cited in illustration a case in which he had freely excised an elbow-joint in a woman, and, as a result, the arm appeared to be little better than a flail. After an angular splint had been applied the patient could use the limb quite well. He thought that she could not do without the splint, until it was removed for a time in order that it might be repaired, when she found that she could dispense with it. She was now able to perform her household work without any trouble. He has within a year excised the elbows of two children at the Presbyterian Hospital, whose ages were about the same as that of Dr. Wyeth's patient. In one case tuberculous arthritis was present, and there was a long sinus leading into the joint. A bone drain was introduced, and this was filled with iodoform. There was no suppuration whatever, and the patient was well in seven weeks. The second case was one of badly united fracture, and healing was perfect at the end of four weeks. The patient had been repeatedly examined since the operation, and the motions of the joint were entirely satisfactory.

In answer to a question from the President DR. WYETH said that by employing passive motion he expected to produce gradual stretching of the contracted ligaments. Limitation of flexion in the case presented was probably due to this condition, but extension was prevented by the contact of bony surfaces.

DR. GERSTER'S experience in the fifteen or sixteen excisions which he had performed had been this, that more *personal* attention was needed on the part of the surgeon in cases where only small portions of bone were removed, especially in children. It was necessary to employ passive motion very carefully, or serious harm might be done. Active motion intelligently directed, and massage were the agents to be used, the latter being especially valuable when a small amount of bone had been removed. The obstacles to motion

were, in the first place, the swelling of the parts, and in the second, the pain and resistance on the part of the patient. Whenever, the speaker added, he did not attend personally to the details of after-treatment, the result had been unsatisfactory. Suppuration was not such an important element as regarded the final result; better results sometimes followed in cases that did not heal by first intention, because the surgeon gave more attention to the case than when healing was uninterrupted. Dr. Gerster had never had a case of ankylosis after excision, and in several instances there had not been a drop of pus.

DR. SANDS contended that it was important to avoid suppuration in cases of partial excision. He cited the case of a patient, presented to the Society by Dr. Hall, in whom he (Dr. Sands) had excised only a portion of the olecranon, for limited tuberculous disease, the whole hinge-joint being preserved. There was an entire absence of suppuration and motion was almost perfect. The speaker could hardly imagine how suppuration could occur in a joint thus excised, in which the opposed surfaces were so intimately related, without resulting ankylosis, or, at least, some limitation of motion. When a large amount of bone was removed, it did not make so much difference.

DR. GERSTER accepted Dr. Sands's amendment with regard to the class of cases in which it was important to avoid suppuration entirely. The more nearly an excision approached an arthrotomy, the more necessary was it to secure an absence of suppuration. The speaker acknowledged that he should have expressed himself more exactly by using the terms *septic* suppuration, meaning a suppurative process that resulted in the extensive destruction of the tissues belonging to a joint.

DR. ROBERT ABBE read a paper entitled

ANEURISMS TREATED BY THE INTRODUCTION OF CATGUT, OR OF WIRE, WITH ELECTRICITY.

(See page 397.)

DR. PETERS asked Dr. Abbe if he had met with a record of Dr. Buck's case, in which wire or horsehair was introduced into the sac.

DR. ABBE replied that there were several recorded cases in which horsehair and other foreign bodies had been employed, but that his paper dealt exclusively with the use of wire and catgut.

DR. WEIR asked whether it was desirable to use electricity so long if the wire was really disintegrated.

DR. ABBE did not think that harm could result.

DR. WYETH did not see what additional advantage was obtained by passing a galvanic current through the wire after it had been introduced, since experiments on animals had shown that the mere presence of a foreign body in a bloodvessel was sufficient to produce this result. As he understood the purpose of the operation, it should be to favor *slow* not *rapid* coagulation, since the latter process is fraught with more danger than is gradual solidification of the tumor.

DR. SAND called attention to the fact that the idea that rapid coagulation of the blood in an aneurism is injurious, had been abandoned. There are many cases on record in which large aneurisms had been cured by total compression continued for not more than an hour, or an hour and a half, the coagulation being perfect and the cure permanent.

DR. WYETH replied that about nine years before he had made a special study of large aneurisms at the root of the neck and at the arch of the aorta, and had published a paper on the subject. At that time after a careful review of the evidence on the subject, he had reached the conclusion that rapid coagulation of the blood within the sac was more apt to be followed by disastrous consequences.

DR. WEIR thought that the brilliant results obtained by Esmarch's method of treatment showed that rapid coagulation was not dangerous. The best results had been obtained in cases of sacculated aneurism. He was struck while examining Dr. Lange's specimen with the fact that many of the loops of wire remained free within the cavity of the sac, were quite bright, and had no clot adherent to them. Dr. Weir thought that there was something in the idea advanced by the reader, that the galvanic current served to roughen the surface of the wire, and thus favored the deposition of clot.

DR. GERSTER said that he had practised the method described by the reader in one instance. The patient was an undertaker, forty-five years of age, who entered the German Hospital, early in January, with a large dissecting aneurism that involved the arch of the aorta and protruded behind the sternum and clavicle, interfering with respiration. Shooting pains in the occipital region formed a prominent symptom in the case, while hoarseness was also marked. Although the patient's physician affirmed that the tumor had first appeared only three weeks before, the pains in the head and in the nape of the neck, supposed to be of a rheumatic character, had been present for a year. Dr. Gerster inserted a canula into the sac, and introduced through it thirty-six feet of thoroughly disinfected steel wire similar to that used by Dr. Abbe, care being taken not to push in the canula beyond the middle of the sac. It was noticed that as a fresh portion of wire was thrust in, there was a rhythmical protrusion of the opposite wall of the sac. The operation was easy, lasting only thirty minutes, and caused no discomfort to the patient. The spot where the puncture was made was carefully covered with iodoform gauze. There were no bad symptoms until the end of the third day, when the temperature began to rise. It eventually reached 102° F. The size and state of the tumor were certainly not favorably affected by the operation, while the patient's general condition became worse. The tumor grew softer, and on the seventeenth day after the operation a sudden and fatal hemorrhage into the pleural cavity occurred. An autopsy was not permitted. In this case there was not even an apparent improvement after the introduction of the wire. The speaker added that, if he had occasion to repeat the operation, he would use ordinary unpolished iron wire, because he believed that its roughness would be more likely to favor coagulation.

DR. BRIDDON asked if catgut introduced into an aneurism did not soon become softened, and float in the blood-current, so that there was danger of its being carried into the distal vessels.

DR. ABBE thought that it was desirable the artery leading from the sac should be plugged; doubtless this sometimes occurred.

DR. BRIDDON explained that he referred, not to the distal portion of the artery at its exit from the sac, but to the distal vessels. If only one vessel was occluded,

no harm would result, but all the efferent vessels might be plugged. The reader did not see how this accident could occur, as the catgut became so matted together that a portion of it could not escape from the sac unless the entire mass was dislodged.

Dr. Gerster referred to a case in which during the introduction of wire into an aneurism of the aortic arch, alarming symptoms occurred. It was found that a portion of the wire had become separated and was pushed downward through the lower opening of the sac until it rested upon the aortic valves.

Dr. Abbe said that a similar accident had occurred in Dr. Ransohoff's case. A piece of wire was pushed through the sac and came in contact with one of the valves, in consequence of which the patient had a severe attack of syncope during the operation. In reply to a question by the President, the reader admitted that the operation was not entirely devoid of risk, but then, he added, it must be remembered that the cases were all desperate ones.

Dr. Wyeth said that he had been disappointed to see that none of the speakers had drawn a comparison between the results of the method described by Dr. Abbe and distal ligation. All the cases mentioned by the reader had terminated fatally within three months at the longest, the average duration of life after the operation being about twenty-five days. The results of distal ligature had certainly been much better as regarded both the prolongation of life, and the cure of the aneurism. He cited in this connection the case of a patient in whom he had tied the right subclavian and carotid for an aneurism involving the sinus magnus of the aorta, which had advanced so far as to cause erosion of one rib. The patient was clearly in a hopeless condition and death was imminent. After the operation she was greatly improved, the tumor decreasing visibly, and lived for a year, dying eventually of acute diarrhœa. At the autopsy it was found that the sac was almost entirely filled with coagulated blood, the space that remained being no larger than an almond. He still had the specimen in his possession. The benefit to this patient was undoubted, and there was no reason to believe that the patient would ever have died in consequence of the aneurism.

CORRESPONDENCE.

A CASE OF SKIN-COLORING FROM THE CONTINUED USE OF NITRATE OF SILVER.

To the Editor of The Medical News,

Sir: Well-authenticated cases of skin-coloring by nitrate of silver are sufficiently rare to warrant a report of the following case:

Mrs. I., æt. forty, who lives in a neighboring town, came to me a few weeks since and said: "Doctor, I wish you would look at my face, and tell me whether you think that there is any probability that this discoloration could be removed by medicine. About two years ago I went to a doctor for treatment to correct a chronic diarrhœa, and he gave me a pill, directing me to take one three times daily, and to continue the medicine for some weeks. I have taken those pills almost every day since that time, never suspecting that this peculiar color of my face and hands was due to the continued use of the medicine. I know the medicine has produced this result, because I called on the doctor the other day, and he told me that I had colored my skin with those pills, and that he did not mean that I should use them for so long a time."

To ascertain the amount of silver she had taken in each pill, I asked for a copy of the prescription, and found the dose had been one-third of a grain. This amount, according to her own statement, she had taken almost continuously for about two years. The coloring of the skin is very marked, a dull, dark, metallic appearance in certain lights, and a bright lustre like burnished silver in others. No other case that I have ever seen would, without hearing the history, suggest at once the deposit of silver in the skin as this case does. Then, too, I had seen the lady on several occasions previous to the use of the medicine, and remember her as having had a singularly fair and transparent complexion. There are certainly few cases on record of this peculiar color of the skin, in which the cause can be so clearly traced to the long-continued use of nitrate of silver.

H. M. Shallenberger.

NEWS ITEMS.

MONTREAL.

(*From our Special Correspondent.*)

McGill University, Medical Faculty, New Graduates.—45 men received the M.D. C.M. degree at the last convention of McGill University, held March 29. There were also 45 men who passed the primary or second year examination in anatomy, physiology, histology, and chemistry. The total number of students in the medical faculty (exclusive of 30 veterinary) was 231. Of these 112 came from the Province of Ontario. Prof. Buller read the valedictory on behalf of the Faculty, and Dr. A. D. McDonald, of New Brunswick, on behalf of the graduating class.

Summer Session.—The summer session of the medical faculty of McGill University commences April 12, and continues three months. The courses are chiefly practical and clinical.

Toronto Medical Schools.—The medical schools of Toronto at present have no power to confer degrees. They merely prepare their men for the provincial examining board and the examinations of the Toronto and Victoria Universities. One of these schools is at present applying to the Legislature for power to grant the M.D. degree; it is opposed by the other. A suggestion is made that the two schools unite and one good school be formed. If this is done, another teaching body is sure to be formed to fill the void and give places to men who desire the prestige and glory (if such there be) of being connected with a medical school.

The Ontario Medical Council are endeavoring to get a bill through the Legislature giving them power to strike off from the register the name of any one guilty of unprofessional conduct.

Medical Legislation in Quebec.—The present session of the Legislature in Quebec promises to be a

short one and there is not much doubt that the consideration of the new medical act will be postponed. The change of government has altered the state of affairs considerably.

INVESTIGATION OF THE INSANE ASYLUMS.—A Royal Commission has been appointed to investigate the various lunatic asylums in the Province of Quebec. If the commission be properly composed of independent and unprejudiced men, the results may be of great value, and the iniquity of the "farming system" will be thoroughly exposed; but a very thorough investigation in the present state of political parties cannot be looked for.

THE NEW YORK BOARD OF HEALTH.—The Board of Health has amended the section of the Sanitary Code governing the removal of stable-manure, so that, in future, such material on any city premises must be baled or removed as soon as a cartload has accumulated, it being also provided that the baled manure shall not be allowed to become a nuisance. This change has been made at the request of the Medical Society of the County of New York, on the recommendation of its Committee on Hygiene.

RESIGNATION OF DR. FRANCIS MINOT.—Dr. Francis Minot has resigned his position as Visiting Physician at the Massachusetts General Hospital.

PRIZE OF $1000.—The Concentrated Produce Company, of London, offer the above prize for the best work upon the "Physiological Action of the Narcotic Principle of Hops." Competition is open until February, 1888.

DEFECTIVE SANITATION AS A CAUSE OF PUERPERAL DISEASE.—Under the above title Dr. W. S. Playfair, one of the leading physicians of London, has recently given an address in which he describes several cases of puerperal fever occurring in houses of the best class, and in which investigation showed that the patients had been exposed to the influences of sewer-air during and immediately after labor. This exposure was caused by leaky and defective fittings in the house plumbing, and in the address, as published in the *Lancet* of February 5, 1887, several diagrams are given, showing the relations of the bedrooms of the sick women to leaky soil-pipes, trapless bath wastes, etc.

Undoubtedly, a woman, immediately after the birth of a child, is specially susceptible to the action of the specific germs which tend to produce inflammation and abscesses, and either soil-pipe or sewer-air is specially liable to contain these germs.

We have had occasion before to comment on the special danger incurred by a woman who is confined in the autumn in a city house of the better class which has been unoccupied during the summer. All such houses are connected with either sewers or cesspools, and unless the traps be kept sealed with fluid, the germs above referred to are liable to enter the bath-rooms, and bedrooms connected with them, and to be found in the dust which settles in various parts of the room. If the house is unoccupied for any length of time the traps will become unsealed by evaporation. This danger can be avoided by filling the traps with glycerine, or by making arrangements to have water run in all the fixtures for a moment or two once every day.

If through ignorance or forgetfulness these precautions have been omitted, a thorough removal of all dust by cloths or sponges moistened with a solution of bichloride of mercury of the strength of 1 to 1000, with aëration of all rooms, is the best way to obtain security. Special care should be taken not to do any dry sweeping or dusting in the rooms until all surfaces have been rubbed with the solution above referred to, for unless this be done the dangerous dust will be merely whisked about and displaced, but not destroyed.—*Sanitary Engineer*, March 26, 1887.

THE HOSPITALS OF GERMANY.—In the Report of the German Exhibition in Hygiene, as noticed in the *British Medical Journal*, of March 5, 1887, DR. BOERNER describes hospitals in Germany as follows: Like the slaughter-houses and market at Berlin, the Friedrichshain Hospital, near that city, bears the palm. It consists of four pavilions for surgical, six for medical, and two for infectious cases, with administrative department offices, etc., all forming detached blocks. Each pavilion has its own operating room, bath room, apartments for attendants, kitchen for minor cookery, heating apparatus, etc., forming a complete and almost independent establishment. The blocks are of one story only, consisting of a general ward with twenty-eight beds, with offices at one end and the apartments at the other; over the latter is a small ward, entirely shut off from the larger one, containing a couple of beds for suspected cases, pending removal to the infectious blocks. The building is warmed by hot water pipes, and the ventilation, when the weather does not admit of perflation by the windows, is effected by warmed air. The system adopted is too complex for description in this place, but is highly ingenious and scientific, and is said to be most satisfactory in every way. Like most of the newer hospitals in Germany, it is outside of the city, and surrounded by park-like grounds. Next, perhaps, to that of Friedrichshain stands the Moabite, also at Berlin, which consists of thirty detached pavilions, each containing thirty beds. It is heated by steam, but natural ventilation only is employed; the ridge of the roof of each ward being formed of two valves, surmounted by a riding roof, also with a valve arrangement. Such a construction would, it seems to us, be admirably adapted to churches. More than thirty other hospitals are described and figured, and the report concludes with a summary or survey of the whole subject by Dr. Boerner. One-storied buildings, he says, are everywhere preferred for surgical, obstetric, and infectious cases, though two stories may be permitted in the treatment of ordinary medical cases. In some hospitals, separate blocks are appropriated to skin diseases, cancer, and ophthalmic cases. At Halle, the several infectious diseases are treated in distinct wards, ingeniously isolated one from the other, and separately ventilated; while, at Magdeburg, convalescents are removed to special blocks. Heating is almost everywhere effected by hot water or steam pipes, and ventilation generally by warmed air, at least in cold weather, but the systems adopted are very diverse. At Dresden, the flues can be laid open for cleaning throughout their entire length; and at Berlin University Hospital, at Halle, and elsewhere, they

are very accessible. At Hamburg alone, the floors are of stone, warmed by flues—a plan which has received but little favor in medical circles. In several hospitals the elaborate systems of combined heating and ventilation leave little to be desired, especially in winter, but in others they are far from successful. None, however, approaches that of the Moabite Hospital at Berlin, where flues and exhaust-shafts are dispensed with, and the warm air, abundantly supplied from below, finds free exit in the valvular arrangements of the ridge and riding roof. Nothing could be simpler; but the working is costly from the large amount of heat wasted, if that can be called waste which secures an unlimited renewal of the air.

WHO SHOULD VISIT CARLSBAD.—DR. TAYLOR, writing in answer to this question in the *New York Medical Journal* of April 2, 1887, describes suitable patients for Carlsbad "cure" as follows:

The typical patients for Carlsbad are, according to my experience and conviction, those with certain affections of the glandular system, especially of the liver and kidneys, and of the mucous membranes. Perhaps I might better say, all those affections depending on, or accompanied by, general capillary stases, terminable in some form of direct disintegration, but excluding cases, like tuberculosis, in which there are formative processes of a low order preceding disintegration.

At any rate, one important effect of the Carlsbad waters seems to be the thorough washing out of the capillaries. Hence the important service it renders the mucous membranes and glands when the nutritive fluids find difficulty in circulating through them.

PROVING THE SOUNDNESS OF AN EYE.—In a large factory in which were employed several hundred persons, one of the workmen, in wielding his hammer, carelessly allowed it to slip from his hand. It flew half way across the room, and struck a fellow-workman in the left eye. The man averred that his eye was blinded by the blow, although a careful examination failed to reveal an injury, there being not a scratch visible. He brought a suit in the courts for compensation for the loss of half of his eyesight, and refused all offers of compromise. Under the law, the owner of the factory was responsible for an injury resulting from an accident of this kind; and although he believed the man was shamming, and that the whole case was an attempt at swindling, he had about made up his mind that he would be compelled to pay the claim. The day of the trial arrived, and in open court an eminent oculist retained by the defence examined the alleged injured member, and gave his opinion that it was as good as the right eye. Upon the plaintiff's loud protest of his inability to see with his left eye, the oculist proved him a perjurer, and satisfied the court and jury of the falsity of his claim. And how do you suppose he did it? Why, simply by knowing that the colors green and red combined make black, He prepared a black card on which a few words were written with green ink. Then the plaintiff was ordered to put on a pair of spectacles with two different glasses, the one for the right eye being red and the one for the left eye consisting of ordinary glass. Then the card was handed him, and he was ordered to read the writing on it. This he did without hesitation, and the cheat was at once exposed. The sound right eye, fitted with the red glass, was unable to distinguish the green writing on the black surface of the card, while the left eye, which he pretended was sightless, was the one with which the reading had to be done.—*Pottery Gazette.*

HOW TO SCALD MILK.—Take a thick glass bottle provided with a rubber cork, fill it with milk nearly up to the neck, and place it uncorked in a kettle of water, which should then be gradually brought to the boil. When steam has commenced to escape from the bottle, cork it tightly, and continue the boiling for thirty-five or forty minutes, and the process will be complete. A bottle of milk thus prepared, it is said, will remain sweet a month if in a cool place.

The above method is suggested by that of PROF. SOXHLET (*Münch. med. Wochenschr.*) in which ten bottles like soda-water bottles, capable of being exposed to heat without cracking, are fitted into an open stand like a cruet stand, or an egg frame. The milk is first prepared by dilution and otherwise for administration, and the bottles are filled to within a short distance of the top. They are then closed with a rubber cork containing an aperture for the feeding tubes. This hole is to be left open. The frame containing the bottles is then placed in a metal pot of water for heating, immersed so as to be covered up to the neck. Heat is applied until the water boils when, after the milk and air in the bottles have expanded sufficiently, the holes are to be closed, glass rods being used for this purpose. The water is afterward kept boiling rapidly for thirty-five or forty minutes, when the stand with the bottles in it is to be lifted out to cool. Milk that has been treated in this way will keep, at the ordinary temperature of the room, for from three to four weeks without curdling. At the same time it is free from the inconvenient formation of skin on the surface, by which the feeding tubes become stopped up and made dirty. When once open, all of the bottle should be quickly used. Any portion not consumed at once should be thrown away.

The process of boiling articles to be preserved in an open vessel and sealing this vessel while steam is escaping, subsequently keeping up the heat for a time, will be familiar to every one who has canned fruit. The reason this method has not been more commonly applied to milk, is perhaps explained by the fact that curdling has been considered an inevitable property of milk. With the progress of the germ theories, however, it has been decided that even this every-day phenomenon depends upon contamination by these pests.

All have realized that stale milk will spoil that which is fresh, if mixed with it in ever so small a proportion. A tainted can or bottle has to be avoided for this reason. If the action of microörganisms produces the coagulation, the tainting of fresh by stale milk is easily understood.

What is effected by Prof. Soxhlet's process? In the first place, by boiling in an open vessel all air is expelled from the surface of the fluid, and thus, by depriving them of oxygen, the further growth of any germs already in the milk is prevented. The subsequent boiling of the sealed vessel is intended to destroy such retained germs.

The reason that milk thus preserved will not keep indefinitely, is entirely due to the imperfect execution of the process with the conditions at our command. It is improbable that thrusting a glass rod into the aperture of the cork will make the bottle completely air-tight; and, further, it is doubtful whether by simply placing the bottle in boiling water we can destroy all germs. Dr. Knapp considers repeated and prolonged exposure to moving steam necessary for perfect sterilization. Prepared in this way, he has in his laboratory flasks of milk which, after many months, are yet perfectly sweet.

But we cannot control the conveniences of a laboratory, and Prof. Soxhlet's method will be found a great improvement upon our usual procedures. It is hoped, that in view of the immense importance of the subject, and the very general acceptance which bacteriology has gained, the nurse will not be difficult to convince in this matter. It is an affair quite within our own province. Instead of "scalding milk" upon the back of the stove, in a tin vessel, one can adopt the bottle with a rubber cork. An ordinary soda-water bottle, if thoroughly cleansed, will answer the purpose. The perforated cork and glass rod are only necessary when the cork is intended to fit the feeding-bottle tube. The milk as it arrives may be immediately subjected to treatment, and afterward prepared as required. The previous dilution and the feeding out of the sterilized bottle, is a further refinement of the process, and a complicated arrangement, which the nurse could not introduce without the physician's order.—*The Nightingale*, March 15, 1887.

FEMALE MEDICAL STUDENTS ABROAD.—*Nature* says in a recent issue some interesting details respecting the number of women engaged in the study of medicine at certain European centres of professional education. At the University of Paris there are at present *in statu pupillari* in this faculty, no fewer than one hundred and eight women, thus distributed as to nationality: Russian, 83; English, 11; French, 7; American 3; Austrian, 2; Roumanian, 1; Turkish, 1. The greater proportion of Russian students is due to the closing of the Female Medical School, founded a short time ago in St. Petersburg, and it is assumed by M. Beclard, in his report to the Academical Council of Paris, that, owing to the fact that the preliminary studies of the Medical Faculty of the University having now been made the same for men and women alike, the number of the latter entering the school will undergo gradual but certain diminution. It is also noted that one lady, Miss Klumpe, has been elected this year to the post of interne in the Paris hospitals, she having secured the second place on the list of successful candidates. At the University of Upsila there are at present three ladies engaged in the study of medicine.—*Obstetric Gazette*, March, 1887.

PASTEURISM AND ITS RESULTS.—M. Bergé, an inhabitant of Bordeaux, who was treated for rabies by M. Pasteur six months ago, developed symptoms of the disease a few days ago. He was taken to the Saint André Hospital, where he died, after a terrible attack of rabies. Dr. Pitres refused to give his opinion upon this case until he had inoculated rabbits with a portion of the patient's spinal marrow.—*British Medical Journal*, March [illegible]

LITTLE PILLOWS.—Miss Brennan suggests in *The Nightingale* of March 15, 1887, that chaff, where it can be obtained, makes a good cushion for preventing pressure, and relieving weariness in the sick. These cushions or pillows are most convenient when about twelve inches long and eight inches broad. They must be both firm and soft. Cotton can be used in the absence of better material. In using cotton, pack it evenly, so as to avoid lumps. Cases or covers of old linen make these pillows particularly grateful where used next to the fevered skin.

Six such cushions are not too many for use about the subject of a tedious illness. Two, one upon each side under the hip-bones, take the place of a ring in averting bedsores, and contributing to the patient's comfort. They can be tucked under the back for a support when the patient is upon the side, answering better than the larger pillows for this purpose. One can be put under the head to save pressure upon the ear, which often becomes tender after being a long time in bed. If the head is to be a little lifted, it is easier for the patient to have one of these cushions slipped under, on top of the pillow, or tucked in so as to prop up the pillow, than to have the whole rearranged. One can be placed between the knees when the patient is upon the side; under the ankle when the heel has become sensitive to pressure. One can be tucked under the shoulder so as to lift the sharp angles of the emaciated body from the bed. In fine, the uses of these little pillows are numberless, and it would be a most acceptable charity if sewing circles and others interested, prepared them in quantities for hospital use. The emaciated patient, dying of consumption or cancer, would employ them with gratitude; also surgical cases, such as cases of fracture of the thigh and leg, which must maintain one position. The relief afforded in these cases by a little pillow, now here and now there, must be seen to be appreciated.

NOTES AND QUERIES.

[illegible] OPERATION.

To the Editor of THE MEDICAL NEWS.

Sir: In your issue of March 26th is published an abstract of a [illegible] by me [illegible] to the Philadelphia Obstetrical Society. The abstract was prepared by the Secretary, who omitted to state that the patient was under the care of Dr. E. J. Groome and others, of Bristol, Pa. It was at the request of Dr. Groome that Dr. Allis and myself proceeded to Bristol, on the seventh day of labor, and performed the operation. We did not attempt version as stated.

BRAIN SURGERY.

REMOVAL OF A LARGE SARCOMA, CAUSING HEMIANOPSIA, FROM THE OCCIPITAL LOBE.[1]

REPORTED BY W. R. BIRDSALL, M.D.,
PHYSICIAN TO THE DEPARTMENT OF NERVOUS DISEASES, MANHATTAN EYE AND EAR HOSPITAL,

AND

BY ROBERT F. WEIR, M.D.,
SURGEON TO THE NEW YORK HOSPITAL, ETC.

THE following history herewith reported conjointly by Dr. Robert F. Weir and myself, is that of a patient who during life presented left hemianopsia, optic neuritis, and certain disturbances in locomotion, from which the diagnosis of tumor of the right occipital lobe was made by several physicians, who also concurred in advising an operation attempting its removal, a fatal result appearing otherwise inevitable. As predicted, the tumor was found in the region described. It was removed in the manner to be stated by Dr. Weir, death resulting subsequently.

Male, æt. forty-two, a Hebrew, native of Poland, came under my observation, October 16, 1886. Until the summer of 1885 he had always been healthy, and denied ever having had any form of venereal disease, or injury to the head. In August, 1885, after a sea-bath, he observed, for the first time, unsteadiness of gait, and had a severe attack of vomiting. Soon after, diplopia for distance and increased awkwardness in walking were observed, and about the same time a disagreeable sensation, akin to numbness, in the right leg, hand, and shoulder, but not in the face. This, and the diplopia were transitory. Headache, usually frontal, was present occasionally, but was never severe. Vertigo, or tendency in a definite direction, was not noticed at this time. No other sensory, motor, or visceral symptoms appeared. He was observed to miss objects when told to pick them up. This was probably due to the diplopia.

He was seen by several physicians at this time, whose opinions are only known to me through "hearsay evidence." Suffice it to state that the diagnoses of locomotor ataxia, chronic spinal meningitis, multiple sclerosis, and dementia, were made by different ones, if they were correctly reported.

Oct. 7, 1885. The patient consulted Dr. E. C. Seguin, and was under his observation for two or three months. Dr. Seguin has kindly given me a summary of the notes of his examination and opinion at the time, which are of interest and importance, as he was the first to recognize in the patient the important localizing symptom—hemianopsia, and to make the correct diagnosis, and also to have seen him before and during the development of the optic neuritis, and at a recurrence of the diplopia.

"Examination: Eye muscles normal (no diplopia with red glass). Left pupil a trifle wider than right; both active; fundus normal. Has left lateral hemianopsia, vertical line passing a little to left of fixation point. No paresis of face, tongue, or limbs; no anæsthesia; patellar reflexes normal; walk is somewhat staggering, with decided tendency to right.

"*29th.* Diplopia has recurred; left externus weak; hemianopsia the same. No hemiopic pupillary reaction. Grasp: R., 42°; L., 30°.

"*Nov. 7.* Beginning neuro-retinitis discovered. This was verified ten days later by Dr. Gruening, who had already seen the patient for hemianopsia, and determined the extent of his visual field, as shown by the accompanying chart (Fig. 1). Both externi paretic (this passed away later). His wife states that drowsiness in the daytime has been a marked symptom from the first; also difficulty in rising from the chair."

Diagnosis made November, 1885: Tumor of mesial aspect of right occipital lobe, involving primarily the cuneus, extending downward toward the tentorium cerebelli, and perhaps also upward toward the paracentral lobule (leg centre). During this period the patient was treated with large and increasing doses of potassium iodide.

From January to July, 1886, he was under the care of the late Dr. McBride. During the early months of this period his diplopia disappeared and never returned. His gait improved somewhat, though he had two attacks in which he suddenly, while walking on the street, felt that he could proceed no further, and at the same time had a strong tendency toward the left, and actually staggered to the left so that his wife was obliged to support him. After resting a few minutes he was able to walk again. No other symptom of importance could be elicited from the patient or his wife covering this period, and Dr. McBride's notes have not been accessible to me. I understand that potassium iodide was his chief reliance for treatment. In July, patient took a trip to California, and returned in September, in about the same condition, from which time on his difficulty in rising, standing, and walking, together with drowsiness, rapidly increased.

At the time of my examination in October, 1886, left lateral hemianopsia was present. The ophthalmoscope revealed double optic neuritis, most marked in the left eye. Iris active to light and accommodation, the left pupil somewhat larger than the right; no diplopia; no ocular paresis evident. Smell, taste, hearing, and speech normal; no word deaf-

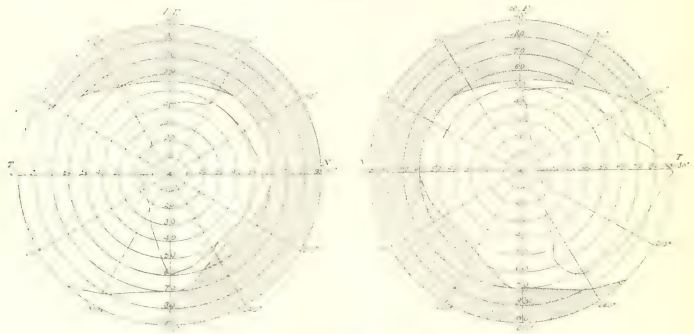
[1] Read before the New York Neurological Society, April 5, 1887.

ness or word blindness; no anæsthesia, analgesia, or disturbance of temperature sense in any part of body. No paresis in muscles of face, trunk, or extremities. No tremor of tongue, face, or extremities. In testing the patient for ataxia by touching finger to the nose with eyes closed, his movements were clumsy rather than truly ataxic, at times being accurate, at others wide of the mark; this was particularly noticeable with the left hand. A similar condition was noticed in the lower extremities, also more marked on the left. His gait was slow and uncertain. He was unable to find words to express the defects which he felt; denying that it was muscular weakness, numbness, pain, tremor, stiffness, or vertigo which caused his cautious yet awkward movements. Uncertainty of control seemed to be the best term for it. He referred this chiefly to the right hip, thigh, and knee. His patellar tendon reflexes were rather active and about equal. In walking, he would frequently hit objects to his left, probably on account of the limitation of the visual field upon that side, and when seated at the table he would turn to the left, bringing a half profile view of the body and face to a person directly opposite. This was, probably, also due to the same cause, being an attempt to bring his limited field fully to the front of the table. There was no tenderness to pressure or pain on percussion of any part of the head. Frequent expectoration of a viscid saliva was an increasing symptom during the last few months of his life.

Diagnosis.—The symptom left hemianopsia could only be accounted for by a destructive lesion in the neighborhood of the gyrus cuneus of the right occipital lobe (Fig. 2). The locomotory disturbances appeared to me to be due to the pressure effects of a tumor on structures below the tentorium, this implying a growth of considerable size.

No new symptoms developed, except that the right patellar tendon reflex became somewhat greater than the left. His disturbance of equilibrium continued to increase in a very irregular manner. On some days he would stand and walk quite well, on others he would suddenly stagger in walking, or fall over to one side when seated, usually forward and to the right, frequently with a twisting tendency of the body to the left. His steps became short, the feet being barely lifted from the floor, and with movements slow and cautious. Yet he could see well, reading the daily papers up to the last. On some days he was dull and listless, though never in a stupor; on others, was bright and talkative. His intellect was not impaired, and his family observed no change in his character or disposition. His sleep was natural, and hallucinations were never observed. He was extremely uncomfortable mentally, not from his visual defects, to which he attached little importance, but from his difficulties in locomotion, and disagreeable sensations.

Fig. 1



Visual field, O. S. (Fig. 1.)

Treatment with potassium iodide, which had been discontinued for some months, was resumed.

On February 17, 1887, he was seen by me with Dr. E. C. Seguin, who proposed an exploratory operation by trephining over the neighborhood of the cuneus, and, if found accessible, to remove the neoplasm. Dr. Weir was consulted, and after reviewing the data of the case consented to undertake the operation. The proposal was made to the patient, the dangers of the operation, and the dangers without it being fully stated. He frankly acknowledged that he would prefer the only chance, that of operation, to waiting for a fatal result by disease, as life was intolerable to him as he then was. He consented, therefore, to be operated upon.

It was considered advisable to have additional confirmations of the opinions expressed, and he was

subsequently seen by me with Dr. E. C. Spitzka, who, without knowing the diagnosis which had been made, after a review of the history and an examination of the case, arrived at the same diagnosis already reached by Dr. Seguin and myself. He also concurred in recommending operation. The same conclusions were reached by Dr. E. G. Janeway. Both he and Dr. Olcott, of Brooklyn, who had seen the patient when he was first affected, agreed upon the advisability of the operation as the only chance left in a case rapidly approaching a fatal issue. They saw him with me during the week before the operation, when pressure symptoms were rapidly increasing. The characteristic feature of all his symptoms, except the hemianopsia and the optic neuritis, was their vacillating and intermittent nature, even to the oculo-motor disturbance, indicating pressure effects, or circulatory disturbance, rather than direct destructive action of the tumor.

As the principal interest of the case lies in its surgical side, the remaining incidents will be reported by Dr. Weir.

The operation was performed March 9, 1887, at the New York Hospital, whither the patient had been sent for more perfect control, and on account of the better antiseptic conditions there present. A dose of Hunyadi water was administered to move the bowels the morning of the operation. The head was also shaved, and the scalp washed with green soap and water, and then with ether, and subsequently covered for several hours with carbolic cloths, wrung out of 1 : 30 solution and by gutta-percha tissue, all secured *in situ* by a bandage.

At 3 P. M., in the presence of Drs. Birdsall and Seguin as neurological counsel, and of Drs. Bull, Markoe, Abbe, Hamilton, C. T. Bull, Olcott, Starr, Dana, Sachs, and others, the operation was undertaken. The bregma, Rolanderic, and median lines having been marked out, and the occipital protuberance with some difficulty identified, and after the patient had had a hypodermatic injection of a quarter of a grain of morphia, and had been etherized, a U-shaped flap, three inches long and three wide, with base upward, was made under a carbolic spray 1 : 30, so as to straddle irregularly the median line in its lesser part (Fig. 3), the greater part being over the right posterior cerebral lobe. The bleeding was free from this, and from the thick periosteum, and also from the skull itself. At one inch above the occipital protuberance, and the same distance from the median line—in other words, beyond the limits of both the longitudinal and lateral sinuses—the circumference of a one inch trephine

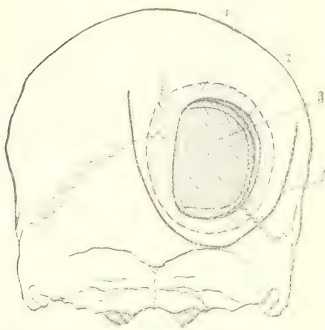
was placed, and the bone, which was rather thin,[1] cut through. A second button was removed immediately above the first, and the intervening bridge gnawed away by a rongeur forceps. The edge of this resulting aperture was further enlarged by taking away externally the cranium with the same

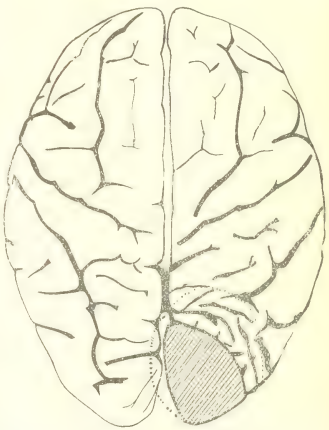


toward the median line.

instrument until an oval opening, measuring two and three-quarters by two and a quarter inches, was made. The dura mater, non-pulsating, rose tensely in the space, and was of a deeper hue than normal. This membrane was divided for two-thirds of the extent of the bone opening, its retained attachment being toward the median line, so as to avoid encroaching on the longitudinal sinus. As it was cut and turned back, the brain—or what was at first taken for brain, but was immediately recognized as the tumor—at once rose into the bony opening. It was of a purplish-red color, like kidney structure, and was covered over by a thin cellular tissue, with large veins ramifying in it. With a director and the edge of a spoon handle, a thin, yellowish layer of flattened out, expanded brain tissue was loosened from the tumor on its outer side (Fig. 4), and in this direction the enucleation was accomplished to a depth of nearly an inch. Similarly proceeding, but without seeing any further brain substance, the tumor was loosened easily on all sides. Additional room was obtained for manipulation by cutting away freely of the cranium externally, but all was insufficient to obtain access to the outlying edges and base of the growth. The tumor was therefore incised, and some of its softened, granular, and fatty-looking contents forced out. This somewhat diminished its size, and enabled the forefinger to be passed between

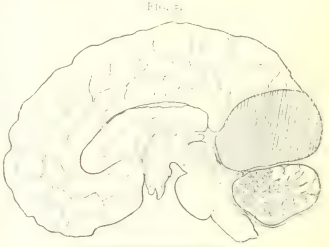
[1] This [illegible] has been noticed in [illegible] cases by W. Hale White, and is [illegible] due to the [illegible] intracranial pressure. Gaz. Hebd. [illegible]

the cranium and tumor, and by its aid the delicate cellular attachments that held the mass in place were felt to yield easily and enucleation became possible and the base finally reached. By now drawing the finger gently but firmly toward the cranial opening, the tumor was torn nearly completely in two, and its



Tumor seen from above. The heavy shading shows the presenting part of the tumor when the dural flap was raised. The dotted line gives the maximum size of the tumor on a deeper level.

outer half lifted out, and then the inner part, with the help of the finger-end and nail, separated from the falx and withdrawn.



Vertical section showing tumor.

Inspection of it showed that it had been entirely removed, and that its probable attachment was toward the posterior border of the falx. A good deal of

venous bleeding took place from the huge cavity left by the removal of the tumor. This was stopped with four sponges, and temporary pressure in this way resorted to. After a few minutes they were removed, and the cavity inspected by the light of a small electric lamp, which showed the immense compression of brain tissue that had taken place, the falx being crowded over toward the left beyond the median line, and the tentorium depressed to a horizontal line (Fig. 5). The tumor itself told the story better, for it, as was afterward learned, weighed one hundred and forty grammes, or five and a quarter ounces, and measured three and a quarter inches by two and three-quarters, and was two and a half inches thick (Fig. 6). Its greater circumference was eight and a half inches, and its lesser seven inches.

Fig. 6.

Tumor, seen from its base, actual size.

As the hollowed-out brain was lifted up by a retractor, two bleeding points were seen, one being in the region of the straight sinus, though not free enough for that vein, and probably belonging to the pedicle of the growth, and the other apparently was arterial, and possibly from a terminal branch of the posterior cerebral artery. The flow from each was readily checked by direct pressure, and it was determined, on consultation, to control them by packing this cavity with iodoform gauze of five per cent. strength. This was done not too strongly, it being assumed that the released brain would also contribute additional pressure, and the ends of the strips of gauze, subsequently, were, for easy extraction, allowed to emerge from the lower angle of the scalp wound. The dura mater was partly united over the gauze by several loose sutures (instead of being closely brought together, as had been done in another case), and the scalp wound closed with catgut sutures, a rubber drainage tube being introduced under the skin up to the skull opening. Over these, sublimated and iodoformed peat bags with sublimated loose compresses of gauze and absorbent cotton were secured with gauze bandages, and the patient put to bed.

The operation was well borne until the final enucleation took place, when the pulse decidedly fell, apparently from the loss of blood, which was then suddenly augmented, and which amounted, in the whole operation, to some ten or twelve ounces—the oozing being persistent from scalp and diploë, and difficult to control entirely by ligatures, clamps, and finger pressure. By bandaging the limbs and by the administration of whiskey subcutaneously his condition improved, and at the close of the surgical work he was in a fair condition. Pulse 132, but regular and of good volume. Slight diverging strabismus was, however, noticed in the left eye. He was ordered stimulants by the skin and rectum. Hot bottles, duly protected, were placed in the bed, and his head kept low, and enemata of whiskey, ℥j. and milk were ordered every two hours, with stimulants hypodermatically, if required.

The patient came out of the ether quickly, and showed considerable restlessness, moving all his limbs and having proper voice. By 7.30 P. M., two hours after the operation, the pulse had become slower, 120, but gradually weaker, and the dressings were stained with blood which had soaked through them at one point. This deterioration of the pulse continued until I saw him with Dr. Birdsall, at about 10 o'clock, when he was found very restless, and with an extremely weak pulse, and increasing marks of blood soakage in the dressings. The patient, however, was conscious, though somewhat dull. A salt transfusion (common salt, 93 grains, carb. sodæ, 16 grains, to one quart of filtered water, to which solution three per cent. of sugar is added, as suggested by Landerer[1]) of nearly two quarts was slowly injected into the median basilic vein at the right elbow with immediate improvement in the pulse and consciousness. He became also more quiet, and could answer questions, and put out his tongue fairly straight. He, however, showed signs of slight paralysis of the ocular branch of the seventh nerve on the left side, and also had decided divergent squint of the left eye. His hemianopsia was tested by Dr. Birdsall, and found to be unchanged.

As it was evident that part of his deterioration was due to a loss of blood, it became imperative to see if its continuance could be arrested. The dressings were, therefore, quickly removed, and the flaps of the scalp freed by cutting the stitches and raised, when blood was seen to escape in a small stream through the tube from the brain cavity. At first it was intended to remove the packing, and to secure the bleeding points by clamps; but his pulse, which had been raised by the transfusion, suddenly gave out, or so nearly so as to cause me to abandon the idea of resorting to any procedure of length, and to con-

[1] Centralbl. f. Chirurg., Beilage, S. 22, 1886.

tent myself, with Dr. Birdsall's approval, of further crowding in additional iodoform gauze toward the supposed source of hemorrhage. This was done, the flaps replaced,[1] but not resutured, and dressings reapplied. Symptoms of stupor quickly came on, and fearing lest the pressure might cause this, the dressings were loosened by cutting, but the patient's condition continued alarming, and his pulse became absent at the wrist, but was restored by a second transfusion. While the circulation was thus improved, the other symptoms were not similarly affected. The transfusion was kept up experimentally,[2] though the patient's condition was hopeless, and by its means the heart was kept acting till 2 o'clock, A. M., when he died.

No autopsy was allowed on account of religious scruples, but on removing the packing of iodoform after death, in the lower and anterior part of the cavity was seen quite a large collection of coagulated blood. The tumor was reported by the pathologist of the hospital, Dr. Peabody, to be a spindle-celled sarcoma with a few round cells sparsely found in it, and not to be very vascular.

Remarks by Dr. Weir.—There are several surgical points of interest in connection with the foregoing case that may be cursorily dwelt upon. The most important, because it largely entered into the cause of death, was the erroneous method adopted of arresting the hemorrhage. I had previously encountered lacerated vessels in the substance of the brain, the first time in 1882, and twice since then, and had secured them by ligature or by torsion, but none of these were at a greater depth than an inch from the surface. From the effect of sponge pressure, I was led to believe in the present case that the openings in the bloodvessels could be easily controlled, in which idea I was mistaken; the bleeding was also probably favored by the headlow position which his shocked condition induced me to direct. It would have been more correct perhaps to have tried cautiously to elevate his head, and in this way diminish the blood pressure. On a review of the case, however, I believe it would have been better surgery, and in another instance I would so act, to control the bleeding at once from vessels too deeply placed for a ligature, by means of clamp forceps which might protrude through an opening in the flap, and be removed after a period of twenty-four or forty-eight hours, as is done by Richolot's forceps in the vaginal removal of the uterus.

The size of the tumor, it is hardly necessary to state, exceeded anticipation, those usually encountered being smaller, although one has recently been reported by Horsley[3] which weighed four ounces, and produced hemiplegia and coma at the time of the operation. In the present operation, though the size of the skull opening was fully two and three-quarters by two and one-quarter inches, further bone room would have allowed an easier extraction of the growth. This enlargement was most desirable toward the median line, and would have been resorted to without much hesitation had the attempt at enucleation failed, for sundry experiences of injuries over the longitudinal and lateral sinuses,[1] together with those obtained in the cadaver, had convinced me that the skull over such a sinus can be removed without opening it, and without giving rise to any incontrollable bleeding or subsequent risk. In the rehearsals made for this particular case, which were conducted on the possibility of the growth projecting from the inner side of the cuneus against the falx, as was seen in one of Dr. Seguin's cases,[2] it was ascertained that after the bone had been gnawed away over the longitudinal sinus, that the dural flap, whose attached base was toward the sinus, could be so pulled upon as to expose fairly the median plane of the brain, aided by a spatula lightly pressing the latter outward. The same procedure could be applied to the inferior surface in respect to the lateral sinus, so as to expose to a considerable depth the tentorium. Such an examination was conducted in a patient whom I shall present in a few moments to illustrate another point, and in whom a frontal lobe was largely opened up to view for the relief of traumatic epilepsy of thirty-five years' duration. The lateral sinus, I may also remark, has been exposed by others beside myself, viz., by Schondorff, Lucae, and by Knapp, to a varying extent, without mishap.

The size of the skull opening, therefore, should be large, and Horsley advises the use of a two inch trephine, and makes two openings with this instrument, connecting them with a saw and cutting forceps. The apprehension that this large vacuity in the calvaria would subsequently expose the patient to the risk of easily inflicted cerebral injury, is not so great as imagined, and can be greatly lessened by resorting to the expedient first practised elsewhere in the body by Macewen, of employing bone grafts, and by sprinkling, as Horsley does, over the dura after its edges have been sewn together, the chopped-up disk of bone, which is to be carefully kept warm till the completion of the operation.

A further step in this direction has been made by Poncet,[3] who has shown that pieces one-third of an inch long and one-sixth of an inch wide, can be similarly used. I recently ventured, in the case of trephining for epilepsy which was just mentioned, after exposing the brain and dividing an adhesion extending between the pia and dura mater, through an opening nearly two and half by three inches, to replace, after closing the dural opening, the two one inch disks of bone which had been removed by the trephine. These had been wrapped in a towel wrung out of warm carbolic solution, which in its turn was then placed in a jar immersed in warm water. The operation lasted fully half an hour before the bones were put back. It is now

[illegible] No. 1.—2

seven weeks since the operation, and you will perceive, in the patient who is now submitted to your inspection, that the wound is all healed, save at one point over the eyebrow, where an opening was made recently downward through an obstructed suppurating frontal sinus to the nose, to permit drainage, and that no communication leads to the circles of bone, which can be felt above the point, solid, resisting, and painless. Later still, Dr. McBurney, at St. Luke's Hospital, has repeated this procedure, after an exploratory operation, for brain disease.[1] This plan, if corroborated by further experience, will relieve our minds of the objections held to large openings in the skull, and will facilitate greatly bolder surgical explorations.

Up to the present time the opening of the skull for the extraction of a contained tumor has been resorted to eight times, once by Bennett and Godlee in 1884,[2] three times by Horsley[3] in 1886—which with the one above narrated make up the five cases of removal of a tumor, the result of which in two of Horsley's is yet unknown, but presumably it was a successful one.[4] Of the three other cases, in one by Hirschfelder and Morse[5] in 1886, the tumor was found, but only a part was removed, the patient dying shortly afterward from suppurative encephalitis; in the two remaining cases no tumor was found, though in the one operated on by me and reported at length in The Medical News for March 5, 1887, at the post-mortem, two and a half months later, a tumor was found pressing upon the cerebellum and spinal cord. The last case is the one reported by Dr. G. M. Hammond, and made the subject of the paper succeeding this, to be read before this Society, in which the search nearly succeeded, as was shown afterward at an autopsy. The cause of the symptoms was the presence of three cysts adjacent one to another, and thought to be of hydatid origin.

For further remarks on the difficulty of relieving the pressure of a tumor of the brain by surgical treatment, I must refer you to the recent collection of 100 cerebral tumors by Dr. W. Hale White,[6] the excellence of which I have elsewhere[7] commented upon. I dare, however, to repeat as facts of weight gleaned from this paper, that multiple tumors are common and that only about ten per cent. of all kinds of growths, and only four per cent. of the sarcomatous tumors, could have been removed by operation, *even though a correct diagnosis could have been made.* Concerning the latter point the members of this Society can better judge of its difficulties than I can—but the art of cerebral localization is, thanks to the efforts of neurologists and physiologists, developing with great rapidity, and with such help surgery will be of more and more avail in rescuing patients otherwise condemned to paralysis and death.

[1] Had the present case permitted, the same course of replacing the trephined bone would have been followed.

[7] The Medical News, March 5, 1887.

Remarks by Dr. Birdsall.—In concluding, I may be allowed a few remarks concerning the tumor which was found. Owing to its large size, so much of the occipital lobe was compressed by it that the case is of little value for the purpose of determining the limitation of the visual area in the occipital lobe. The growth was a sarcoma, originating in the meningeal structures, and producing destruction of the cerebral tissues by pressure alone; no part of it was infiltrated into the cortex. The absence of severe headache in this case should be noted, as it is usually a prominent symptom of tumor involving the meninges.

That convolutions may be reduced to the thinness of paper by such a process is well known, and in this case the apex of the occipital lobe was literally crushed between the tumor and the cranium, while the more frontal portions were compressed in that direction. The parts beneath the tentorium were also compressed, as the symptoms during life led us to infer. The remarkable feature of cases with so large a tumor is not so much that they give rise to localization symptoms, as that they exhibit so few.

One of the most important lessons that the study of cerebral tumors teaches is that growths remaining limited to the meninges may attain a large size before disturbing the function of neighboring parts of the brain; frequently giving rise to less marked symptoms than very small growths, which infiltrate the cortex. In the deeper conducting tracts of the brain, where fibres run more in parallel courses, growths may attain large size without producing much irritation or destruction, by slowly pushing the fibres aside; this gradual expansion could not go on in the felt-like mass of fibres in the cortex without destructive action resulting. Thus, in one of my reported cases[1] a sarcoma the size of a hazelnut displaced the cortex of the arm area, producing spasm and paresis of the arm. While a similar growth under the same area of the opposite hemisphere, but a few lines deeper yet not reaching the cortex, gave rise to no symptoms whatever. Again, when tumors destroy by pressure, the softer mass of the growth may injure less than the rigid walls of bone against which the cerebral tissue is compressed; so that regions away from the tumor may give signs of impairment before those in contact with the tumor. These are some of the contingencies (and there are others) which will probably always constitute obstacles to the correct localization of tumors, as guides to surgical operations for their removal.

While we have much to hope for respecting a more complete knowledge of the functions of different cortical areas and subcortical tracts of the brain, increase in this class of facts for the practical purposes of brain surgery will be of little avail. Indeed, our knowledge of functional localization is already in excess of other factors in the problem. The degree of interference which neural tissue will sustain in different regions is an "unknown quantity" to such an extent that it renders further refinement of functional localization almost super-

[1] Arch. Med., vol. ix. No. 3, 1883.

fluous. And it may be said that from the standpoint of functional localization we are probably as well able to act as the surgeon's guide in the removal of cerebral growths as we ever shall be. This is not a designedly pessimistic statement, but rather, a hint that there will probably never be a better time than now for modern surgery to come to the front, and with her vastly improved methods, seek to eliminate to the extent possible the dangers and difficulties which yet attend operative work upon the human brain. Surely, the extreme fatality of intracranial neoplasms is a high warrant for taking an extreme surgical risk. The coöperation of neurological science and surgical art, in the present state of each, can hardly fail to build up an experience which will in some cases save life that would otherwise be lost.

A CASE OF NEPHROLITHOTOMY DURING THE FIFTH MONTH OF PREGNANCY.

BY LOUIS McLANE TIFFANY, M.D.,

ON February 16, 1887, I saw, with Drs. E. P. Irons and G. W. Miltenberger, Mrs. M., aged twenty-seven years. Her history showed that for several years she had suffered, at irregular intervals, with pain in the left loin, about the region of the kidney; occasionally the pain would shoot downward to the groin. She had been often under medical treatment. On two occasions when she applied to Dr. Irons, during the past few years, pus existed in the urine, but in small quantity; blood was never noticed in the urine.

Seven months ago the patient under consideration married, and two or three months later became pregnant. Two months ago, being three months pregnant, she slipped on the ice and fell forcibly in the sitting posture; great pain in the left side and loin was now complained of, and Dr. Irons was called to attend her; he found it necessary to give large doses of opium. Mrs. M. was no longer able to lie on the left side in bed, and found some relief when bending forward and to the left. A fortnight after the fall Mrs. M. attended a ball, wearing her wedding dress, which was extremely tight, thanks to pregnancy; during the whole evening she experienced much pain in the loin. Since the ball, a period of about seven weeks, pain in the region of the left kidney has been constant; hyperæsthesia has been marked, not only over the same region, but also over the left half of the abdomen; vomiting frequent, appetite capricious; urine ill-smelling, and contained much pus; temperature elevated, pulse increased in frequency; rest either night or day was only to be obtained by opiates.

Dr. Miltenberger now met Dr. Irons in consultation, and a day or two later I was added to the council. The diagnosis made prior to my seeing the patient was "pyelitis, probably from renal calculus." In this opinion I concurred, and operated at my first visit for the removal of the stone. Ether was employed as the anæsthetic, and the operation conducted under antisepsis. Under anæsthesia no tumor or hardening was made out in the loin. At my request, Dr. L. E. Neale examined the generative organs by touch, finding the pregnancy normal.

The usual incision below the last rib and parallel to it was made, the kidney exposed and examined; to sight and touch it was normal, moving freely with respiration. The fat and fascia around the kidney seemed healthy. I then exposed the kidney as far upward as possible and found an elastic spot just under the rib. I here entered a knife, dividing the kidney tissue and evacuated ill-smelling pus. This abscess was in the kidney substance, and my finger discovered no communication with the pelvis. I then explored the inside of the abscess carefully with a probe, which in a moment passed somewhat deeply and touched a stone. Along the probe was passed a director, in the groove of which I slid a pair of slender forceps, opened them widely tearing kidney substance and at once passed my finger into the pelvis, where it rested in contact with a stone.

The calculus was easily extracted. I passed a black woven bougie nearly its whole length down the ureter and greatly regretted that I had not an instrument long enough to be passed into the bladder, in order to test the possibility of such a manœuvre.

The wound was thoroughly irrigated with bichloride solution, 1:4000, a large drainage-tube inserted into the pelvis of the kidney, and an iodoform gauze dressing applied. Vomiting occurred but twice or three times after the operation; pain and hyperæsthesia ceased; convalescence was rapid, the thermometer marking 99° the evening of the third day after operation.

The drainage-tube was removed on the sixth day; four days later no urine passed from the wound in the back.

Three days after the removal of the drainage-tube the patient complained of pain along the course of the ureter, the temperature and pulse rose, there was hyperæsthesia over the left half of the abdomen, and vomiting; four days later the symptoms ameliorated and the patient's condition became normal. The discomfort, etc., was attributed to the passage of urine along the ureter after the removal of the tube from the kidney, carrying, of course, the "cleanings" of the upper part of the ureter.

A slight fever followed the removal of the drainage-tube from the kidney in the patient upon whom I did nephrolithotomy in 1885 (THE MEDICAL NEWS, May 23, 1885), but I did not deem the small elevation of temperature worthy of attention. With Mrs. M. the fever was accompanied by frequency of micturition and slight bladder tenesmus, as though there might be irritation where the ureter passes through the coats of the bladder. Inasmuch as pus was present in the urine, and no urine came through the loin, there was, of course, no obstruction in the passage from the kidney to the bladder; while the drainage-tube remained in the wound, there was little or no pus in the urine, showing a comparatively healthy right kidney.

At present the wound in the loin is healed, the urine contains pus in diminishing quantity, and the pregnancy progresses physiologically. The stone is

calcium oxalate and weighs thirty grains; it is shaped somewhat like a cocked hat.

I have entitled this case one of nephrolithotomy, according to Morris's definition, for there was no tumor in the loin even when searched for under anæsthesia. The abscess found was strictly within the kidney tissue, the kidney not being enlarged so as to be recognized as a tumor. The abscess, I believe, was formed in a Malpighian pyramid, the outlet of which was closed by the stone lodged in a calyx; my probe passed through the corresponding papilla, and grated against the obstruction at once.

This is, I think, the first reported case of nephrolithotomy being done upon a pregnant female. Gilmore's case was a nephrectomy. It is interesting to note that in no wise did the operation or the pregnancy interfere at all one with the other. The movements of the child were not noticed as more violent than natural, at the time of operation or subsequently, and there was nothing denoting disturbance of the reproductive system.

RHIGOLENE AND OIL AS A VEHICLE FOR SPRAYS.

PRELIMINARY NOTE.

By AUGUSTUS STABLER, M.D.,
OF LAWRENCE, MASS.

For several years past I have been alive to the fact that oil is far less irritating to the nose and throat than any mixture or combination that has water as a basis. This irritating quality is not wholly overcome by the addition of glycerine or honey to the water, and these substances greatly impede its passage through an atomizer. Water, moreover, is not a good basis for spray, for it collects and condenses too readily—hence the common observation that a spray of water does not pass the chink of the glottis except in very small amount. Olive oil or almond oil may be passed through an atomizer if the apparatus be of suitable construction, in perfect working order, and kept at a warm temperature, but they require a higher pressure of air and are very liable to gum the tube or orifice.

Less than a month ago, the idea occurred to me that perhaps a mixture of rhigolene with one of the expressed oils would be free from the above objections. This proved to be true. A mixture of two drachms of rhigolene (by measure) with six drachms of olive oil, or almond oil, requires no more pressure than water, to convert it into the finest and most permanent spray that I have ever seen issue from an atomizer.

If sprayed into the mouth, the lips being closed upon the tube and the patient being instructed to breathe very quietly through the nose, the spray issues like a cloud of smoke from each nostril, and is so permanent that I have observed the little globules of oil floating in the sunlight more than thirty minutes after the atomizer ceased. It is perfectly unirritating to the most sensitive tissues, and, indeed, seems in some cases to act as a mild local anæsthetic. This spray does not catch fire when directed into an uncovered lighted gas jet, and does not produce general anæsthesia, thus being free from the objections attending the use of pure rhigolene.

In connection with my friend, Mr. John H. Greer, an accomplished pharmacist of this city, I have made a large number of experiments for the purpose of determining what useful drugs are soluble in this mixture.

We find that the following are readily soluble:

Copaiba balsam, cubebæ ol., camphor, eucalyptol, iodine, iodol, iodoform, menthol (crystals), naphthalene (crystals), phenol (crystals), resorcine, sassafras ol., salol, terebinthinæ ol., thymol.

Resorcine is insoluble in rhigolene, but dissolves in olive oil to the amount of nearly five per cent. The mixture will hold about three per cent. in solution. Every oil that we have thus far tried seems to be readily miscible with the rhigolene and sweet oil, so that the entire list of essential oils and turpentines may, *a priori*, be added to the above list.

We have not found any astringent that will dissolve in olive oil or in the mixture containing it, but *todo-tannin* may be prepared as follows:

Take a saturated tincture of iodine and dissolve in it as much tannin as it will hold. This will mix with castor oil in any proportion, and the mixture may be thinned with rhigolene to the desired consistence. It makes a very handsome, clear red solution, and though slightly irritating, is not excessively so, and the irritation very rapidly subsides.

Cocaine is insoluble in the olive oil and rhigolene mixture, but like tannin makes a perfect solution if first dissolved in alcohol and then mixed with castor oil and rhigolene.

It has been my object in this paper merely to indicate the wide range of applicability of a mixture of rhigolene with oil as a basis of sprays, and leave a discussion of results to future papers, and perhaps to other observers whose clinical opportunities are greater than mine.

8 Charles Street, Lawrence, Mass.

THE STOMACH:

IMPORTANT POINTS IN ITS ANATOMY AND PHYSIOLOGY, AND THEIR APPLICATION IN PRACTICE.

By A. W. P. LEUF, M.D.,
OF PHILADELPHIA.

The object of this note is briefly to call attention to the normal position of the stomach, its tubular shape, some points in its physiology, and their bearing upon treatment. The paper is the outcome of five years of thought, some vivisections, post-mortem observations, and clinical experience. It is due to Dr. A. H. Buckmaster, of Brooklyn, to acknowledge that he was the one who, more than five years ago, called my attention to the tubular condition of the stomach, as shown in Kussmaul's *Physiology*.

The normal position of the stomach is almost vertical. This is best noticed along the lesser curvature, for the greater has a long roundabout curve, which, when the organ is distended, gives the impression of its being horizontal in position. The pylorus is relatively fixed; the cardiac orifice absolutely so. The lesser border connecting them is

also capable of but limited motion. The greater margin of the stomach is unattached and freely movable. During distention, the gastric pouch is forced mainly downward and forward, as well as upward and to the left. The lesser curvature is comparatively stationary, while the greater is the most movable portion of the organ. On this account the stomach, when viewed along the pyloric or visible half or third of its border, appears more horizontal in proportion as it becomes distended.

The cardiac pouch, instead of projecting to the left during distention, actually moves upward against the base of the lung, and with but a moderate inclination to the side.

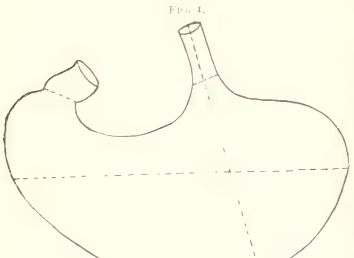
The pyloric orifice is variously situated in front of the upper lumbar vertebræ, and rarely more than two or three centimetres (about one inch) to the right of the median line. It is often on the median line, and occasionally all of the stomach lies wholly within the left abdominal cavity.

The heart normally projects further to the right than does the stomach.

The cardiac orifice is further from the cardiac end of the stomach and relatively nearer the pylorus than is generally supposed. It is almost midway between the two extremities of the organ, but nearer the cardiac end. The œsophagus, instead of entering the stomach at right angles, or nearly so, forms a very obtuse angle with the right or lesser border.

The shape of the stomach varies with the degree of distention. The same, of course, is true of the thickness of its walls. The shape of the stomach, as generally and erroneously pictured, is shown in Fig. 1, which is an outline of the organ shown in

FIG. 1.



Outline of stomach pictured in Gray's *Anatomy*, being an illustration of what is [illegible] shape [illegible] of the organ.

Gray's *Anatomy*. The normal shape and position of the distended organ are depicted in Fig. 2, while its changed appearance is shown in Fig. 3, when empty. This latter is quite appropriately called a "tubular stomach." Its calibre is very small, the mucous membrane deeply corrugated or folded, the muscular coat contracted and thickened, and the external measurement of the stomach not much greater than that of the jejunum when moderately distended. It is very thick, however, and quite round instead of flat. The cardiac end is not obliterated in the tubular condition, but appears jutting upward very much like the hump on Punch's back.

FIG. 2.

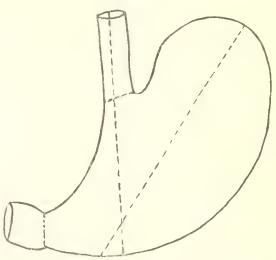


Diagram of a moderately distended stomach, showing its correct anatomical shape and position.

FIG. 3.

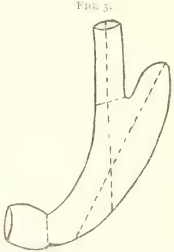

Diagram of an empty, contracted, so-called "tubular," stomach, showing that the position of the two orifices and lesser curvature remain undisturbed during the distensile changes of the viscus.

Why is the stomach ever tubular? is a proper question. Let us see. In an experience that includes the making of many hundreds of autopsies, especially in cases of sudden death, it has been my good fortune to see quite frequently the human stomach in tubular form. As well as I now remember, I cannot recall an instance in which a perfectly healthy stomach was not found to be tubular in a person having met with sudden death eight or nine hours after a meal. For instance, I have, on several occasions, been called to examine the bodies of apparently healthy laboring men, who, having eaten a supper between 6 and 7 P M., spent a quiet evening, and then went to bed, in which they died the next morning. These deaths were due to various causes, such as cerebral apoplexy, sudden heart failure, ruptured aneurism, fatal accidents, murder, and one

curious case of bronchial lymphadenoma, which choked the patient in less than an hour by compression of the trachea and primary bronchi. In all of these cases death occurred before there was time or opportunity to breakfast, and when nothing had been taken during the night. These stomachs were all empty and tubular—in other words, contracted, as we frequently find the colon, especially on the left side.

Gaseous distention of the stomach, though frequently found, is not the rule, nor is it strictly physiological. The firm contraction of every part of the alimentary tract, when empty, is normal and its distention with gas is abnormal.

These post-mortem experiences amply show that the tubular stomach is a fact in human beings, and exists when it has normally contracted upon the last remnant of its nutritive contents.

Vivisection upon dogs, cats, and rabbits, establishes the same facts with reference to them. It is only necessary, and especially in the dog, to wait a much longer time for the stomach to become empty and hence tubular. It may require as long a time as forty-eight hours. Care was taken not to disturb the natural process by vomiting the dogs or other animals. They all recovered and regained their liberty, or were sacrificed at the same time for some other end. Some full and partly full animal stomachs were also examined. The abdomen was opened and the walls elevated so that the stomach could readily be seen. The organ itself was not touched. A soft rubber catheter, connected with a small glass funnel, was introduced a short distance into the œsophagus, down which a little water was poured. In a moment, the stomach was seen to become slightly distended. This was followed by contraction, and the water poured into the duodenum. Its passage through the stomach occupied but a few seconds, and produced a double wave, one of distention, marking the entrance and passage of the first part of the water, and the other, one of contraction, indicating the progress of the latter portion of the liquid. In these instances the water was lukewarm; when cold or hot, it sometimes passed a little slower, and at other times not, and this difference seemed to be entirely due to the contraction of the pylorus caused by the rise in temperature. The difference in the time required to pass through, however, was not great.

When the water was passed in continually, and especially in large amount, the stomach became moderately distended, but the pylorus remained partly open, so that most of the water continued passing down, and could readily be seen by the waves and vermicular motion it generated in the gut.

In the full and partly full stomachs, the water, instead of mingling with the food, as we are so generally taught to believe, passed along rather quickly between it and the lesser curvature toward the pylorus and through this opening into and down the gut.

In this connection it is well to mention an observation made by Dr. Benjamin F. Westbrook. He noticed during the process of washing out stomachs that when he attempted to siphon the water back, it failed to return in several instances. In a letter to me, upon the subject, he writes as follows: ". . . . . instances in which, on attempting to wash the stomach, the water all mysteriously disappeared, and would not be coaxed, bullied, or cajoled into returning through the siphon—it had, evidently, passed directly onward into the duodenum; and the inference is that, in normal stomachs, with a proper normal tonicity, the tubular form was maintained during the period of rest, and that such stomachs would allow fluids to flow directly through into the duodenum."

The reason for this seems clear. The pylorus is decidedly reflex in its action. Unirritating fluids, or semifluids make no impression upon it, and they are allowed to pass through the partly open orifice. Solids and irritant fluids stimulate it to firm contraction and consequent occlusion. In exceptional cases, irritant bodies may have entered the stomach, which so stimulate its walls to contraction, that they are forced through either one or both of the two orifices. But this is an abnormal condition.

As soon as food, therefore, has been sufficiently reduced in consistence, it no longer affects the pylorus, and is permitted to pass through, and thus the stomach contents are diminished, except as far as the removal of some directly through the gastric wall. Water, being an unirritating liquid, readily passes through. It meets with no obstacle, therefore, in an empty stomach; does not linger there, but simply passes directly through to the gut. When the stomach is full of solid food the same is true, only that the water passes along the lesser border with a large bolus of food on one side, instead of gastric wall all around. When the stomach contents are largely fluid, the water most likely mingles with this, and is not allowed to pass so quickly.

These few facts are of daily use in practice. I will give reasons and clinical experience. Of course, a knowledge of the correct anatomical position of the stomach is of great value to the laparotomist having designs upon it. No more need be said on that score.

The experiments of several observers, whose names are well known to physiology, upon the secretion of gastric juice in the human stomach, through gastric fistulæ, have determined that this juice flows only periodically. It is called forth by the stimulus of food in direct contact with the gastric mucous membrane. Direct contact is required. The intervention of normal gastric mucus prevents or modifies the reflex action that would cause a copious outpouring of the gastric juice, for it prevents direct contact between the food and mucous membrane.

The flow of mucus is constant. It is especially noticeable during the intervals between the periods of digestion. Foreign bodies, when introduced within the empty stomach, whether it be distended with gas or not, increase the flow of mucus without causing the secretion of the digestive juice. Mucus is normally secreted during the night. Some of its liquid portions are absorbed. That which is left behind is, therefore, thick and tenacious.

This teaches us that a normal stomach in the morning contains a considerable quantity of thick,

tenacious mucus that is spread over, and adherent to its wall. It also shows that, if food enters at this time, it will become covered with a coating of the tenacious mucus, and the gastric wall being already so covered, there cannot be the requisite direct contact between the food and stomach. The mechanical stimulus of food, however, causes an increased flow of mucus. This renders that already present less tenacious and eventually permits the food to touch the mucous membrane and a flow of gastric juice, hitherto delayed, is the result; then digestion begins.

The tubular or contracted stomach with its puckered mucous lining, always normal in the morning before breakfast, is not in a condition to receive food. The mucus it contains interferes with prompt digestion and its firm contraction is an obstacle to the free circulation of blood through its vessels.

A goblet of water, taken before breakfast, does several things. 1st. It passes through the stomach into the small intestine in a continuous and uninterrupted flow. 2d. It partly distends the stomach, stretching, and, to some extent, obliterating the rugæ. 3d. It thins and washes out into the gut most of the tenacious mucus. 4th. It increases the fulness of the capillaries of the stomach, directly if the water is warm, and indirectly, in a reactionary way, if it is cold. 5th. It causes peristalsis of the whole alimentary tract, wakes it up (so to speak), and gives it a morning's exercise and washing.

The beneficial effects of a drink of water before breakfast may account for the desire for water at this time of the day, particularly on rising. How often we find that when we are very hungry (when our stomachs are tubular and filled with mucus) we want a drink before beginning to eat.

Moderately cold water taken into the stomach chills locally, it stimulates to contraction and produces a reaction. A warm, healthy glow succeeds the contraction due to the cold. The clean and hyperæmic mucous membrane is in excellent condition to receive food, which now can come in direct contact with the bare gastric wall. The reflexes act to best advantage. A copious flow of digestive juice is the result, and the food not being covered with mucus, digestion is easy and rapid, for it takes place under the most favorable conditions and in a minimum time.

Care must be taken not to give cold water when the circulation, either local or general, is so feeble as to make reaction improbable. We should not risk it in advanced age, nor in the feeble, whether old or young, nor should it be given in local troubles like chronic gastric catarrh. In these cases it is best to give warm, or hot, water. The addition of salt is very beneficial, both as regards taste and the effects of sodium chloride in preventing the formation of parapeptones, as was first shown by Dr. R. G. Eccles, of Brooklyn. Care must be taken not to give cold water when it will induce exaggerated reflexes, for instance, in the case of children, where it has been known to produce fatal intussusception of the bowel, or a severe "cold," or diarrhœa at all ages.

Dr. A. G. Kimberly, of Brooklyn, informs me that he has noticed and experienced the beneficial effects of sea-water digestion, and says that sea-going people are often in the habit of drinking sea-water before meals to improve the digestive process. "It not only does this, but sometimes entirely prevents nausea on rising," says Dr. Kimberly.

I have frequently ordered patients suffering with chronic gastric catarrh to drink a glass of warm or hot water before breakfast. It was followed by gratifying results; salt may be added with additional benefit in almost all instances. In fact, it is proper to give water before meals, as it washes out of the stomach the mucus that has accumulated since the preceding meal. When taken during meals its effects are good in washing out digested food and exposing new surfaces to be acted upon by the gastric juice.

The writer, at one time thinking it inconsistent with the laws of physiology to eat soup before meals and thus dilute the digestive fluid, took his after the usual meal. This did not agree nearly as well as taking it at the beginning. Such a time-honored custom, however, as eating soup at the beginning of a meal, could only have been so persistently adhered to because of its having been found by experience to be the most appropriate time. It does exactly what warm or hot water with the addition of salt does, and more, in that it is nutritive and excites the flow of gastric juice.

Pepsin is a catalytic body and a given quantity will work indefinitely provided the effects of its work are constantly removed so as to enable the catalytic body to come in contact with new material. This has again been recently shown by Dr. Eccles in his experiments on drugs and digestion.

Another fact worthy of note in this connection is that vomiting may very often be prevented by a patient remaining on the right side. This I would account for principally in two ways:

First. Pressure by the liver upon the stomach and duodenum is prevented.

Second. Gravity attracts the gastric contents to the pylorus, and the spleen, by its weight, tends to crowd the food out of the cardiac pouch toward the duodenal orifice. I do not mean to say that this postural treatment will always prevent emesis, but I do claim that it will often do so when nothing else will, especially in those cases where vomiting is due either to pressure from the liver, relaxation of the cardiac orifice, spasm of the pylorus, or general irritability of the stomach, or any or all of these combined. This fact has often been clinically confirmed.

The following is a brief summary of the major points I have sought to bring out in this note:

1. The position of the stomach is more nearly vertical than horizontal.

2. An empty stomach, if in good tone, is always tubular.

3. A tubular stomach should be the rule on rising.

4. Non-irritating liquids pass directly through the tubular stomach.

5. They do likewise if the stomach contains food, and in such cases pass along the lesser curvature.

6. The morning mucus contained in the stomach hinders or retards digestion.

7. Water drank before meals dilutes and washes out this mucus, stimulates the gastro-enteric tract to peristalsis, and causes hyperæmia of its lining membrane, thus greatly aiding digestion as well as elimination.

8. Cold water should be given to those who have the power to react, while warm or hot water must be administered to all others.

9. Salt added to the water is very beneficial in preventing the formation of unabsorbable parapeptone.

10. It is perfectly proper to drink water before, during, and after meals.

MEDICAL PROGRESS.

Renal Calculus treated by Solvents.—Dr. Ralfe exhibited at a meeting of the Medical Society of London, reported in the *British Medical Journal* of March 26, 1887, a specimen of renal calculus passed after six weeks solvent treatment. It was oat-shaped, eroded on the surface, and measured one-third of an inch in length, and weighed three and a half grains. It was composed chiefly of oxalate of lime, with a few crystals of uric acid scattered over the surface. The remedies employed were lithia and turpentine in a mixture and Dover's powder at night. The patient was directed to drink at least three pints of filtered rain-water daily. Under this treatment the urine, which at first had a specific gravity of 1.025, and contained much blood and pus, became clear, and the specific gravity fell to 1.014, while the attacks of colic diminished. Dr. Ralfe's method differed from that proposed by Sir William Roberts in that he did not seek to diminish the size of the calculus by chemical solvents, a doubtful and difficult process, but to check its growth by keeping the specific gravity of the urine low, and also by diminishing existing pyelitis. Dr. Ralfe observed that there were many calculi small enough to pass easily down a ureter, which were prevented doing so by the swollen condition of the orifice. He illustrated this by a specimen which had been retained for several days, owing to the patient suffering from gouty pyelitis, though the concretion was quite minute; as soon, however, as the pyelitis was relieved, the calculus slipped down easily. In addition to distilled water and turpentine, Dr. Ralfe spoke highly of benzoate of lithia or potash. The mode of treatment should be adopted in the following instances: 1, when the calculus was recently formed and still small, and was retained chiefly by the swollen condition of the mucous membrane of the kidney; 2, in recurrent calculi—the pisiform concretions of elderly people, in these cases the calculi passed before the administration of remedies were of the size of a pea, afterward they diminished to that of a mustard-seed (a specimen shown), or ceased altogether; 3, in cases when, owing to the obesity of the patient or his broken health, nephrolithotomy was not advisable. In these instances it might be hoped that the distilled water might at length lead to the disintegration of the calculus, as in a case reported by Dr. Ralfe (*Path. Soc. Trans.*, vol. xxxiii.), whilst the terebinthine remedies undoubtedly diminished the pyelitis and the tendency to colic.

Mr. B. Jessett said that larger calculi than those shown had often been passed without treatment, the benefit of which was rather in the increase of the amount of urinary flow. He doubted whether there is any really solvent action.

Dr. Ralfe said he attached the greatest importance to relieving the pyelitis. He certainly did think that a solvent action is produced under favorable circumstances.

The Prophylaxis of the Teeth.—Miller, of Berlin, in an article upon the care of the teeth, published in the *Therapeutische Monatshefte* for March, 1887, gives the following as useful formulæ:

℞.—Calcii carbon. præcip. . . ʒiij.
Cort. chin. fusc. . . . ʒij.
Conch. præparat. . . . ʒij.
Pulv. myrrh. . . . ʒ½.
Pulv. carophyll. . . . ʒiij.
Ol. cinnamoni . . . gtt. 10–15.
M. exact. f. pulv.

The following is recommended as an efficient tooth soap:

℞.—Magnesiæ carbon.,
Rhiz. irid. florent.,
Talci,
Sapo. medicat. . . . . āā grs. 75
Ol. menth. pip. . . . . gtt. 10.
Mucilag. gum. arab. . . . q. s.

After a series of experiments the writer has fixed upon the following mouth-wash as the best germicide and antiseptic for use in the mouth:

℞.—Acid. thymic . . . . grs. 4.
Acid. benzoic . . . . grs. 45.
Tinct. eucalypt. . . . ʒiij½.
Alcohol. absol. . . . ʒij.
Ol. gaultheriæ . . . . gtt. 25.
(Sive ol. menth. pip. . . . gtt. 20.)
M. D. S.

Of this liquid a teaspoonful should be put in a glass of water, and the mouth should be rinsed after each meal, and before retiring.

An Economical Method of Preparing Antiseptic Gauze.—Dr. Gerster, of New York, in an article in the *New York Medical Journal* of April 2, 1887, describes his method of preparing gauze as follows:

Gauze—that is, *cheese or tobacco cloth*, as it is called by the trade—can be procured at any dry-goods store for a trifling sum of money. Twenty-five yards of this fabric are divided into four equal parts. Each of these is folded eight times, and the piece is rolled up loosely and tied with a string. These four pieces of gauze are next made absorbent by freeing them of their oily contents adhering to the cotton from the gin or mill. They are put into a common wash-boiler, covered with water to which a pound of washing soda or saleratus was added, and boiled for an hour. After this they are rinsed in cold water for ten minutes to free them from the soda, are passed through a clothes-wringer and placed in a stone or glass jar or an enamelled kettle, filled with a corrosive sublimate lotion of 1 to 1000 strength, to remain therein for twenty-four hours. From this they

are passed through the wringer again, and hung up to dry over night when the air is freest from dust. The string put about each piece should not be removed until the time of drying, as it will keep the folds from getting disarranged. The dried pieces are ready for use, and will keep clean wrapped in a towel or put away in a jar.

Whenever dressings are used, suitably sized compresses, each having eight folds of cloth, can be cut out of the piece with a stout pair of sharp scissors.

Iodoformized gauze is made by sprinkling iodoform dust from a pepper-shaker uniformly over the moist compress, and rubbing it thoroughly into the meshes between the fingers.

An excellent substitute for gauze in an emergency is common cotton batting well soaked in a solution of corrosive sublimate (1 to 1000). The package of batting is unrolled in an ordinary manner, and cut into square pieces of desired size. Each of these is refolded into a small square and thoroughly kneaded in a washbasin filled with the mercuric lotion till complete saturation is evident. Well wrung out, each piece is unfolded again to its original shape and is ready for use.

Any clean textile fabric of cotton or linen, soaked in mercuric lotion, will be a good antiseptic dressing.

CONDURANGO IN CANCER OF THE STOMACH.—Fifteen years ago there was introduced from Brazil a remedy which was claimed to be a specific for cancer. Since then, as before, other remedies have been similarly vaunted, and none have stood the test of experience. The remedy in question was condurango bark, of which a trial was made at the Middlesex Hospital, the negative results being read before the Clinical Society by Messrs. Hulke and De Morgan (*Clin. Soc. Trans.*, vol. v.). In Germany almost the only favorable report came from Professor Friedreich, who related instances of its value in gastric cancer. Since then it has fallen much into disrepute, having been regarded as little better than a stomachic, and prescribed thus with advantage (Wilhem, *Year-book of Treatment*, 1886, p. 49) in cases of carcinoma and ulcer. But Dr. Riess, of Berlin, has just published (*Berl. klin. Wochensch.*, March 7th) some striking testimony to the value of the drug in gastric carcinoma, more conclusive than any that has hitherto appeared. It is noteworthy that he doubts whether its qualities as a stomachic are better than those of other drugs of that class, and that he has not found it efficacious in cases of cancer where the stomach is not primarily involved. (Messrs. Hulke and De Morgan's reports did not deal with gastric cancer.) It was in cases presenting the symptoms of cancer of the stomach (many with a tumor) that the best effects were noticed. In 105 such cases—*i. e.*, where gastric cancer was diagnosticated—treated at the General Hospital from 1878 to 1886, condurango was prescribed, and in no case, even in those in the last stage, without some effect. The drug was often given every hour—the total amount per diem reaching ten grammes of the decoction—and continued for long periods without ill effect. The appetite improved in a few days, vomiting and pain diminished, and eventually ceased, and the patient gained in weight. Whether life is actually prolonged is, of course, difficult to prove; but Riess quotes statistics which show that the cases treated with condurango, both the fatal ones and those discharged in improved health, remained much longer in hospital than those not treated by the drug. He even states that of sixty-four cases in which a palpable tumor was present, in seventeen it diminished in size, and in eight quite disappeared; and he details three cases of such disappearance of obvious tumors, which, subsequently dying, presented only cicatricial structure, with no trace of malignant disease. Obviously, before we can accept such cases as examples of the *cure* of cancer we must be certain that the original diagnosis was correct, and the same scepticism may be allowed respecting the whole series of cases. For cancer of the stomach may not only be latent, but may be simulated by non-malignant ulceration, as every physician knows. Dr. Riess fairly discusses this point, being quite alive to the objection. He claims, at least, that condurango has some local effect upon a diseased stomach, and considers that in all suspected cases it should be prescribed. It need hardly be pointed out that local action as here claimed is a different thing from specific action in cancer generally, which was sufficiently disproved by the observations at the Middlesex Hospital.—*Lancet*, March 19, 1887.

CONTAGION OF EPIDEMIC PAROTITIS.—ROTH reports three interesting observations upon this point. The first was the case of a woman brought to the hospital with parotitis; eighteen days after her arrival a neighboring patient became ill with the same disease; on the same day a patient outside the hospital, whom the hospital physician had visited after making his rounds, was attacked by parotitis.

In the hospital the bed was carefully disinfected after the patient suffering from parotitis had vacated it. A diphtheritic patient who was placed in this bed developed parotitis eighteen days afterward. Roth considers, therefore, eighteen days to be the period of incubation. *Fortschritte der Medicin*, February 15, 1887.

TREATMENT OF VOMITING ASSOCIATED WITH UTERINE CATARRH.—AUDHOUI describes the following treatment in the *Revue de Thérapeutique* of March 1, 1887.

The patient is to take at evening, before retiring, one of the following pills; the dose may be increased to two or more if needed:

℞.—Ext. nucis vom. . . . gr. 15.
Ext. belladonnæ,
Ext. opii . . . . . āā gr. 3.
M. div. in pil. 20 in num.

Twice daily, at 11 A.M. and 7 P.M. the patient should take 30–40 drops of tincture of ferric tartrate (French Pharmacopœia), a preparation corresponding to the tartrate of iron and potassium of the U. S. Pharmacopœia.

The patient should also take, morning and evening, a vaginal injection of Parthenium (Feverfew) as follows:

℞.—Matricaria Parthenium . . 35.
Boiling water . . . . 02.

An infusion should be made and to the liquid resulting a small quantity of cologne should be added; the temperature of the injection should be moderately high.

In addition, at least one full bath should be taken

weekly, to which should be added an alkaline salt as follows:

℞.—Bicarbonate of soda . . ℥ss.
Volatile oil of lavender,
Volatile oil of mint . . āā ♏15.

Dual Conception.—Dr. Nowlin, of Nashville, Tennessee, reports in the *Southern Practitioner*, for March, 1887, the case of a negro who gave birth to twins, one a pure African, with all the typical features of that race, and the other a very bright mulatto, exhibiting evident characteristics of the Caucasian race.

The mother was a pure black, with all the typical features of the African, as was also the husband. It became an interesting inquiry to account for the difference in color of the two children. Upon inquiry he ascertained from the mother that she had permitted intercourse with a white man living with her master, the day succeeding the same act with her husband.

There were two separate and distinct placentæ and cords, and the midwife, having no knowledge that such a state of affairs could exist, had caused inversion by pulling at the second cord. The womb was readily reduced by the usual manipulations.

Myxœdema in Berlin.—A case of myxœdema was exhibited at the Berlin Medical Society by Professor Senator, on February 9th. He remarked that this was only the second case observed in Berlin, the other having been reported by Dr. Reiss at the end of last year. Together with two cases described by Professor Erb, of Heidelberg, this case made the fourth reported in Germany.—*Lancet*, March 5, 1887.

Wound of Fœtus in Utero by Stab Wound of the Mother.—The patient was a woman in the eighth month of pregnancy, who was stabbed in the gluteal region. About two and one-half litres of sanguinolent fluid escaped, and on the following day she was delivered of a dead child. Dr. Guelliot found on the left parietal bone of the infant an incised wound traversing the bone. The mother was necessarily exposed to serious risk of peritonitis and hemorrhage, but, curiously enough, she recovered without the slightest untoward symptoms. The wound in the buttock was situated ten centimetres from the great trochanter. He reproduced this wound on the cadaver, and found that, under similar circumstances, the peritoneum is not injured, but that the sciatic nerve and gluteal artery were liable to damage. The patient in question had some anæsthesia, indicative of injury to the sciatic nerve. The liquid which escaped was probably liquor amnii.—*Archives of Gynecology*, February, 1887.

Treatment of Habitual Constipation in Children.—Dr. Day, at a recent meeting of the Harveian Society of London (*British Medical Journal*, March 26, 1887) read an interesting paper on this subject. Most cases, he said, are due to: 1, a sluggish state of the muscular coat of the intestine; 2, to a diminution of secretion from the mucous membrane, or the liver; 3, to improper diet. Children are variously affected by constipation; the bilious and plethoric require a daily evacuation, whilst the neurotic, eating similar food, may have no evacuation for days together without inconvenience. Prolonged constipation is apt to lead to disease of the cæcum, chronic inflammation and thickening of the intestinal walls, dilatation of the tube, and occasionally perforation of the gut. Highly nutritious food, by not furnishing any residuum to be carried into the intestine, is conducive to constipation. As regards treatment, it is important that the child should make a voluntary effort every morning. Enemata are valuable when the colon is torpid and the rectum blocked. Mellin's food is advocated as a valuable preparation in the constipation of young children. Among drugs, strychnine and belladonna are useful in imparting tone to the bowels, relieving spasm, and lessening flatulence. Nitric acid was recommended in some cases of chronic constipation. An occasional mercurial purgative is useful in constipation from deficient secretion of bile, but, if repeated too frequently, it causes lassitude, pallor of the face, softness of muscle, and irritability of temper. Saline aperients are sometimes useful in children of full habit. Massage is a powerful remedy in chronic constipation, and, if conducted by a competent person, the process is pleasant and soothing to the child. Attention to diet is of primary importance.

Menthol-lanoline Ointment.—

℞.—Mentholi . . . . . grs. 15.
Ol. olivarum . . . . . ♏ 8.
Lanolini . . . . . ad. ℥ss.
M. f. unguentum.
Sig.—Lanoline ointment for migraine.—*Therapeutische Monatshefte*, March, 1887.

Rupture of the Bladder.—A patient was admitted into St. Bartholomew's Hospital on the morning of March 1st with symptoms of a ruptured bladder, in consequence of a blow on the hypogastrium whilst the bladder was distended. The injury had been received the previous evening, and Mr. Walsham operated soon after admission. A large quantity of urine escaped from the peritoneal cavity when the abdomen was opened, and a rent about an inch and a half long was found in the bladder wall. Sutures were used, passing through the peritoneal and muscular coats only; the abdominal cavity was irrigated with a one per cent. solution of boracic acid, and the abdominal wound closed as after ovariotomy. The patient suffered very little shock, and passed his urine naturally without the aid of a catheter every four hours. There has been no sign of peritonitis, and he may be looked upon as convalescent.—*Lancet*, March 19, 1887.

Gastrotomy in Italy.—The *Gazetta degli Ospitali* of February 23d gives the details of a gastrotomy performed by Professor Loreta, of Bologna, on account of severe pain suffered by a young woman who had swallowed a large quantity of needles with the intention of committing suicide. On searching the stomach carefully with the hand, few needles could be found. The cause of the pain and suffering was explained by further search and extension of the abdominal incision to the right over the liver. The points of several needles were found protruding above the surface of the margin of the left lobe of the liver, and these were deemed to be the

source of the pain. Some were withdrawn, but others were so fragile that they broke off. The wound in the stomach and the abdominal parietes were accurately sutured, and the patient recovered without a bad symptom, entirely freed from her suffering.—*Lancet*, March 19, 1887.

OINTMENTS FROM THE FORMULARY OF THE NEW YORK HOSPITALS.—The following is prescribed by DR. W. F. MITTENDORF in recent burns and injuries of the eye; it should be applied every hour:

℞.—Cocaine hydrochloratis . . gr. 2.
Petrolati . . . . . ℥ss—M.

Petrolatum is commonly known as petroleum ointment, paraffin jelly, or vaseline. Also,

℞ [illegible] . . . . . ℥ss.
[illegible] 1
Petrolati . . . . . ℥ss.—M.

To be applied to the conjunctiva every evening in chronic phlyctenular ulcers.

The following is the formula for Hebra's (or Wilkinson's) compound sulphur ointment:

℞.—Calcii carbonat. præcip. . . 2 parts.
[illegible] . . . . . 3 "
Olei cadoni . . . . . 3 "
Saponis viridis . . . . . " "
Adipis . . . . . "

Melt the lard at gentle heat. Then add the green soap and incorporate the other ingredients, stirring until the ointment is cold.

THE USE OF MENTHOL.—The following semi-fluid will be found useful when it is desirable to apply menthol to the mucous membranes—a camel's-hair brush is the most convenient agent for its application:

℞.—Mentholi . . . . . grs. 15.
[illegible] . . . . . ℥ss.

and add

[illegible] . . . . . ℥iij.

M. f. unguent.

In burns, the following is an excellent application:

℞.—Menthol. . . . . grs. 75
Olei olivarum . . . . . ℥iij.
Aquæ [illegible] . . . . . ℥iij.

M. f. linimentum.

This preparation may be spread as a plaster, and as such may be most conveniently applied.

EXAMINATION OF THE HIP-JOINT THROUGH THE RECTUM.—Valuable information as to the condition of the acetabulum may be obtained by examination with the finger in the rectum. Three cases are reported by SCHMITZ in the *Centralblatt für Chirurgie*, in which this mode of examination proved useful. The patients were children from three to five years of age, in whom symptoms of coxalgia had existed for three, six, and twenty-one months respectively. In all three the thigh was slightly flexed, abducted, and rotated inward. In one case rectal palpation revealed a well-defined tumor in the acetabular region; in the others, abscesses varying in size from a hen's egg to a nut were detected. Movement of the femur during anæsthesia produced no friction. Resection was performed in all the cases, and the head of the femur, with its cartilage, was found to be quite healthy, but the acetabulum was extensively diseased. Schmitz recommends the use of this method of examination in all cases of suspected hip-disease.—*British Medical Journal*, March 19, 1886.

"BLACK DROPS" AND CARBOLIC ACID FOR PAINFUL EMESIS.—PECHOLIER has used the following prescription:

℞.—Acid. carbol. liquefact. . . . ℥ 2.
Aceti opii . . . . . ℥ 6.

Four drops in sweetened water three times daily, five or ten minutes before meals.—*Therapeutische Monatshefte*, March, 1887.

COCAINE IN ORAL SURGERY.—TELSCHOW is quoted as follows by the *Therapeutische Monatshefte* for March, 1887, in his observations with the use of cocaine:

The quantity used must depend upon the vigor of the patient; it will ordinarily vary from three-fifths to one and one-fifth grains; to the solution of cocaine Telschow adds a solution of carbolic acid 1 to 1000.

The injections should be made as nearly as possible to the nerve branches, as the effect is then more marked.

When possible, the injections should be made at the borders of the mucous membrane about the teeth; injections are also made in the distribution of the lingual, buccal, and labial nerves.

In about two minutes after the injections the mucous membrane may be separated from the teeth by a knife, and a 20 per cent. solution of cocaine may be pencilled between the teeth and the tissue separated.

In about three or five minutes the operation contemplated may be commenced; all pain may not be avoided, but no great suffering will ensue.

The unfavorable effects of cocaine were witnessed among nervous women and the aged only, and followed the use of large quantities; the best restoratives were five or six drops of amyl nitrite, and alcoholics.

THE USE OF CORROSIVE SUBLIMATE IN OBSTETRICS.—[illegible] at Budapesth, reports in the *Archiv für Gynäkologie*, vol. XXX., First Part, the following conclusions from his observations in the use of this antiseptic in the Budapesth Clinic:

1. For disinfecting the hands a sublimate solution, 1 to 1000, is recommended.

2. For disinfecting the genitals a solution of 1 to 2000.

3. For injections, vaginal and intrauterine, solutions of 1 to 4000 are used.

4. The vagina, and especially the uterine cavity, should be injected for the most positive indications only, either at the time of birth or during the puerperal period.

5. When such injections are given, not more than two quarts of sublimate solution should be used.

6. When injections are made to check hemorrhage, in a relaxed condition of the uterus, a solution, 1 to 8000, should be employed.

7. Sublimate should not be used when patients are anæmic, cachectic, or suffering from phthisis, affections of the kidneys, or of the digestive apparatus.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance . . . . . $5.00.

Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

Address, LEA BROTHERS & CO.,

Philadelphia.

SATURDAY, APRIL 16, 1887.

ASEPTIC OPHTHALMIC SURGERY.

The advent of antisepsis and its development into asepsis have not been revolutionary in ophthalmic surgery as in the surgery of other regions. As there was here the less need of such a reform in methods of surgical procedure, it has been less violent, less rapid, and, perhaps, less complete. The provisions of nature to guard the eyes—the lids, the tears with their increased flow after any injury of the organ, the outflow of aqueous humor when the globe is penetrated, the draining away of serum when the extensive lymph spaces of the orbit are opened—are all admirably adapted to prevent the infection of wounds, either accidental or operative. Then the small extent of the operative wounds, the accuracy and delicacy with which they must be made, and the need for absolutely keen, smooth edges to the knives and needles used, led to special care of instruments.

The accessibility of the eye to observation, and the importance of its function, fostered the most painstaking and accurate observation, and gave clinical experience a weight that enabled it to dominate practice. It has abundantly proved the value of cleanliness, and the dangers of introducing unnecessary instruments into the eyeball, or of operating on an eye in the presence of purulent disease of the conjunctiva or of the lachrymal passages. If sepsis was avoided, it mattered not what theories were held to give a *rationale* of the practice. So the methods of operative ophthalmic surgery of a generation ago, in many respects, conformed closely to the precepts of the wider aseptic surgery of to-day. A sense of this made the ophthalmic surgeon slow to adopt the antiseptic methods that seemed to constitute such a marked advance in many departments of surgery; but it must not keep him from carefully studying and profiting by the present practice of asepsis.

In the selecting of antiseptics for application to the eye, two things are to be borne in mind, viz., that the small surface for absorption prevents general poisoning by drugs like iodoform or mercuric chloride; and that the sensitiveness of the conjunctiva contraindicates the use of very irritant solutions. The latter condition has prevented the extension of any general favor to carbolic acid; though Gillet de Grandmont has recently advised, in the *Journal de Médecine* for January 23, 1887, the use of the carbolic spray during operations. He, however, does not direct it upon the eye, but uses it in the room for its effect on the instruments, the hands of the surgeon and the assistants, and, perhaps, though he does not mention it, on the minds of the patient's friends.

The most important use of the so-called antiseptics in ophthalmic surgery is that of solutions to cleanse the conjunctival sac, the lachrymal passages, and the lids and neighboring parts. For these purposes boric acid in saturated solution 1 to 25 has been used. It is entirely non-irritant, but a feeble antiseptic. Mercuric iodide 1 to 25,000 is also non-irritant, and a more reliable antiseptic. More powerful still is mercuric chloride in solution of 1 to 5000 or 1 to 2000. It is, however, slightly irritant, and, especially, in the stronger solution, should be used with care. Besides these solutions, iodoform may be applied in substance to the conjunctiva, always with the proviso that it be in the form of an impalpable powder, with no large, sharp crystals. For injection into the anterior chamber and lens capsule, for the washing out of adherent lens substance, in cataract extraction, after the method of McKeown and Wicherkiewitz; distilled water, and the boric acid and mercuric iodide solutions, have been used with equal freedom from irritation, and equal success.

To render them aseptic, such instruments as forceps, hooks, and specula, may be placed in a 3 per cent. solution of carbolic acid, although thoroughly efficient chemical disinfectants all seem to blunt the delicate cutting edges of knives and needles. The flame is out of the question, because it would spoil the temper of the metal; recourse must be had to boiling water or to mechanical means. If the surface of the metal be perfectly smooth, polished, and free from flaws and specks of rust, washing in pure water, and thorough rubbing with a clean towel, or piece of absorbent cotton, is all that is needed, culture experiments having indicated that polished metallic surfaces are thus rendered entirely aseptic. Of course, aseptic instruments must not touch hands, case-linings, or anything else which

may carry infection. In the after dressing of wounds, aseptic hands and materials, and the washing away of all discharges with one of the solutions above mentioned, are the essentials.

Special applications of antiseptics are seen in the use of corrosive sublimate, nitrate of silver, and sulphate of copper in purulent and granular conjunctivitis. Another treatment for panophthalmitis recently advised by Chibret in the *Archivd' Ophthalmol.* for Nov.–Dec. 1886, consists in extracting the lens by a flap operation, and washing out the globe by injecting a solution of mercuric chloride 1 to 2000. This solution is injected at intervals for a couple of days, during which time great improvement occurs, and the healing is rapid and satisfactory.

The destruction of noxious germs is accomplished by the use of the actual cautery in the treatment of sloughing corneal ulcers; and it is not improbable that the treatment of purulent conjunctivitis by hot fomentations, which has grown into favor, is but a form of antisepsis by heat. Freyer states in the *Transactions of the American Ophthalmological Society*, 1886, that, to be effective, the temperature of the water must be 140° Fahrenheit, or upward; and this is so near the thermal death-line of pathogenic bacteria, as determined by Sternberg and others, that it seems very likely that the good results of the treatment are due, in part at least, to the direct effect of heat on the pyogenetic organism.

Although the old-fashioned surgeon may claim that the doctrines of antisepsis and asepsis only affirm the correctness of methods of practice whose value has already been well demonstrated by clinical experience, no light shed upon the reason of their correctness can be regarded as superfluous. So long as the proper precautions are preserved, whether ignorantly or knowingly, they prove effective. But in ignorance of their true import, they are sure, sometime, and in some essential particular, to be neglected, to the misfortune of the patient. And a careful revision and supervision of all operative procedures about the eye, in the light of the bacterial theory of suppuration, may subtract from the catalogue of bad results those cases, which occasionally occur, of an eye going or sent to destruction after an, often trivial, operation in a healthy patient.

ICE OR HOT WATER IN UTERINE HEMORRHAGE?

IN a case of post-partum hemorrhage, which occurred recently at the Philadelphia Hospital, the resident physician, after vainly using vinegar and then introducing a lump of ice into the uterus, stopped the flow by intrauterine injections of hot water. The patient got on well until the third day, when septicæmia was manifested, the disease happily yielding to intrauterine injections of corrosive sublimate, as indeed most cases of this disorder in the puerperium do when these injections are properly used. But the question naturally arises as to the origin of this isolated and single case of the disease. Considering the very remarkable results obtained by Prudden, stated in a recent number of THE MEDICAL NEWS, as to the enormous number of living bacteria found in the ice supplied to many of the citizens of New York, often from twenty to fifty thousand in a cubic centimetre, and with the probability that some of the Philadelphia ice is no better, it does not seem impossible that the disease was conveyed to the patient by the ice which was put into the uterus.

The choice between ice and hot water for the arrest of post-partum hemorrhage ought not to be doubtful, for most assuredly the latter is more certain in its action, and does not produce the depression that follows the application of cold. But if it is possible that septic infection may be conveyed by the introduction of ice into the uterus, we have a still stronger argument against its employment.

REMOVAL OF AN INTRACRANIAL TUMOR.

IN the current number of THE MEDICAL NEWS BIRDSALL and WEIR record a remarkable case of removal of a huge sarcoma, which originated in the meninges, and by its pressure destroyed the occipital lobe. The case not only reflects great credit upon the diagnostic skill of Seguin, Birdsall, and Spitzka, thereby constituting another triumph of the art of cerebral localization, but it contains several lessons of importance to the practical surgeon, of which the most striking is the proper means of arresting hemorrhage.

In this particular instance the bleeding was so profuse as to give rise to marked general symptoms. For its arrest, Weir, with the consent of his surgical colleagues, plugged the large cavity with strips of iodoform gauze. As the loss of blood continued, the outer dressings were removed in about five hours after the completion of the operation, and more gauze was crowded in, but death ensued four hours later, as stated by Weir, from the erroneous method resorted to for controlling the hemorrhage. Hence, in a similar case of bleeding from vessels too deeply seated for ligature, he would employ clamp forceps.

PUDDING OR PRAISE.

CARLYLE once stated that the great majority of human beings lived either for pudding or for praise. Since physicians compose so large and important a class of the race, they, too, work either for the substantial things of this world, or for commendation, for pudding or for praise. As this is the period of the year when several hundred are added to the great army of doctors, possibly a word or two upon these topics may be useful, as they are timely, to the new recruits.

First of pudding. Medicine belongs to what have been called the bread and butter sciences; it is practised as a means of obtaining a livelihood, and while philanthropic motives ought ever to govern the physician's life, yet few would pursue it solely out of love for his fellow-man. The doctor is a workman, and ought to be worthy of his hire; that is, he ought to receive a just compensation for his services, and at the same time this compensation should not be so great as to do injury to the one paying it. We knew an eminent surgeon in one of our western cities, whose inquiry of patients coming from the country, was, "What is the size of your farm?" and the bill for his services corresponded. It is always better before doing an operation, to have a definite understanding as to the fee, remembering that we should never take advantage of the sufferings of fellow beings to extort from them in their distress an amount which will put them to serious inconvenience; some of them have to borrow the money to pay the bill, and possibly this may be so great that they painfully struggle all the rest of their days under the load of debt.

But it is not by operations that most doctors chiefly earn their living, but by visits and office consultations. It is important that the physician should keep careful and complete accounts of these multiplied services, and collect his bills at least twice a year; "many a mickle makes a muckle," and constant and assiduous attention to collecting the little amounts due for professional services may, after many years, make all the difference between pinching poverty and pecuniary comfort in old age. We have known so many physicians whose lives of labor did not bring them an old age of ease, and who died leaving their families in destitution, that we are urgent in pressing the importance of this attention to the pecuniary returns of business.

The young physician, eager for patients, may be tempted to take some upon the no cure no pay basis, but he will generally come to grief by pursuing this plan; the sort of patients that are thus caught are generally fickle in their attachments, and have no proper conception of the medical character and office. There are some who are incurable, no matter what therapeutic means are used; yet efforts to cure deserve a reward. One of our own guild, Sir Thomas Browne, has said: "There are not only diseases incurable in physick, but cases indissolvable in law, vices incorrigible in divinity." He further states in regard to charging the uncured patient: "Where I do him no good, methinks it is scarce honest gain, though I confess 'tis but the worthy salary of our well-intended endeavors." The last clause furnishes the ethical rule which should govern the physician in collecting his bill, even though his services have been in vain.

It is not unusual for physicians in villages and smaller towns to make their daily purchases from their clients and thus keep running accounts which are only settled at long intervals. Now this way often leads to misunderstandings, to disputes, and to final alienation between those who have been friends. It is better for the physician to pay cash for all that he buys.

However crowded the profession is, the young doctor may be assured that, with a fair amount of attainments, with common sense and wise conduct, he is sure to meet with success ultimately. He may have to wait, especially in cities and towns, for some years before income and outlay shall be equal, still longer before the former exceeds the latter; but if he spends those years in working, in attaining larger knowledge and greater fitness for professional duty, instead of indulging in frivolous amusements or gloomy forebodings, that success will be more certain and greater.

Very exaggerated notions are sometimes held, even by physicians, as to the income derived from medical practice, and we sometimes see not only in lay, but also in medical, journals, extravagant statements as to the annual amounts received by practitioners. *Dat Galenus opes* is only exceptionally true; for one hundred medical men whose income is counted by thousands, there are thousands whose income is within the hundreds. The fact is that for the majority of physicians a fair support is all their professional work yields them; they and their families nearly or quite consume all the pudding that society gives them.

Having devoted so much space to one aspect of the subject, we leave the other to a future occasion.

TREATMENT OF THE MORPHIA HABIT.

In *L'Encephale*, No. 2, 1887, Jennings gives his experience with a new plan of treatment of morphiomania. The amount of the narcotic is gradually reduced, and in the period of inquietude and distress various forms of dynamic stimulation are employed, such as faradization, massage, dry friction, mechanical vibration by Granville's percuteur; sounds, as music; and heat, by warm bath. By these means the insupportable craving is allayed, and the dose can be progressively diminished. The only medicines employed are bicarbonate of sodium, preparations of valerian and nitro-glycerine, which produce a glow and pleasant sensation, not unlike that of morphia. The essential features of this method have been employed with success by Weir Mitchell, who has found seclusion, careful nursing, massage, and electricity most valuable adjuncts in the treatment of this distressing and obstinate condition.

A MONUMENT TO RUSH

THE American Medical Association have undertaken a most commendable work in endeavoring to raise a fund for the erection of a monument to Rush, at Washington. It is by no means creditable to this city, for which he did so much, the reputation of which as a medical centre he may be said to have laid, and in the service of which he died, that no public memorial attests the gratitude of his fellow-citizens. The appeal is now made to the profession of the entire country to subscribe a sum of $40,000, the amount which it is estimated that a suitable statue will cost. The subscription rate has been fixed at one dollar, though voluntary donations of other sums will be received. Dr. John H. Musser, of Philadelphia, is the member of the committee for Pennsylvania, and entitled to receive subscriptions.

THE SATURDAY AND SUNDAY HOSPITAL FUND of New York City is a vital and growing charity. The amount of its collections this year, thus far reported, about $53,000, is 15 per cent. above the sum contributed in the year previous, when the total was $46,023.43. This betokens a growing popularity from year to year, and is in striking contrast with the situation of the like fund in London, in which there has been a falling off this year of $2500 from the sum of a year ago, when about $28,000 was the amount received.

MESSRS. PARKE, DAVIS & CO., have just issued an excellent lithographic portrait of Dr. Robert Koch, the eminent bacteriologist, and they kindly offer to mail a copy to any physician applying to them for it.

WE are informed that Dr. Wm. T. Lusk, of New York, successfully performed Cæsarean section at Bellevue Hospital, March 23d.

REVIEWS.

MANUAL OF OPERATIVE SURGERY. By JOSEPH D. BRYANT, M.D., Professor of Anatomy and Clinical Surgery and Associate Professor of Orthopedic Surgery in Bellevue Hospital Medical College, Visiting Surgeon to Bellevue Hospital, etc. 8vo. pp. 530; with about eight hundred illustrations. New York: D. Appleton & Co., 1887.

DR. BRYANT has succeeded in producing a very creditable work upon operative surgery, and one which can be consulted with pleasure and profit. It is less comprehensive than Smith's work, there being no chapters devoted to the diseases peculiar to women, those of the eye or ear, or fractures and dislocations, but the various operative procedures of general surgery are carefully described, and the indications for and against operations discussed in a judicious yet progressive manner. Amongst the methods of anæsthetization mentioned we note that by "intestinal etherization," which was prominently again brought to notice a few years ago; but as it is dangerous, a number of fatal cases having occurred, and possesses few or no advantages over the usual method of administering ether, the mention of the method is of more interest historically than practically.

The usual typical operations are carefully described, and the surgical anatomy involved is accurately explained and illustrated. Various innovations and new methods which have been introduced during the past few years have appropriate notice and discussion in the text, such as cerebral localization, operations upon the nerves, nerve suturing and nerve transplantation, suturing of tendons, transplantation of bone, etc. We note, in passing, that the author regards the old circular amputation as the method best adapted to the majority of cases.

It is needless to specify particularly any special portion of the work; all parts are excellent, fully up to date, judicious in regard to methods which are still on trial, with good anatomical cuts and explanations, and a lucid style.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 7, 1887.

THE PRESIDENT, A. JACOBI, M.D., IN THE CHAIR.

THE PROPER SELECTION OF ETHER OR CHLOROFORM AS AN ANÆSTHETIC.

THE PRESIDENT stated that Dr. Arpad G. Gerster was to have read a paper on this topic, but as he was temporarily detained, he would make a few remarks introductory of the subject. He said that he understood that the reason why Dr. Gerster had written his paper was because in several cases of death under chloroform occurring in this city, the attending surgeons only with difficulty escaped legal penalties, the ground being taken, by the authorities investigating the cause of death, that it is unjustifiable to administer chloroform for anæsthetic purposes. On the other hand, several deaths of patients under ether had been reported in our own hospitals. Dr. Gerster, therefore, thought it desirable that the Academy should give expression to its opinion whether it is always, and under all circumstances, advisable to give chloroform, or whether in certain conditions it is not preferable to ether, or, again, it is a matter of indifference which agent is employed.

DR. JACOBI then read a letter from Dr. Hermann Knapp, who was unable to be present, in which he briefly related his personal experience with the two anæsthetics. From 1860 to 1874 he used chloroform in some three thousand cases. While he had had no fatal results, in many instances the effects were very unpleasant, and he had met with a considerable number of critical cases. During this period about once a month he was obliged to resort to artificial respiration and other measures for the resuscitation of his patients. Since the year 1874 he had used ether exclusively, and

since then he had found no ground for complaint, and no contraindication for the administration of this agent.

It is his practice to employ what is known as the "choking plan" in giving it; though at the beginning of the anæsthetization the patient is allowed to have enough air to prevent the sensation of strangulation often complained of by those taking ether.

He had found that many operations performed by the ophthalmic surgeon could be completed during preliminary anæsthesia—that is, before profound narcosis is induced. In several hundred of his cases the average duration of the maintenance of the anæsthesia was one minute and thirty-seven seconds. He had met with no fatal cases, and only a very few in which there was any trouble whatever on account of the anæsthetic. The secondary effects, moreover, he had not found any more unpleasant than those of chloroform. On the whole, therefore, he regarded ether as an invaluable anæsthetic, and he looked upon it with especial favor, from the fact that now that he habitually employed it his mind was quite free from that anxiety as to the effect of the anæsthetic which, in the case of chloroform, he could never overcome.

DR. GERSTER said that in approaching this subject it is necessary to cast away all prejudice and consider it in a spirit of candid inquiry. In the first place it is to be borne in mind that both ether and chloroform are dangerous anæsthetics. Researches with the aid of the sphygmograph, demonstrating the effect upon the pulse, have shown, however, that chloroform is infinitely the more powerful agent of the two. Still, this fact does not afford ground for the universal condemnation of chloroform, though it renders greater caution necessary during any operation in which it is used. As soon as the patient recovers consciousness, however, all danger from the anæsthetic is past. This is not the case with ether, because the latter is liable to give rise to nephritis and catarrhal bronchitis. To sum the matter up, then, while chloroform is the more powerful agent, and consequently attended with more danger at the time of the operation, its use is not followed by the secondary affections of the lungs and kidneys which are apt to result from that of ether.

The statement frequently made by partisan zealots, that ether is always and under all circumstances safe, is not true. In hospital practice it is found that in a considerable number of patients, particularly those addicted to the use of alcohol, it is exceedingly difficult to produce profound anæsthesia with this agent, and in such cases, from the effect of the excessive and irritating mucous secretions excited, catarrhal or septic pneumonia is very apt to ensue. Admitting that, on the whole, ether is safer than chloroform, Dr. Gerster proceeded to speak of the manner of administration, and recommended as superior to any other that by means of Ormsby's inhaler. He then went on to say that ether is contraindicated in all affections impairing the renal functions, a circumstance, the credit for first pointing out which belonged to Dr. Emmet. In this connection he related a case in which herniotomy was performed. The operation lasted twenty-five minutes, and the patient recovered perfectly from anæsthesia. Albumen and hyaline casts were noticed in his urine, however, and in a short time he died from uræmia. Other similar cases had been noted by Drs. Emmet, Wesley M. Carpenter, Van Santvoord, Hunt, and Morris. An examination of the urine, he thought, should be made in every case before administering an anæsthetic, except where the urgency of the circumstances precluded this, and if Bright's disease is found to be present chloroform will be the safer agent to employ.

Ether is also contraindicated when in the aged or in young children, or generally in the feeble, there are catarrhal conditions of the air passages. He related the following cases in illustration:

Case I.—Mary B., aged forty-three. On the 20th of August last she was admitted to Mt. Sinai Hospital suffering from cancerous stricture of the rectum and chronic bronchitis. On August 23 lumbar colectomy was performed under ether. On the 23d she had a severe chill, followed by a temperature of 105°, and on the 24th pneumonia of the entire right lung was found to be present, and death ensued.

Case II.—Moses H., admitted to Mt. Sinai Hospital in January, 1887, with tubercular disease of the testes. On the 23d of the month castration was performed under ether. On the 24th the temperature went up to 106°, pneumonia of the right lung developed, and the patient died. In this case, as in the preceding, the wound made at the operation was found at the autopsy to be in a healthy condition.

Case III.—Stephen W., aged sixty-one years, admitted to Mt. Sinai Hospital in November, 1886, suffering from cancer of the rectum. Inguinal colotomy was performed under ether, and pneumonia of the left lung afterward developed.

In the year 1886 three cases of pneumonia occurred in the Mt. Sinai Hospital after the administration of ether; in two of which the patients died, while in the third recovery took place. There were also five cases of severe bronchitis arising under similar circumstances, reported during the year. Dr. Gerster said he had four more cases in his notes, but as in these operations were performed either upon the trachea, larynx, or lower jaw, it was possible that the entrance of blood into the air-passages might perhaps have caused the pulmonary disease; and he would not, therefore, insist upon them. As narcosis by ether is dangerous in young children suffering from affections of the air-passages, chloroform is always to be preferred under these circumstances, although in healthy young children ether is borne well.

The third class of patients in which chloroform is to be preferred is those who cannot be satisfactorily brought under the influence of ether. In the incomplete anæsthesia thus caused there is an amount of muscular rigidity remaining which constitutes an insuperable difficulty in quite a large class of cases. Not only loss of sensation, but total relaxation of all the voluntary muscles is indispensable in many operations. In spite of proper preliminary precautions, and the greatest amount of care in the administration of the anæsthetic, in 11 cases out of 125 at the Mt. Sinai Hospital, it was found impossible to produce with ether the complete anæsthesia required. In all these instances, however, a change to chloroform was followed by the happiest results. Five cases were related in illustration. To recapitulate, then, he said ether should not be used as an anæsthetic in any case—

(1) Where acute or chronic nephritis is present or is suspected to exist.

(2) Where there is any chronic pulmonary affection, especially in the old or feeble.

(3) Where ether will not produce the complete anæsthesia and relaxation indispensable for the successful performance of the operation in question. In such cases, if local anæsthesia cannot be secured by cocaine or the ether spray, chloroform should be resorted to.

Dr. Gerster then went on to say that while, in general, the administration of chloroform undoubtedly required greater caution than that of ether, there was only one contraindication against chloroform, viz., the presence of a fatty or weak heart. In the hands of a careless giver of anæsthetics, chloroform is, no doubt, more dangerous than ether. In those addicted to the habitual use of alcohol, normal anæsthesia with ether is generally impossible, as such patients usually drift from a state of violent excitement into alarming narcosis. Sometimes the same result is noticed, however, in the perfectly temperate, and a case in point was given. Bright's disease offers no contraindication to chloroform, and he said that in a number of cases in his own experience, two of which he related, he had used it with no bad results whatever in those suffering from pure kidney affections. In eight years' hospital experience he had met with only two cases in which pneumonia followed the administration of chloroform, and in both these the probable cause of the pulmonary trouble was the entrance of blood into the bronchi.

The existence of valvular disease of the heart, again, is not a contraindication to chloroform if there is satisfactory compensation by muscular hypertrophy, as indicated by the good quality and regularity of the pulse. In such cases, especially when there is a kidney complication, ether should not be used. On the other hand, if the heart is feeble from any cause, chloroform should never be used. In such cases ether is also dangerous, but to a less degree. In anæmia ether is, as a rule, safer.

Dr. Gerster next spoke of the special danger of chloroform in cases of marked nervous depression, and said it should never be used when the patient is in a state of fright. It is a fact that most of the deaths from its use are in cases of slight operations, and he thought this was explained by the dread of the operation or the anæsthetic. In severe operations the patient generally nerves himself for the ordeal, and hence there is less danger from this source. There are many cases of pallor and weak pulse, however, in which the condition is markedly improved by the anæsthetic, whether chloroform or ether.

On February 10, 1886, Thomas R., aged thirty-two years, consulted him at his office for a tumor of the maxilla. When an exploratory excision was proposed he became so much alarmed that he asked for chloroform, which was not given at this time. Five days later he was admitted to the hospital as a private patient, and on the 17th Dr. Gerster proceeded to operate on the tumor, which proved to be a glandular abscess. He subsequently learned that the patient expressed the conviction that he would never leave the operating-room alive. When two drachms of chloroform had been administered by means of Esmarch's mask, opisthotonos suddenly occurred, the pupils became dilated, and the abdominal muscles were found to be rigid. The pulse ceased and within a minute the man was dead. The most active efforts at resuscitation were carried on for forty-five minutes, but without avail. The heart was previously carefully examined; the pulse was found to be good up to the time of the operation, and the kidneys were normal. The experience gained in this case, Dr. Gerster said, led him to administer stimulants and a small dose of morphia prior to operating in all cases where the patient was not in a perfectly good condition, and he would now never give chloroform to any one who was the subject of deadly fear. In every instance in which it is feasible a careful physical examination should be made, and the probable prognosis duly announced to the patient or his friends before proceeding to employ this anæsthetic.

DR. R. F. WEIR said that there seemed to be a growing feeling in the minds of the profession that ether is not as safe an anæsthetic as we have for many years been supposing. The points presented by Dr. Gerster were certainly worthy of consideration; but he thought he had stated the case too strongly against ether. While in some instances kidney trouble might be aggravated by the administration of ether, he had seen too many cases of this kind in which it had been given with safety, since Emmet and Hunt, of Philadelphia, had so prominently called attention to the matter, to make him willing to acknowledge that the presence of nephritis was always a contraindication to the use of ether. He did think, however, that in such cases it should be given with special caution. Dr. Gerster was perfectly correct in his statement that there are a certain proportion of cases in which it is practically impossible to produce perfect anæsthesia with ether.

As to the production of pneumonia, while it is possible that it may sometimes be due to the local effect of the cold ether vapor, he is inclined to think that in many instances it is directly attributable to certain measures which have come into vogue since the introduction of antiseptics. The spray had formerly been instrumental in giving patients cold, and since this had been to a great extent abandoned, the practice of laying cloths wet with antiseptic solutions upon the surface of the body was, probably, sometimes the cause of pneumonia. This incautious exposure of the patient is to be avoided, and he thought general surgeons should take a lesson in this respect from gynecologists, who, it is noticeable, are always very careful to protect the patient from all such influences. Some time since, he had called the attention of the house staff of the New York Hospital to the matter, directing warm and dry towels to be placed next the body, except just at the seat of operation, and since this precaution has been taken, he has met with less trouble of the kind in question.

Personally, he did not think the bad consequences arising from the use of ether are as frequent as had been represented in the paper; but, after all, Dr. Gerster had admitted very frankly that chloroform is much more dangerous than ether at the time of administration. The question then arises—Is the danger which follows the use of ether greater or less than that which attends that of chloroform during an operation? Dr. Weir answered this by saying that, as for himself, he would prefer to take ether rather than chloroform, if an anæsthetic was required, even if he were the subject of kidney trouble.

The deaths from chloroform from 1873 to 1879, collected by a single journal, the London *Lancet*, amounted to 92; while those from ether, from 1873 to 1880, as collected by Dr. Roberts, of Philadelphia, amounted to only 18. This showing, he thought, corroborated the position which he desired to take before the Academy in the present discussion.

He believed it would be of interest to present the statistics of such a venerable and well-known institution as the New York Hospital, and he had, therefore, taken the trouble to look up the records. In this hospital ether and chloroform had been used since 1847. Shortly after this date, however, a number of mishaps occurred in connection with chloroform, and since 1850 ether alone has been employed. From 1847 to 1870, when the old buildings on Broadway were given up, some 7700 operations were performed under ether, and in only 3 of these did death result from the anæsthetic. One of the fatal cases has been published by the late Dr. Allen, but the other two had never been placed on public record. Dr. Allen's case was one of operation upon the lower jaw, and the other two were both of hernia. One of them occurred while Dr. Weir was house-surgeon (1859–60), and the patient had a double scrotal hernia. No cause for death could be found at the autopsy, and it seemed probable that this was attributable to pressure upon the diaphragm, or, possibly, the heart itself, from the forcing of such a large mass of intestines into the abdominal cavity. The other case referred to, occurred in the practice of Dr. Markoe, and was one of strangulated hernia in a fat, old man, who was in a very low condition at the time.

From 1876, when the new hospital buildings were opened, to 1886, 2287 operations were performed under ether, with one death from the anæsthetic. The case was believed to be one of rupture of the bladder, and when the autopsy was made, a portion of undigested food was found to have lodged in the larynx. In the House of Relief, from 1876 to 1886, 802 operations were performed under ether, with one death from the anæsthetic. At the autopsy in this case there were found atheroma of the aorta and a tuberculous condition of the lungs. It would thus be seen that at the New York Hospital there had been only 5 cases of death from ether in nearly 11,000 operations.

Though he appreciated the fact, as he had already intimated, that there were a great many cases in which the patients "take ether badly," as it is generally expressed, he could not remember a single case in which the operation had to be postponed on this account. By summoning aid to assist in holding the patient, he had always been able to get along without resorting to chloroform. Until an anæsthetic free from all objections was discovered, he thought, therefore, we could go on with the use of sulphuric ether with a fair amount of satisfaction.

Dr. Lewis A. Sayre stated that he was well aware that the views which he entertained on this subject were entirely different from those held by the great majority of the profession in this country; but, in spite of opposition, he had for many years continued to hold them with ever-increasing confidence. He preferred chloroform because it is agreeable to take, speedy in action, excites no spasmodic rigidity, and is not followed by the sad effects which are sometimes noticed in the case of ether. It is the usual practice to allow the patient to have plenty of fresh air with the chloroform, thus permitting its antidote to act against the anæsthetic. In consequence, a much larger quantity of chloroform is taken into the system than is required if the proper manner of administering it were employed. The method of pouring an unmeasured quantity of an anæsthetic into a cone or inhaler, and then every few minutes adding one or two ounces more, he thought entirely wrong. We do not, he said, use arsenic, strychnia, morphia, or other potent agents, in this way. Chloroform and ether are both powerful drugs, and he thought, therefore, that they should be used with the same caution as any other potent agent.

Dr. Sayre then exhibited the inhaler, a modification of Lente's which he had used exclusively for many years. By means of a rubber attachment devised by his son, the late Dr. Charles H. Sayre, it can be made to fit accurately to any face, and it is thus possible to exclude all air from the patient except that permeated with the anæsthetic. Ten, twenty, or thirty drops of chloroform, poured in upon the sponge with which the cup is provided will almost invariably produce anæsthesia, and if from any cause the heart should show signs of weakness or cease to act, a few expirations caused by artificial respiration will be sufficient to get rid of the entire amount of chloroform, and thus save the patient. As he had stated, he had practised this method for many years, and in proof of this he read an extract from the Proceedings of the International Medical Congress in 1876 (page 574), giving a report of his remarks on this subject in connection with a case of exsection of the hip, which he performed at the Pennsylvania Hospital in the presence of a number of distinguished foreign and American surgeons. When chloroform is freely mixed with air, anæsthesia is not produced for a long time, and great injury is liable to result from the violent muscular exertion made by the patient, especially when there is disease of the joints present. In addition, if in any case in which chloroform is given in this way trouble should arise from the anæsthetic, a fatal result will probably ensue on account of the larger quantity of the drug which it had been necessary to administer before anæsthesia was produced.

Dr. W. Gill Wylie said that until very recently he had never had a death from anæsthetics in his practice occurring during or near an operation; but within the last two months he had lost two patients, both of whose deaths he attributed to ether. In general, he approved of the opinions expressed by Dr. Gerster in the paper; although he thought that he was somewhat too strongly in favor of chloroform. On the whole, he would therefore say, he preferred ether, as a rule; but there are many cases in which it is advisable to use chloroform. There could be no doubt that ether was often used too carelessly, in New York, as well as in other places, and this is probably due to the prevalent impression that there is little danger to be apprehended from this agent. Some years ago, when a new interne in Bellevue Hospital was administering ether to a patient, he saw the latter suddenly cease to breathe. The man was apparently dead, and it was only with great difficulty that he was resuscitated. When spoken to in reference to the accident, the interne remarked, that he "didn't know that a person could be killed with ether."

Like most other members of the profession in New York, he had used ether almost exclusively in surgical cases, though he had always employed chloroform in his obstetrical practice; and until two months ago had never met with any trouble from ether. At that time he operated on a patient with a large abdominal tumor, using ether as an anæsthetic. The urine had been previously examined, and found to contain no albumen. Not long after the operation the pulse went up to 140°, afterward it never fell much below this; the patient dying of Bright's disease. At the autopsy it was found that nothing whatever was wrong with the abdominal wound. It was a case of chronic interstitial nephritis, in which acute nephritis was suddenly developed after the operation. The liver and heart were also found to be somewhat diseased. In this instance he thought that the administration of chloroform would not have been followed by the disastrous results which were met with after the use of ether.

There was another point which he thought was of some value. He had found that patients who have taken ether more than once are apt to acquire a certain tolerance of the drug, so that it is often very difficult to get them under its influence. He had an opportunity of noticing this a number of times at the Woman's Hospital, when patients with affections like vesico-vaginal fistula had to undergo several successive operations.

The other fatal case to which he had alluded was one in which he was called upon very suddenly to operate in a case of strangulated umbilical hernia. The patient, a female, appeared to be in good condition. It was true that she had been vomiting for quite a long time, but the vomit was not stercoraceous in character. She was very stout, and as she reminded him quite strongly of the other patient who died, he at first refused to give ether, and advised chloroform. As the attending physician objected to this, however, he finally consented to use ether, and accordingly this anæsthetic was very carefully administered. Presently, however, the patient became cyanotic, and nearly died on the table. She was temporarily revived, but died about an hour afterward, apparently from suffocation. In another case of this kind he said he would employ cocaine as the anæsthetic, as he had come to the conclusion that in very fat women ether is dangerous. The lung capacity is so small that any extra strain upon the lungs will be apt to prove fatal. In such cases the presence of a very little fluid in the trachea may be attended with grave consequences. In conclusion, he said that he had to confess that three or four years ago he was more or less prejudiced in favor of ether in almost all cases. He had now, however, modified his views somewhat. In general, he preferred ether, but if there were any trouble about the lungs or kidneys he would use chloroform. As a rule, he would use ether in surgery, and chloroform in obstetrics.

Dr. Weir remarked that it had been shown that operations for hernia, and upon the peritoneum in general, had of themselves a direct effect upon the kidneys, independent of the anæsthetic used for the operation.

Dr. John H. Wyeth said that he had formulated his views as to the cases in which the use of chloroform is justified as follows:

1. In children under six years of age, where it is less apt to cause an accumulation of mucus in the trachea and bronchi than ether. Its more rapid and less irritating action renders it preferable in this class of cases.

2. In women in childbirth, where the recumbent position is imperative.

3. In an emergency where ether cannot be obtained.

4. In a patient who has previously been in ether narcosis, in whom dangerous symptoms were caused by the ether.

5. In an emergency where it becomes necessary to perform an operation within two or three hours after the ingestion of solid food.

6. In some exceptional cases of laryngeal or tracheal stenosis.

In regard to the existence of nephritis, he would not consider this a positive contraindication. When this is present, however, he would always proceed with unusual caution, and if any trouble should arise he would change to chloroform. He entirely agreed, in the main, with what Drs. Knapp and Weir had said. In his own practice, he said, he had used ether exclusively, except in the classes of cases mentioned, and although his experience had been quite extensive, he had not met with a single case of trouble from it. He had never seen such cases as those referred to by Dr. Gerster. Some of the operations mentioned by him in which ether was followed by such disastrous results were very long and tedious, lasting from three to six hours, and in individuals suffering from cancer; so that the fatal termination was not a matter of surprise. In his work on surgery, Professor Agnew has collected statistics of 195 deaths from chloroform and only 6 from ether, from 1859 to 1872: a proportion of 65 to 1. Moreover, in three of the deaths attributed to ether, a mixture of ether and chloroform was employed. As to the good results which Dr. Sayre had met with from chloroform, he believed that his experience with it had been to a large extent confined to young children and parturient women.

Dr. Robert Abbe said that he had seen but one death from ether. It was a case of tetanus in which the late Dr. Little was performing amputation of the leg, and the patient died, apparently from spasm of the heart, before the operation was completed. It seemed to him that ether is preferable to chloroform from the fact that the two principal dangers which have been urged as objections against ether, viz., the possible occurrence of acute pneumonia and acute nephritis, are to a large extent under the control of the physician, while the dangers incident to chloroform are entirely beyond control. When asphyxia occurs during ether narcosis, the use of artificial respiration and other appropriate measures is usually successful in restoring the patient; and if acute nephritis occurs after the employment of this anæsthetic, it is, in his opinion, amenable to treatment by means of such agents as sinapisms, digitalis, acetate of potassium, and possibly opium. He had never seen a case of this kind in which death resulted. With regard to acute bronchitis and pneumonia, he believed that many of the cases following operations are due, not to the ether which has been employed, but to the exposure of the patient in being carried from the operating-room and in draughty wards. If such troubles are caused by ether, he believed that we should meet with laryngitis much more frequently than is actually

the case. During the three years in which he had been in St. Luke's Hospital, seeing medical and surgical cases alike, he had found that acute pneumonia arising in the hospital was more frequent in the medical than in the surgical wards. These considerations, he said, gave him great confidence in the use of ether, although he quite agreed with some of the other speakers that when chronic nephritis is present it should be administered with great caution.

Dr. Paul F. Mundé said that in his earlier professional career, spent abroad, he had been accustomed to use chloroform, and that since he had been practising in New York he had used ether almost entirely in surgical cases. He had seen no deaths or subsequent bad effects from the latter, either in his own practice or that of others. On three occasions, however, twice in children and once in an adult, he had met with cases in which death would have resulted from the primary effects of the ether if artificial respiration and other active measures had not been resorted to. While he had been trained to use chloroform exclusively, he would confess that he felt ether to be safer if it was properly administered. The giving of the anæsthetic was, in his opinion, often a more important point than the operation itself. He, therefore, thought it was entirely wrong to entrust so serious a matter to young hospital internes of little or no experience, since to administer an anæsthetic properly required as much experience as to assist intelligently in the actual performance of an operation.

The method for giving ether which he prefers is by means of Clover's inhaler, in which the amount of air admitted can be carefully regulated. He had seen some cases which could not be well anæsthetized with ether, and therefore when he noticed that the mucous membrane was particularly sensitive, he generally substituted chloroform for it for a time, and then afterward went on with the ether again. He almost always gave bromide, and sometimes a hypodermatic injection of morphia, preparatory to administering the anæsthetic. He was inclined to think, however, that morphia might possibly sometimes increase the danger. For short operations, and also in the case of children, as well as in obstetrical practice, he preferred chloroform to ether.

Dr. R. W. Amidon said that while, as Dr. Gerster had stated, the only real contraindication against chloroform was a weak heart, it was at the same time true that deaths occur more unexpectedly—often, indeed, entirely without any warning whatever—than when ether is used. As Dr. Reeve said in a note in Holmes's *System of Surgery*, "There is a danger attending the use of chloroform which no foresight can discern, no precaution avoid, and no skill avert."

As to the collection of mucus in the air-passages which Dr. Gerster had referred to as liable to cause such unpleasant and dangerous results, this could readily be avoided by the preliminary hypodermatic injection of atropia, as he had pointed out in a paper which he read by invitation two years ago before the New York Surgical Society. When, therefore, any respiratory impediment is anticipated from the effects of the ether, from one-fiftieth to one-thirtieth of a grain of atropia should be administered. By this agent the bronchial and tracheal secretions are diminished, and it also tends to increase the activity of the respiratory centres, and strengthen the heart. Dr. Thallon, of Brooklyn, and Dr. Weir had employed atropia to a considerable extent in this connection, and quite recently a case had been reported in The Medical News of January 22, 1887, in which impending death was averted by the administration of digitalis and belladonna.

Dr. Thallon thought that Dr. Gerster was too strongly in favor of chloroform. He agreed with Drs. Weir and Wyeth that the presence of nephritis should not be considered a positive contraindication against the use of ether, although it should make us cautious in giving it. He related a case which had nearly died from the effects of ether in the hands of Dr. Emmet, and afterward came under his own care. After an examination of the urine and the heart he determined to give ether for an operation that had to be performed, and the patient took it without experiencing any trouble, either at the time or subsequently. Still later, she took chloroform, and this likewise was unattended with any difficulty. He thought, as Dr. Sayre had suggested, that the administration of anæsthetics is largely a question of dosage.

The apparatus which he had adopted he regarded as far superior to Clover's or almost any other, and it was simply the inhaler ordinarily used by dentists for nitrous oxide gas. As in the case of the one exhibited by Dr. Sayre, at each inspiration the anæsthetic was inhaled, while the expiration got rid of the foul air. By means of this apparatus he had been able to keep a patient anæsthetized for hours, and yet had not used more than a quarter of a pound of ether altogether. With it he had never had any kicking or struggling on the part of the patient, or failed to secure complete anæsthesia. There is much ignorance in the profession as to the proper administration of anæsthetics, and he thought that the ordinary way of giving ether is little less than brutal. The point suggested by Dr. Amidon he thought one of much value. He had first seen the idea proposed in the *Lancet*, in 1880, if he remembered rightly. It is well known that atropia is one of the best stimulants to the respiratory centres, and it is, therefore, a valuable prophylactic in this connection.

Dr. Gerster, in closing the discussion, said that he regretted that he had been charged with partiality, when he had endeavored to present an entirely unbiassed opinion, and that his position had been misunderstood. He had not defended chloroform; but he did mean to say that it is unscientific to claim that either ether or chloroform is, so to speak, our "only salvation." The proper choice of the anæsthetic in each case should be left to the intelligence and experience of the surgeon. Whatever might be the case with others, he himself had certainly met with a certain proportion of instances in which he could not properly anæsthetize the patient with ether. He had not hesitated to say, however, that he considered ether safer than chloroform, and that it should be preferred to the latter as a rule. Still, he did not think that the statistics which had been quoted were at all reliable, from the fact that while in fatal cases from chloroform the patients died while upon the operating table and were thus sure to attract public attention, in many of these when ether was the cause of death the fatal issue did not take place for some time

after the anæsthetic was given. He himself knew of a number of cases of death from ether which had never been published.

CORRESPONDENCE.

THE DANGERS OF COCAINE.

To the Editor of THE MEDICAL NEWS,

SIR: Your timely editorial, to-day, on "Untoward Effects of Cocaine," in which you remark: "The literature of the subject is so scattered that little attention has been given to it," prompts me to say that I have recently devoted no little time to a study of this topic; the result of which was lately presented to the Medical Society of the County of Kings, in a paper on "Cocaine Dosage and Cocaine Addiction," which is, it has been asserted, "the most extensive ever presented on one phase of a subject that is now attracting attention at home and abroad. It referred to forty authorities—English, French, German, Austrian, Russian, and American—and cited more than fifty cases, to which others have been added, in support of the assertion that there is a danger, near and remote, in the use of this drug, on some patients, that does not warrant the reckless disregard of care which one or two opinions lately presented imply."

The cases, noted more or less in detail, showed that cocaine caused toxic symptoms, so marked in four as to produce death. The amount of the drug used varied from a small fraction of a grain to twenty-four grains, and was applied to the eye, ear, nose, throat, larynx, teeth, gums, stomach, bowel, bladder, uterus, urethra, and under the skin.

The symptoms noted were nausea, vomiting, headache, lividity, deafness, blindness, loss of taste and smell, profuse sweats, cold perspiration, gastric cramps; frequent, feeble, irregular, intermittent, uncountable pulse; shallow, gasping, irregular, difficult, convulsive, suspended breathing—artificial respiration required in some cases; speech, gait, and swallowing greatly impaired; rigid muscles, palpitation, sense of suffocation and great constriction about the chest; loss of motion and sensation in arms and legs; intense restlessness. Extreme prostration, vertigo, faintness, feeling of impending death; unconsciousness, convulsions, paralyses, hallucinations, mania, delusions, delirium—death.

Surely, it seems to me, such a record proves the truth of your closing words, "it certainly seems of the greatest importance that the profession in general be reminded that cocaine is not to be used recklessly and without proper care."

I shall be pleased to furnish a reprint of my paper to any who may desire it.

Yours, very cordially,

J. B. MATTISON.

PARIS.

From our Special Correspondent.

METHYLAL.—For some time past therapeutists have sought a new hypnotic among acetals. Methylal, which belongs to these, was first classed by M. Malaguti, in 1839. Methylal is highly volatile. It boils at 42° C. (107.6° F.), and possesses a density of about 0.85. It is soluble in water, alcohol, and oil. M. Personali's experiments proved that methylal rapidly produced sleep in frogs after a dose of 50 per cent. of their own weight; in rabbits, after a dose of 25 per cent. of their weight; in birds, after a dose of 20 per cent.; and in dogs, after a dose of 10 to 16 per cent. A dose of a gramme and a half caused mortality in a pigeon.

Methylal is rapidly eliminated. It modifies the action of the heart, and increases the number of heart-beats during hypnosis. It lowers arterial pressure and increases the cardiac pulsations. At the same time the temperature is lowered. Methylal lessens the activity of exchange in the tissues while it modifies the circulation and respiration. If methylal be administered to a warm-blooded animal at the onset of accidents caused by strychnine, the tetanic convulsions are checked, and the poison being eliminated the animal may recover. In the case of cold-blooded animals, where the process of elimination occupies a considerable time, the toxic phenomena are suspended while the action of the methylal lasts, and reappear when this action ceases.

Methylal may be administered without difficulty, either by hypodermatic method or introduced into the stomach. M. Nicot proposed to administer it externally, prepared with oil of sweet almonds as a liniment, 85 grammes of the excipient to 15 grammes of methylal; or with alcohol at 80 degrees, in the proportion of 10 grammes of methylal to 110 grammes of alcohol and 5 grammes of lavender essence. A pomade might be made with methylal, containing 33 grammes of fatty substances and 5 grammes of the medicament, and an odontalgic mixture with 8 grammes of alsan and 2 grammes of methylal. A potion might be composed of 1 gramme of methylal mixed with 150 grammes of water and currant syrup. A syrup is made with 1½ grammes of methylal to 100 grammes of golden syrup, and an injection composed of 1 gramme of methylal in 125 grammes of gum water.

GIFT OF A NEW BUILDING TO BELLEVUE HOSPITAL.—The corner-stone of the Townsend pavilion annex to Bellevue Hospital was laid with impressive ceremonies on the 11th inst. The new building is for women afflicted with tumors and kindred troubles. It is intended as a thank-offering by Mrs. R. H. L. Townsend, of New York, in gratitude for the success attending an operation upon herself.

Dr. Wylie will be the surgeon in charge of the annex. The building will be of Philadelphia pressed-brick, with blue-stone trimmings. It will have a frontage of 70 feet on First Avenue, and will be connected by an inclosed gallery with the women's surgical ward. It will be a two-story, cottage-like structure. One side will contain wards for patients, each 11 by 16 feet, carefully ventilated, with all modern sanitary and surgical appliances. The rest of the building will be devoted to operations. The cost will be $7000.

THE VASSAR HOSPITAL.—Another monument to the memory of Matthew Vassar, and to the worth of John Guy Vassar, known as the Vassar Brothers' Hospital, was opened at Poughkeepsie last Monday for the recep-

tion of visitors. It is situated on the bank of the Hudson, at the southwestern edge of the city, and commands a magnificent river view. The architectural design of the building takes in towers and turrets, gabled roofs, and Queen Anne formations, dulled red brick predominating. The building is lighted by gas, heated by steam, and is connected with city water and sewerage. Cook rooms, laundry, dining-room, closets, pantries, bedrooms, pharmacy, operating room, etc., are all fitted up in the best possible manner. All the walls are hard-wood finished, with no mouldings or projecting surfaces. The hospital grounds contain 15 acres, all of which are sodded. The wards are situated in two wings. Iron cots are ranged along each wall, 5 on each side and 10 in a ward, making a total of 40 in the two wings. The floors of the closets are of English tiles, and a system of ventilation by means of pipes running through the building to a tower on the roof carries off all odors. The resident physician is Dr. Guy C. Bayley, and he has 10 physicians on his staff. The property and building are valued at $125,000, and the present endowment is about $300,000. It is free to those who, in the judgment of the Executive Committee, are unable to pay for their board and treatment. Preference is given, first to residents of Poughkeepsie, second, to residents of Dutchess County, and third, to the State at large.

Hospital Mismanagement in Chicago.—The warden and others of the officials of Cook County Hospital have been indicted for fraud by the Grand Jury, and with several of the County Commissioners, with whom they were in connivance, will shortly be tried for fraud and malfeasance. The abuses which they have perpetrated are said to be flagrant and of long standing.

Vermont State Board of Health.—A State Board of Health has just been organized in Vermont, making twenty-nine States which now have State boards.

The Mississippi State Medical Association will hold its sixth annual meeting at Jackson, on Wednesday, April 20th, at which time a number of papers on interesting topics are promised.

American Public Health Association.—The fifteenth annual meeting of the American Public Health Association will be held at Memphis, Tenn., November 8 to 11, 1887. The Executive Committee have selected the following topics for consideration at said meeting: I. The Pollution of Water-supplies. II. The Disposal of Refuse Matter of Cities. III. The Disposal of Refuse Matter of Villages, Summer Resorts, and Isolated Tenements. IV. Animal Diseases Dangerous to Man. The Local Committee of Arrangements at Memphis have already begun the work essential to a large and successful meeting. While the locality alone would insure a large attendance, no efforts will be spared by the Committee to make the meeting both profitable and enjoyable for all who attend. A circular will be issued in ample time before the meeting, giving full information in regard to transportation and hotel rates. All communications relating to local matters should be addressed to G. B. Thornton, M.D., Chairman local Board of Health, Memphis, Tenn. Blank applications for membership can be obtained by addressing the Secretary, Irving A. Watson, Concord, N. H.

Henry Hun, M.D., Harvard Medical College, 1879, has been appointed Professor of Psychological Medicine at the Albany Medical College, *vice* John P. Gray, M.D., deceased.

Certificates of Illness of College Students.—The Faculty of Harvard College has promulgated the extraordinary rule that in all cases in which the college has heretofore required a physician's certificate to the fact of illness of absent students, such certificates must specify the *cause* of illness in order that the faculty may he able to judge of the validity of the excuse for absence! The faculty may not be aware that a similar attempt to require information as to the cause of illness of government employés at Washington was resisted by one of the most prominent practitioners of that city, and that his refusal to comply was supported by the head of the department, Secretary Bayard. The faculty makes the double mistake of requiring the physician to betray his professional confidence and of assuming a power of supervision over a medical opinion as to the severity of the disease, or the requirements for its treatment.—*Boston Medical and Surgical Journal*, March 31, 1887.

Dr. Holmes and Apothecaries.—At a banquet given to Mr. Theodore Metcalf, by the Boston Druggists' Association, Oliver Wendell Holmes gave his opinion of apothecaries, as follows: "I have always had a great opinion of the medical advice of apothecaries. The truth is, they put up the prescriptions of all the best physicians in the place in which they live, and they have the very cream of all their wisdom at their fingers' ends. So, when I have myself been suffering from any slight bodily inconvenience, I am ashamed to say—or ought to be, perhaps—instead of going to a professional brother, I have quietly crept into the back room and asked Mr. Metcalf what such and such a doctor was in the habit of prescribing."—*Boston Medical and Surgical Journal*, April 7, 1887.

A Pasteur Institute for Havana.—*Las Novedades*, a Spanish newspaper published in New York, has news from Cuba of the return of a commission, consisting of Drs. Tamayo, Vidósola, and Albarrán, from Paris, whither it had been sent, as the result of a movement started by the "Crónica Médico-quirúrgica de la Habana," to study M. Pasteur's system of anti-rabic inoculation. It is added that the Havana laboratory will soon be in readiness to carry out the system, but that for the present, owing to the lack of proper virus, persons bitten by rabid animals will be sent to Paris.—*New York Medical Journal*, April 9, 1887.

The Microörganisms of the Atmosphere.—In a paper recently read by Dr. Percy Frankland at the Society of Arts on Some of the Conditions affecting the Distribution of Microörganisms in the Atmosphere, reference was made to Pasteur's experiments as showing that mountain air is comparatively free from organisms. Dr. Tyndall had conclusively shown the com-

paratively short time required for suspended microörganisms to subside in calm air. The various methods used to demonstrate the number of living microörganisms present in a given volume of air, which were only partially successful, were described. Hesse's experiments had brought to light the rapid gravitation of organisms in comparatively still air, and the more rapid gravitation of bacterial organisms than mould-organisms. He (Dr. Frankland) had availed himself of Hesse's method to test the condition of the atmosphere in London and some country places. At Reigate and in Norwich a smaller number of microörganisms was observed than in London. In fact, the more remote the place from human habitations, the freer was the air from suspended microbes. The London parks, though containing fewer microbes than were to be found in the streets, contained more than were present in country air. With regard to sea air, experiments showed that the maximum distance to which, under ordinary circumstances microörganisms can be transported across the sea, lies between 70 and 120 sea miles. Beyond this distance they are almost invariably absent. Dr. Percy Frankland described his system for remedying the defects in Hesse's method of testing the atmosphere. A definite volume of air is drawn, by means of an air-pump, through a short piece of glass tubing containing two small porous plugs placed one in front of the other. Of these two plugs, the first is constructed of glass-wool only, the second being formed of glass-wool and glass or sugar-powder. The object of this arrangement is that the second plug, through which the aspirated air has to pass, shall offer more resistance than the first, and consequently, if the second plug is found to be free from microbes, it may safely be assumed that the first plug has been sufficiently obstructive to the microörganisms in the air passing through, and that they have all been retained by it. Each plug is afterward transferred to a small flask, where the results of the experiment can be examined.—*British Medical Journal*, March 26, 1887.

IMPROPER VENTILATION FROM SEWERS NOT POISONING.—The assumed fact that plumbers escape disease and infection from the inhalation of sewer-air is often referred to as indicating the harmlessness of this air or gas. Were all the facts known, this view would undoubtedly be much modified. A recent occurrence in England would seem to prove that men who follow this trade are not so exempt as is generally supposed. An inquest was held during the past month, in Liverpool, on the body of a plumber's apprentice who had been engaged during the previous week in repairing pipes which connected with a sewer. Quantities of gas came through these pipes, and at the time the young man complained of pain and sickness; in forty hours he died. The medical evidence was to the effect that death was due to the inhalation of sewer-air, and the jury rendered a verdict to that effect.—*Science*, April 8, 1887.

POISONING BY CARBONIC OXIDE.—It will be remembered that, some months ago, a party of excursionists went on a steamer from Glasgow to witness the effect of certain large blasting operations, which were to take place on Loch Fyne. In the blast, six and a half tons of gunpowder were exploded; and after it was over, the excursionists went on shore to look at the effect of the shock. In a short time many of them were seized with faintness; six of them died almost immediately, one died shortly after, and five were made very sick, but eventually recovered. The results of the scientific inquest which followed this sad affair have been published, and have brought out the fact that the mischief was probably due to carbonic oxide, of which it was calculated 468 pounds could be generated by an explosion of the quantity of gunpowder named above, an amount which, at the ordinary temperature and pressure, would occupy a space of 6333 cubic feet. This would be sufficient to vitiate one hundred times as many cubic feet of air. But, in the presence of carbonic anhydride, of which the explosion would generate 3575 pounds, it would render 1,266,000 cubic feet of air fatal to human life. The symptoms of those who have suffered or died agreed with those attributed to poisoning by carbonic anhydride, and it is said that the blood of one of the deceased was so liquefied after death that it flowed through the coffin.—*Boston Medical and Surgical Journal*, April 7, 1887.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 5 TO APRIL 11, 1887.

[illegible] JOHN VAN R. [illegible], *Assistant Surgeon*.—Ordered for duty at Fort Reno, Indian Territory.—*S. O. 43, Department of [illegible]*, April 4, 1887.

[illegible] W. H., *Assistant Surgeon*.—Granted leave of absence for one month.—*S. O. 35, Department of Arizona*, [illegible] 1887.

[illegible], HENRY, *Captain and Assistant Surgeon*.—Ordered to [illegible] Barracks, New York, for temporary duty.—*S. O. 74, A. G. O.*, April 5, 1887.

[illegible], CHARLES L., *Captain and Assistant Surgeon*.—Ordered for duty at Fort Assiniboine, Montana Territory.—*S. O. 78, A. G. O.*, [illegible] 1887.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING APRIL 9, 1887.

BAILHACHE, P. H., *Surgeon*.—Detailed as Chairman, Board of Examiners, to meet in Washington, April 25, 1887. April 4, 1887.

PURVIANCE, GEORGE, *Surgeon*.—Detailed as member Board of Examiners, to meet in Washington, April 25, 1887. April 4, 1887.

GODFREY, JOHN, *Surgeon*.—Detailed as Recorder, Board of Examiners, to meet in Washington, April 25, 1887. April 4, 1887.

[illegible], *Passed Assistant Surgeon*.—To proceed to Baltimore, Md., on special duty. April 8, 1887.

[illegible], *Assistant Surgeon*.—To proceed to Norfolk, Va., for temporary duty. April 4, 1887.

ORIGINAL LECTURES.

FATTY HEART, WEAK HEART, PSEUDO-ANGINA PECTORIS, AND ALLIED STATES SUCCESSFULLY TREATED BY A NEW METHOD.

A Clinical Lecture,

Delivered at the Jefferson Medical College Hospital, March, 1887.

BY PROF. ROBERTS BARTHOLOW, M.D., LL.D.

GENTLEMEN: During my present clinical term, now near its end with the closing of the College session, I have called your attention to certain cases of heart disease treated by a method not conformable to the accepted canons of cardiac therapeutics. During my clinical term last year, and before, I have illustrated by example the same therapeutical conception. I purpose now to summarize my opinions and practice and illustrate these anew, by the aid of the case before us and some others that have been in my charge. I am the more inclined to utilize this opportunity before we separate for the present term, because I could not fail to see that those amongst you who had had clinical advantages, either in hospital or private practice, appeared to be somewhat sceptical of a plan of treatment differing in so many respects from that in ordinary use. This judicial attitude is in every way commendable, especially as a hasty approval of novelties is one of the evils of our time.

In the case before us we have a typical example of the most common and sometimes most important of the cardiac diseases under consideration. In the course of my remarks, to make the clinical picture more complete, I shall not hesitate to refer to other characteristic examples. Not to enlarge needlessly on points of minor importance, it will suffice to say that we have here an example of weak heart, and in consequence of the waning strength of the muscular tissue of the organ, the valves are not competent to close the orifices properly. The sounds of the heart are muffled, indistinct, and vary in time, in strength, and in volume. The pulse is arhythmical, and unequal in force and tension, and the walls of the arteries are rigid, this being especially well exhibited in the tortuosity and prominence of the temporals. There is no proper murmur. The position of the præcordial distress, and the manner in which the symptoms have developed, indicate that the right cavities have been the chief seat of the mischief, the incompetence being of the tricuspid.

If the physical signs are not distinctive, the rational signs are eminently so. Now, gentlemen, please consider this statement attentively. It has fundamental importance. The recognition of cardiac lesions is, now-a-days, so much an affair of physical diagnosis that the immense significance of the rational signs is not sufficiently—indeed, sometimes not at all—appreciated. These rational signs are the more dependable when the therapeutical diagnosis is to be decided on; for then the condition of the respiratory and circulatory organs, as manifested by these signs, constitutes the ground on which the treatment must be based.

You must not fail to understand the supreme importance of the rational signs of cardiac disease. Indeed, I may assert that any case in which the physical signs even are unequivocal, has importance in proportion to the extent and severity of the rational signs. The case before us illustrates this principle perfectly. Observe his appearance and manner. His face is pallid, lips purplish, eyes swollen, and his countenance expresses distress and anxiety. His breath is short, evidently embarrassed; he tells us that when he makes any exertion he becomes much oppressed, and that he has at times paroxysms of dyspnœa like asthma. Almost the first symptom that attracted his attention, was seizures of difficult breathing and severe præcordial distress, with pains shooting through the chest, coming on suddenly when walking on the street. These paroxysms compelled him to stop "to get breath" for a few minutes, but a short rest restored him. After a time the difficulty of breathing attended every effort at motion, and at length became constant, compelled him to sit half-erect to sleep, and prevented active exertion of any kind. The permanent difficulty of breathing was coincident with general œdema and more or less pulmonary œdema, which we find to be present now. Every now and then our patient has attacks of pseudo-angina pectoris, coming on after taking some indigestible food, in consequence of some depressing moral emotion, or in attempting exercise, especially in walking against a strong wind. These attacks have the ordinary characteristics of this state: severe pain and constriction of the chest, pain shooting into the left shoulder and arm, irregularity of pulse, feebleness, faintness, pallor, coldness of the surface, difficult breathing, and unspeakable anxiety and distress of mind. There is really no difference between the pseudo- and the true angina pectoris in respect to the complex of symptoms. The real difference consists in the extent of the damage the motor apparatus of the heart has suffered. At the outset, in many of the cases of heart disease under consideration, and for a long time in others, these attacks of pseudo-angina pectoris are almost the only indication of heart trouble, except some weakness and irregularity of action.

I must now ask you to consider briefly the mechanism of these cases. We must carefully analyze the personal and clinical history of the patients, if we would form an accurate conception of the nature of this cardiac affection. As a rule, the individuals who are thus affected lead sedentary lives, make use of a faulty diet, and suffer from the effects of some unwonted exertion or profound moral emotion; or they are, if active, and accustomed to an outdoor life, addicted to fermented

liquors or spirits; or they have been infected by some specific poison, or under the influence of some dyscrasia. A sedentary life is one of the most influential factors. The patient before us has taken hardly any exercise, indoors or outdoors, and his occupation has permitted him to indulge his natural inclination. I do not mean that our patient is to be compared to the poet Smart, celebrated by Boswell, the incomparable biographer of Johnson. Some one having mentioned that Smart owed his mental failure to a lack of exercise, Johnson characteristically opposed the suggestion. "Before his confinement," said Johnson, "Smart used for exercise to walk to the ale house, but he was *carried* back again." Now our patient did not have sufficient fondness for beer to force him to the ale house, and he has not indulged with any degree of freedom in spirits, so that the degradation of his tissues which we find, must be referred to other causes—to the need of exercise, to a deficient supply of oxygen, and to the lack of proper aliment. His diet has had an important influence over the origin and progress of the degenerative changes. He has always had a fondness for sweets, and for farinaceous foods in general, and these have constituted the principal part of his diet. Thence followed acid indigeston, intestinal fermentation ending in such a production of acid as, probably, to change the normal alkalnity of the intestinal juices to neutral—even to acid. I must ask you to note this point with care. If the intestinal juices do not effect the proper changes in the starch and sugar of the food, what happens? These substances undergo acetic and lactic fermentation, it may be because of the presence of some of the microbes of fermentation. Certain changes in the vascular system are well known to be induced by the presence of a form of lactic acid in the blood. By injecting lactic acid into the blood of animals, and by the administration of lactic acid for diabetes—a practice formerly quite popular—endocarditis and rheumatic fever have been caused. To these pathogenic influences must be added the ill-effects of an insufficient supply of oxygen.

Just consider for a moment. The imperfect primary assimilation charges the blood with crudities. The products of digestion not properly acted on by the oxygen of the air, are ultimately either deposited as mere fatty tissue, or excreted as uric acid and urates. We should not be surprised to find that these processes acting through several years, bring about the pathological changes illustrated in the history of this patient. It has happened to me to meet with various cases, in the course of my private practice, in which the same effects followed the persistent operation of the same causes. Amongst the most perfect examples of the kind coming into my hands, have been some of the judges on the bench, and I shall presently speak with some particularity of the case of an eminent jurist in the Southwest. The enforced quiet of their lives, the extremely sedentary occupation of trying causes, and other circumstances precluding exercise of a sufficient kind, combine in the case of the judges, to bring about the result.

Men of literary tastes, and pursuing mental occupations, have an instinctive fondness for sweet things. If the time were not wanting, and the occasion suitable, I could demonstrate that this fondness for sweets, which I have just said is instinctive, is based on an actual need; they are brain foods, in that they furnish the force and the constructive materials most readily available by the nervous system for work and for repair. Whether this explanation be correct or not, it yet remains that these subjects are given to the consumption of a good deal of saccharine and starchy food.

When the heart falls into a condition of weakness from the causes I have been discussing, it is readily damaged by strain. This is generally admitted and needs no further statement. It is not so well understood, however, that sudden and strong emotion—anger, grief, fear, etc.—may cause the walls of the heart to yield, when certain degenerative changes have occurred in them. It seems to me quite possible, also, that reflex disturbances—severe paroxysms of palpitation—produced by irritation elsewhere, may, also, cause yielding of the walls of the right heart.

When the circulation is carried on in the languid and inefficient way characteristic of weak heart, it follows that all the organs of the body functionate imperfectly, or, at least, slowly. The digestive juices are inadequately produced, and hence this cause of impaired digestion must be added to the others already mentioned. Poorer blood than normal, and an insufficient supply, not only lessens functional activity, but hastens retrograde change. Watery blood favors transudations, and thus the operation of mechanical causes in producing œdema is facilitated.

You will observe that I do not include the cases of heart diseases having their origin in previous attacks of acute rheumatism, nor those secondary to a neighboring pleuritis. I refer to the cases essentially chronic that have developed slowly from the middle period of life onward and out of the conditions, personal and social, which I have described. It may be well, now, to define the pathological change supposed to have taken place. Hitherto, I have indicated the mode in which weak heart is brought about, but it remains now to say something more definite about the actual state of the organ.

The condition of general weakness having occurred, the heart tissues participate to a greater or less extent in the decline of nutritional activity. It is probable that an inherited predisposition is not without influence—for, although the diseases themselves are not transmitted, a certain vulnerability of the cardiac tissues may descend. Whether this have any influence or not, the fact remains that under the conditions already mentioned the heart grows weak by fatty degeneration or fatty substitution. In other words, the muscular substance of the heart undergoes a change in which the muscular elements themselves become granular and fatty, the striæ grow cloudy, and are ultimately obliterated. Or, without being changed in structure, it is supposed, in some instances, that the muscular tissue is displaced by fatty; but it is in a high degree probable that in every case the muscular elements are more or less altered in structure. I have a strong impression that mere weakness of the cardiac muscle, especially of the right heart, is sometimes the sole change, and that under conditions involving sudden strong intravascular pressure, the muscular tissue yields, the cavity enlarges, and hence the valves become incompetent to close the orifices.

Of course, when a patient presents the evidences of atheroma of the bloodvessels, and at the same time the

symptoms of weak heart appear, it may be supposed that a chronic arteritis of the coronary artery had something to do in bringing about degenerative changes in the muscular tissue. I hold it to be probable that long-continued insufficient action of the heart also promotes the pathological alterations, by limiting the amount of blood passing through the organ in a given time. It is the right heart, more especially, which is first affected, and sometimes it may be the only part of the organ affected throughout.

Of late, current medical literature has contained some fresh statements regarding the part taken by the right heart in the development of the diseases we are now considering, I should have said, probably, *fresh pretensions*—for it has long been known that such is the fact. Twenty years ago a London physician published a most suggestive brochure, in which due importance is given to the dilatation of the right cavities as the initial change. I must again remind you that the physical signs are rather negative, and hence to learn the true condition of affairs we must carefully study the rational. Before any of the more pronounced symptoms, such as have been spoken of, present themselves, the patient has a peculiar uneasiness at or about the ensiform cartilage, usually extending somewhat to the right of the cartilage, and nearly in the position over the right side of the heart. This uneasiness which is not acute pain, is a very distressing and foreboding sensation, accompanied by rather quick, shallow, and oppressed breathing, and a weak pulse. In the severest form the pain assumes the aspect of angina pectoris, and is associated with a weak, fluttering pulse, faintness, nausea, extreme pallor, a cold sweat, etc. I have no doubt, this peculiar pain, with its accompanying symptoms, is produced by the change going on in the right heart, and hence it has grave significance, and is ominous of future calamity unless the measures instituted will remove the morbid state.

But, gentlemen, I fear I have lingered too long in this preliminary discussion. I must hasten to place before you in one view, the therapeutical measures which I have found so effective. These have been referred to in my didactic course, and have several times, during the past three years, been illustrated by appropriate cases in this clinical hall. Nevertheless, it is desirable to restate the whole therapeutical plan in the light of my most recent experiences. One of these is described in a letter from which I will read you some sentences. If, as it has been defined, "History is philosophy teaching by example," not less is such a conception applicable to practical therapeutics, and hence cases which teach us the value of a mode of treatment are peculiarly instructive. Especially is this one instructive, for the testimony is independent, and the witness whom we examine is unprejudiced, or if affected by any bias, it was against rather than in favor of the plan—for before I was called on to prescribe the management of the case, all the various remedies to improve the condition of the heart, now most approved, were resorted to in vain, and little hope was entertained of the success of a different method. The patient, an eminent jurist, and the physician, a distinguished practitioner, belong to a city of the Southwest:

March 2, 1887.

"I am happy to inform you that Judge ——— is doing remarkably well. His condition has improved wonderfully under the influence of trinitrin—so much so that he is now able to walk a mile and ascend two flights of stairs without fatigue or oppression. The swelling has entirely disappeared, allowing him to wear a tight shoe. The appetite is fair but is restrained by the patient, who could eat much more than he does. Gain in weight over eight pounds during the last two weeks.

"I must say, however, the improvement came on slowly at first; the patient had to take fifteen drops four times daily before feeling the characteristic pain in the forehead and the flushing of the face. Since, the dose has been gradually reduced to four drops t. d. and the physiological effects of the medicine are invariably produced within a few minutes after its ingestion.

"Now, dear sir, please let me know what is to be done? Must the same dose (4 d., t. d.) be kept up? If so, how long? Or must we stop the medication for a while and resume it later on?

"Liq. potass. arsen. has been faithfully and steadily taken in the dose of two drops thrice daily before meals. If your occupations will permit you to send me further instructions as to the course to be followed, you will confer a great favor upon the judge and upon your most obliged Dr. ———"

Gentlemen, this admirably clear and well-expressed letter gives the facts of the treatment in the most compendious form.

Of course an iron-clad rule, admitting of no variations, cannot be adapted to all cases; but in general terms, the method of treatment consists in a regulated diet, systematized exercise, the use of trinitrin (nitroglycerin) and arsenic.

I should also state the negative side—why digitalis is not given; why iron is avoided, and why the digestive organs are not forced by supplying food of all kinds; but this contention may be settled the more clearly in the course of my observations on the plan under consideration.

I mention foremost among the remedies a regulated diet. You will all bear witness how persistently I have advocated a dietary adapted to the conditions present. Whether the theory I have constructed be true or not, the results have been most fortunate. I have not urged a full diet. I have not prescribed tonics so-called, and remedies to goad the sluggish digestion. The principle has consisted in giving the few foods which the patient can digest, and which can best repair damages. Under the circumstances it is not so much force-developing and heat-producing foods that the patients require, as tissue-making. The sweets, starches, and fats for the most part, are cut off from the diet, and milk, eggs, fresh meat, game, or poultry, and the succulent vegetables are given. I have explained the part which certain kinds of fermentation, stomachal and intestinal, take in some pathological processes, but the reflex effects on the heart's movements are also important. I warn you against large draughts of cold milk. Bulk becomes a cause of offense, and cold affects the heart injuriously through the solar plexus. Only a moderate quantity of hot skimmed milk is admissible, but this is a precious resource. A small amount of fresh meat—beef, mutton, chicken, broiled or roasted, excluding all the parts

charred in cooking, should be given once a day, and eggs allowed for breakfast. Bread must be eaten in moderation and it should be a day old at least. All hot breads, cakes, pastry, crackers, all gravies, sauces, condiments, pickles, fried articles, dried and preserved fruits, "canned" fruits and vegetables, salted meats, pork, bacon, ham, etc., are strictly prohibited. Such vegetables as lettuce, asparagus, celery, spinach, tomatoes, a single boiled or baked potato, if unexceptionable in quality, are advised. Stewed apple (fresh) without sugar is allowed as a vegetable, or a baked apple at the conclusion of a meal. Berries generally are advised against, unless known to agree, and then only in the fresh state, when they can be eaten quite moderately without the addition of sugar or cream. Such a simple dessert as wine or lemon jelly may be allowed if it does not give trouble.

Such in general terms is the diet of those who have still fairly good digestion; but in cases of extreme gastric disorder, an absolute milk diet may be required, or such modifications made in the dietary just given as experience may demonstrate to be necessary. The capital point is to allow the patient no aliment that can give rise to indigestion or to fermentation in the least degree. After a time the number and quality of the foods can be slowly increased as the condition of the digestive apparatus will permit, but the general plan of alimentation already sketched must be adhered to.

The next point in the treatment is exercise. Rest, but not sleep, is enjoined for a half hour to an hour after meals, and two to three hours after meals, or longer, if digestion be slow, a definite quantity of exercise is prescribed. This is not left to chance, but the amount of exertion the patient can make with safety, is ascertained, and the length of the excursion is slowly increased from day to day. Warn patients against the gymnasium. The constrained exercises taught in these institutions are a fruitful cause of heart trouble, and, hence, I do not advise them. The exercise which can be most accurately adjusted to the requirements of the case is walking, and this should be made an habitual duty. Of late, the necessity of exercise in certain forms of heart disease, has been brought forward from abroad, as a new addition to the present treatment, and, as usual, we are likely to see exercise in heart diseases carried to a ridiculous excess. Those of you who have attended my clinics here for several years past, and have been familiar with my practice, know that I have persistently urged systematized exercise as a means of increasing the strength of the heart and of improving its nutrition. I have not proposed that mountains be scaled, that somersets be turned, or that "ground and lofty tumbling" become the daily occupation. On the contrary, whilst I have advised systematic walking, regularly increased as the improvement warrants, I have sedulously warned against sudden and powerful muscular effort, and all movements that endanger the heart by overstrain. If you ask me why exercise is so important, I will tell you first, that walking increases the quantity of oxygen obtained, thus improving the blood by an addition to the amount of an essential constituent, and by burning off unnecessary materials. Exercise favors nutrition by increasing the quantity of blood received by the tissues in a given time, and this result is as true of the heart as of any other part of the body. Also, regulated exercise, by increasing the work of the heart, improves the tone and energy of the muscular elements.

I have now to call your attention to the application of drugs to the treatment of the fatty heart or weak heart —to the use of the medicinal agents, strictly speaking. In the letter, extracts from which were just now read, the most important of the remedies are named: Trinitrin, or nitroglycerin solution of *one per cent.*, and arsenic. You observe, I do not mention digitalis. I do not, at all, subscribe to the doctrine that digitalis is a "heart tonic." From my point of view this is a pernicious phrase—for, misled by this conception of its mode of action, physicians have not hesitated to administer it under all circumstances, if the heart were only weak. When the arterial tension is high, there is increased resistance to the flow of blood; and, hence, the heart must compensate by putting forth stronger efforts. Now, digitalis, given in the full doses considered proper, raises the arterial tension, and thus adds to the work of the heart, and by slowing the beat whilst the calibre of the vessels is narrowed, the amount of blood distributed is lessened. A fatal case of poisoning by digitalis, reported by Böhm, admirably demonstrates the fallacy of this "heart tonic" notion, and this is, probably, the only fatal case reported free from any source of erroneous interpretation. The victim, a girl, who had taken but one dose, died on the fifth day, suddenly, on attempting to get out of bed. Paralysis of the heart occurred, you see, when a little extra demand was made on its contractile energy. Does not this history throw an ominous light on those cases of fatty heart that die suddenly when taking digitalis as a "heart tonic?"

We have an admirable proof of the utility of physiological investigations as a means of ascertaining the therapeutic powers of remedies in the applications of nitroglycerin to the treatment of diseases; for its real value as a remedy, and the conditions in which it will prove curative, could not otherwise have been known.

The special reasons for its good effects in weak heart are the following:

It lowers the vascular tension by dilating the arterioles;

It increases the rate of the heart's movements;

It lessens that irritability of the nervous system which finds expression in spasm, especially of the nervous system of organic life.

It follows from these actions that the quantity of blood sent through the arterial system is much increased, and this increase includes, of course, the arterioles in the cardiac muscular tissue, and, hence, in this way the heart is provided with more abundant materials for its nutrition. A greater activity of movement, sustained in force, contributes to the reparative process. As the treatment, also, removes the disorders of digestion, and furnishes a more appropriate supply of aliment, the making of good blood is assured, and thus in turn all the tissues of the body gain in nutrition and the functions are rendered more active in a corresponding degree. Under no plan of treatment have I seen so rapid and thorough improvement in the condition of the weak, the anæmic, and the ill-nourished.

The capital fact which I would have you realize in all its significance is, that by this means the nutrition of

the heart is so promoted that morbid conditions of a dangerous kind are prevented, and, indeed, removed. I am firmly convinced that incompetence of the valves caused by yielding of the weakened walls of the heart, may be recovered from entirely under the influence of these remedial measures.

One of the cases amongst many others which seem to prove this statement, is that of a physician of this city, who in consequence of fatty heart with extreme weakness and irregularity in the action of the organ, was confined to bed, and incapable of movement. The diagnosis of this case had been made by one of our ablest clinicians, and I cannot, therefore, be accused of exaggeration to enhance the merit of the treatment. In this case, as in others we have had under consideration, the original cause of the cardiac derangement was a severe gastro-intestinal catarrh. At the period of maximum cardiac disorder, the stomachal distress was most extreme. The case required the most careful handling, but the final result was that the heart was restored to the normal state, the digestive organs, by a discreet graduation of the quality of the food stuffs, became able ultimately to dispose of a mixed diet, and the patient's health is so completely restored that he has returned to a daily life of most vigorous exertion, undisturbed by those irregularities of the circulation which at one time threatened early dissolution. Many similar cases have been observed, but I prefer to mention those that may be quickly referred to, in answer to the unbelief of the sceptical.

I must state with more particularity the manner of administration of trinitrin. As you have often observed here, I prescribe the one per cent. solution beginning with one drop, and adding one drop at each dose until the characteristic effects are produced. The susceptibility to its action varies greatly. The amount required ranges from one to ten drops for the largest number. When the patient feels the least degree of the action the dose is sufficient, and that quantity should be continued, the intervals being from two to six hours, according to the character of the symptoms, and the persistence of the effects. It follows that the preparation of nitroglycerin used must be such that fine gradations in the quantity administered, can be effected.[1] If the dose necessary to produce distinct physiological effects is large at the outset, it often happens that a considerable reduction can be made and yet the action be maintained. On the other hand, if a small dose suffice at first, after a time it becomes necessary to increase it a little. I am thus particular in referring to these practical matters, because I meet physicians who complain that they cannot accomplish the results claimed by others, and they, therefore, cry out "humbug!" and never suspect that the deficiency may be in themselves. Other medical sceptics and pessimists illustrate the philosophy of Mrs. Gummidge—"Everythink goes contrairy with me."

I must not fail to mention the other remedy—arsenic. I usually prescribe Fowler's solution (two to three drops three times a day); sometimes Pearson's solution of the arseniate of soda (three to six drops three times a day). This remedy plays an important part in several ways:

It removes the morbid state of the gastro-intestinal mucous membrane;

It stimulates the appetite, the primary assimilation, and thus powerfully contributes to improve the nutrition of the body;

It lessens the irritability, and the abnormal readiness of reflex action of the nervous apparatus, and imparts that influence to the cardiac and respiratory functions, which we call *tonic*. I have said nothing about iron and tonics, and all the armamentarium of supporting treatment. I have advised nothing of these remedies because they are hurtful rather than beneficial. They keep the stomach in a turmoil, interfere with the proper alimentation, and in this way retard if they do not prevent improvement. We must not lose our hold on that elementary fact—that blood is made from food and not from medicine, and that other basic truth, that the construction and repair of the tissues can only be effected by good blood.

Above all, I have surely taught in vain if I have not convinced you of the value of simplicity in therapeutics. Not less in medicine than in philosophy, are necessary—"clear thinking and straight seeing." Without these all our efforts are blind and aimless.

[1] At the present time excellent tablets of trinitrin are made. The writer can speak in praise, especially of Wyeth's, which are so made that the dose can be varied with the utmost nicety.

ORIGINAL ARTICLES.

A CASE OF PHTHISIS TREATED FOR EIGHT WEEKS BY RECTAL INJECTIONS OF GAS.

WITH NOTES AND EXPERIMENTS.

BY E. L. TRUDEAU, M.D.,
OF SARANAC LAKE, N. Y.

Dr. Bergeon's purposed plan of treatment for diseases of the lungs is put forward as embodying the application of scientific data to clinical medicine, and is so novel a departure, in the field of pulmonary therapeutics, as to demand general attention.

The claims made for the method, and which are still "sub judice," are, first, that by its use antiseptic substances may be conveyed through the lungs; secondly, that the gas injections, on account of the germicidal influence which they exercise on the morbid processes going on in those organs, are a specific in incipient phthisis as well as in acute miliary tuberculosis (which is claimed to have been cured in six weeks by their use) and are beneficial to a greater or less degree in all forms of consumption, bronchitis, and asthma at any stage. As the validity of these claims can only be settled by a comparison of the results noted by many observers, I venture to put the accompanying case on record, with a few experiments and notes made at the time bearing on the germicidal value of the gas.

J. R., æt. nineteen, American, clerk, an only son, mother still living and in good health, father died of apoplexy. Patient had been in good health until August, 1886, when he began to cough; soon afterward he had a hemorrhage, and has been running down steadily ever since. Physical examination March 26, 1887, revealed dulness on percussion over upper two-thirds of right lung, with bronchial breathing under the right clavicle accompanied by many coarse and fine rales. In lower portion of lung

coarse crackling râles were heard accompanied by fair resonance. At left apex nothing but slight crepitation was made out. Temperature, 8 P.M., 100½°; pulse 120; respiration 28. Patient had lost ten pounds, had occasionally night-sweats, a severe cough, profuse expectoration, breathlessness, and loss of appetite.

Treatment was begun Feb. 4th, and continued without intermission until April 2d, two injections of six litres (six and one-third quarts) of gas each, being given daily. This was soon increased to seven litres at a sitting (fourteen litres daily) and this amount was made use of until the treatment had been continued eight weeks. Dr. Bergeon's directions were minutely followed in every respect, and the freshly made carbonic acid gas passed either through Eaux-Bonnes water, bisulphuret of carbon vapor, or Richfield Springs water.

The patient's vital signs were daily noted, and tabulated as follows:

in mind that improvement quite as marked frequently occurs in this disease without any specific treatment whatever. The procedure, though grotesque and tedious to patient and nurse, apparently produces no disturbance of any of the functions of the body, and, provided the amount of sulphuretted hydrogen introduced is moderate, appears free from danger.

The Eaux-Bonnes water, the bisulphuret of carbon vapor, and the Richfield Springs water, were each made use of in turn. The Eaux-Bonnes water, to which Dr. Bergeon gives the preference, was soon discarded, on account of the very small quantity of sulphuretted hydrogen which remains in the bottles after so long a transportation, as shown by chemical tests. The bisulphuret of carbon vapor produced headache and some intestinal irritation, and was for these reasons discarded, after a few injections. The Richfield water was obtained fresh from the springs, having been bottled a few days previous to use, and

Table of Symptoms.

	Average of			Physical signs at beginning of treatment	
				Right lung.	Left lung.
Beginning of treatment	[illegible]	[illegible]	Occasional bacilli.	Dulness on percussion over upper two-thirds. Bronchial breathing under clavicle, with many fine and coarse râles in lower portion of lung coarse râles; weakness of [illegible]	No dulness. Some fine râles in suprascapular region.
End of 1st week	99½	[illegible]			
End of 2d week	[illegible]	26			
End of 3d week	99	[illegible]			
End of 4th week	99	[illegible]			
				At end of treatment.	
End of 5th week	[illegible]	[illegible]		[illegible]	No dulness.
End of 6th week	[illegible]	[illegible]		per two-thirds. Bronchial breathing under clavicle same; a few fine râles only.	No râles, except on cough-ing, and then difficult of de- [illegible] vesicular murmur.
End of 7th week	[illegible]	[illegible]			
End of 8th week	[illegible]	20			
On 2d day, after discontinuing treatment, temperature	[illegible]	[illegible]			

Though noted at this early stage of the case, these results are, on the whole, encouraging, and indicate that the gas exercised a beneficial influence on the suppurative processes going on in the lungs of this patient. The temperature during the last three weeks of treatment, never once reached 99° F., but rose at once on discontinuing the injections for a few days. This would indicate the necessity of continuing treatment for long periods of time, and even after all the symptoms of septic poisoning have disappeared. The tubercle bacilli, however, remained present in the expectoration, and the pulse and respiration fell but little. The physical signs showed no decrease in the area of consolidation, though a very marked diminution in the moist sounds was noted. At the left apex these almost entirely disappeared.

Satisfactory as are these results, it must be borne in mind that improvement quite as marked frequently occurs in this disease without any specific treatment whatever. The procedure, though grotesque and tedious to patient and nurse, apparently produces no disturbance of any of the functions of the body, and, provided the amount of sulphuretted hydrogen introduced is moderate, appears free from danger.

The Eaux-Bonnes water, the bisulphuret of carbon vapor, and the Richfield Springs water, were each made use of in turn. The Eaux-Bonnes water, to which Dr. Bergeon gives the preference, was soon discarded, on account of the very small quantity of sulphuretted hydrogen which remains in the bottles after so long a transportation, as shown by chemical tests. The bisulphuret of carbon vapor produced headache and some intestinal irritation, and was for these reasons discarded, after a few injections. The Richfield water was obtained fresh from the springs, having been bottled a few days previous to use, and was found loaded with sulphuretted hydrogen, containing fully seven per cent. of the gas. It was admirably borne by the intestine, and its rapid absorption was in striking contrast to the tedious manner in which the bisulphuret of carbon vapor was disposed of.

I could not myself detect the odor of the gas in the breath of the patient, and I failed to obtain any appreciable precipitate of sulphide of lead by directing him to blow for ten minutes at a time through a solution of the acetate, immediately after taking the enema.

Sulphurous acid and sulphuretted hydrogen have already been used as germicides in phthisis. Vallin[1] found sulphurous acid efficient in rendering innocuous tubercular products, and Germain Sée[2] considers

[1] [illegible]

[2] [illegible]

it superior to carbolic and salicylic acids in destroying the bacilli of the disease.

Sulphuretted hydrogen has been tried by Cantani in the form of inhalations in phthisis, and this observer has claimed good results from their use, but its antiseptic value is far less than sulphurous acid. The possibility of its oxidation while passing through the body, whereby its efficiency may be increased, should be kept in view.

As the germicidal value of the gas as it enters the body seems so far to have been assumed rather than demonstrated, the following experiments bearing on this point were instituted.

Experiments.—A pure culture of the tubercle bacillus was mixed with two cubic centimetres of sterilized water in sufficient quantity to render the liquid quite opaque, and through this eight litres of gas precisely as taken by the patient were slowly passed by being directed to the bottom of the test-tube through a finely drawn glass pipette. This quantity of carbonic acid is the largest amount that can be used at one treatment, and it was forced through an entire bottle of Eaux Bonnes mineral water moderately heated in order to insure its being thoroughly loaded with the sulphuretted hydrogen. The quantity of sterilized water in which the germs were suspended was so small that as the gas slowly bubbled up through it, they must of necessity have been brought in contact with the entire quantity of the vapor used.

After the operation had been completed, the bacilli were planted in six tubes of coagulated blood serum, and together with two control tubes containing plants made from the same germs prior to the experiment, were all put in the thermostat together.

The remainder of the liquid, containing the microbes which had been subjected to the action of the gas, was taken up in a Koch's inoculating syringe, and injected in the right pleural cavity of two healthy rabbits. Precisely the same experiment was repeated two days later, except that the Richfield water was substituted for the Eaux Bonnes.

In two weeks fifteen out of the sixteen tubes showed an abundant growth of tubercle bacilli.

The four rabbits died on the twenty-sixth, twenty-eighth, thirty-first, and thirty-second days, respectively, and all showed small, cheesy masses in the injected lung, and miliary tubercles scattered through the spleen, liver, pleura, and peritoneum.

The rather unusal rapidity with which death was produced in these animals was no doubt due to the large number of bacilli injected. As the tubercle bacillus, however, is a spore-forming organism, and for this reason most difficult to destroy, and as other bacteria play an important part in the destructive and septic processes of advanced phthisis, the effect of the gas on some of these germs was tested.

The bacterium of blue pus and the staphylococcus pyogenes aureus, were selected for this experiment, as they are both intimately connected with the lesions found in the lungs of consumptive patients. These organisms form no spores, multiply by fission, and are, therefore, more susceptible to the action of chemical substances than the tubercle bacillus.

Pure cultures of the bacterium of blue pus, and the staphylococcus pyogenes aureus were each mixed in two separate tubes, with 2 c.c. sterilized water, and through each tube of the fluid, made appreciably turbid by the microbes, 8 litres of the gas were passed exactly as in the foregoing experiment, the Richfield spring water being chosen. Ten of the twelve agar tubes, planted with the organisms thus treated, showed an abundant growth of both varieties of bacteria in less than three days.

The gas, therefore, as it enters the body appears to have no germicidal value whatever.

A satisfactory conclusion as to the real therapeutic merit of this method, cannot necessarily be reached for many months to come, but so far as the evidence procured by its application to one case for so short a time may be of value, it would seem that rectal injections of gas by Bergeon's method have a beneficial influence on the suppurative processes of phthisis. The method seems deserving of a most thorough and extended investigation, and *though the treatment may prove in the future to be a useful therapeutic measure, a consideration of the facts here presented does not in the least warrant the assumption that a specific for tuberculosis has been discovered.*

A NEW COLOR-TEST (ROUX'S) FOR THE DETECTION OF THE GONOCOCCUS;

WITH REMARKS ON ITS PRACTICAL IMPORTANCE.

By EDMUND C. WENDT, M.D.,
of New York.

For the past three years the relation of Neisser's gonococci to gonorrhœa has been engaging my attention. My studies were pursued with the view mainly of adding to our clinical knowledge of the subject, and were carried on conjointly with Dr. Charles W. Allen, of New York. I was early struck with the difficulty, if not the impossibility, of differentiating the microbes of blennorrhœa from similar diplococci.

Like other observers, I was unable to confirm Neisser's statement regarding the characteristic appearance of the specific micrococci of gonorrhœa. And, indeed, it is now generally admitted by those most competent to judge, that the gonococcus is not sufficiently well characterized by its morphological attributes, to admit of our establishing its identity. Again, while it is quite true that, in most cases, the peculiar intracellular grouping of the gonococci will render a diagnosis highly probable, nevertheless, I cannot allow to go unchallenged the claim of Bümm, to the effect that this constitutes a truly pathognomonic sign. Among about one thousand specimens, of various secretions examined, I have several times observed this alleged pathognomonic arrangement of microbes within the pus-corpuscles, although gonorrhœa was quite out of the question.

It was not until I had become thoroughly acquainted with Roux's color-test for gonococci, that I felt confident that blennorrhœa could be diagnosticated with certainty, by the aid of the microscope. The method of Roux was made public at a meeting of the Académie des Sciences, held November 8,

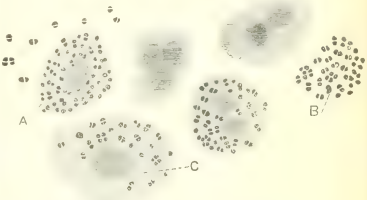
1886. After a considerable number of experiments, I am able to state my belief that it is a reliable one. The method itself is based on the peculiarity of gonococci to hold aniline colors only very loosely, and to become speedily decolorized when subjected to the action of ordinary reagents for that purpose. Although Bumm has found and described no less than five different kinds of diplococci,[1] it does not appear that any but the true gonococci retain aniline colors so poorly as to almost immediately fade from view in the presence of decolorizing fluids. On the contrary, by employing the method of Gram, the ordinary bacteria, as is well known, appear deeply stained. But in a given specimen stained after the manner of Gram, all gonococci invariably disappear, even more quickly than do the anatomical elements thereof.

It appears that Gram's solution of iodine and iodide of potash, so far from fixing the aniline color upon gonococci, as it does upon the other schizomycetes, causes them to give up the stain previously imbibed.

I will now describe, step by step, the method of procedure which I have found to yield the best results, and which differs in no essential respects at least, from that advocated by Roux, to whom is due the credit of having first applied it for purposes of differential diagnosis. The material to be examined is spread in a thin film upon a glass slide by drawing a second slide over it. It is then allowed to dry at the ordinary temperature of the room.[2] The specimen is next stained by one or two drops of a saturated solution of methyl-violet in aniline water. Twenty to thirty seconds are amply sufficient to accomplish this purpose. After washing in distilled water, and placing a cover glass on the slide, it is ready for the first examination. The gonococci are found deeply stained, precisely like all the other microörganisms present in the specimen. The cover-slip is now removed, Gram's solution of iodine in iodide of potassium (iodine 1 part, iodide of potassium 2 parts, distilled water 300 parts) is poured upon the slide and allowed to act for three minutes. After again washing in water, absolute alcohol is poured over the specimen and quickly removed by a gentle stream of water. The cover-slip is now replaced and the specimen submitted to a second examination. This procedure brings out ordinary bacteria in so strikingly beautiful a manner, that it has been called by Friedländer "nearly ideal." But while this is true of microbes in general, the gonococci are found to have disappeared.

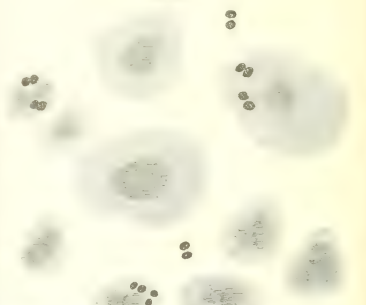
In typical gonorrhœal pus from the male urethra the gonococci exist in such abundance as to overshadow by their presence all other microörganisms. While the intracellular grouping of the microbes is certainly characteristic, that sign alone should not be relied upon in making a positive diagnosis. But if, in addition, the bacteria disappear on the application of the above method, it is safe to assume the presence of blennorrhœa. If, on the other hand, these microörganisms persist, the inference is justifiable that they are not gonococci, even though they should occur in groups within the cells.

FIG. 1.



Usual appearance of the discharge in acute gonorrhœa. A. Intracellular group of gonococci (pathognomonic according to Bumm). B. Extracellular group of gonococci. C. Urethral epithelium containing gonococci. Schematic.

FIG. 2.



Usual appearance of discharge in "nearly cured" gonorrhœa. Schematic.

I have not found it necessary to employ eosine as a contrast-stain, as recommended by Roux. But there is no harm in its employment, and it facilitates focussing in those cases where only gonococci exist in a specimen. The eosine always causes the anatomical elements to reappear with a faint rosy hue, the gonococci also assuming a very faint color. The other bacteria remain purple, and thus a double coloration appears. But it is necessary to have some experience with the use of eosine, or the specimen will be spoiled. I employ an alcoholic solution,

[1] I [illegible] were obtained from various sources, such as ordinary atmospheric air, the preputial smegma, the discharge in acute vaginitis of children, etc. They are all accurately described in the second edition of Bumm's work, entitled "Der Mikro-Organismus der [illegible] Schleimhaut Erkrankungen, Gonococcus Neisser," Wiesbaden, 1877.

[2] I have come to discard the use of heat for drying specimens of gonococci, since their shape is better preserved without passing the glass-slide through the flame.

and allow it to act about one minute. On the whole, I do not regard it as necessary for purposes of diagnosis.

If the experience of others will be found to substantiate, as Dr. Allen's and my own has done, the claim to absolute accuracy made for his method by Roux, then I doubt not a decided step in advance will have been taken. Those familiar with bacteriological methods know only too well how difficult it is to obtain the supreme proof of the etiological significance of the gonococcus by the implantation of pure cultures. Thus so able and competent an observer as Sternberg was compelled recently to admit (The Medical News, February 26, 1887) that he had mistaken a non-pathogenic culture of diplococci for one of the true gonococcus, and that, therefore, the negative outcome of his inoculation experiments was devoid of significance.[1]

Bumm himself only succeeded after many futile efforts, and according to him the gonococcus grows well, outside of the body, only upon human blood-serum. Moreover, in our country it would be difficult to find healthy men or women who would submit to having their sexual organs tampered with to the extent of artificially producing, or attempting to produce, a typical gonorrhœa. In Germany there appears to be no lack of "human material" for the experiments of the enterprising mycologist. As gonorrhœa cannot be produced in animals, we must either depend upon microscopical evidence for purposes of diagnosis, or go without. It is for these reasons that the new color-test described above will be welcomed by the practitioner as placing within his reach a ready means of deciding positively as to the true nature of a discharge.

A word of caution is perhaps necessary here. Granting the absolute reliability of Roux's method as applied to intracellular groups of diplococci, it does not follow that the presence, in a suspected discharge, of the microbes of gonorrhœa must result in a communication of disease under favoring conditions. It does prove the infective capacity of a secretion just as positively as the absence of the gonococci proves the opposite. But that is all. It is a well-known clinical fact that exposure to infection does not always result in an attack of the particular disease in question. This is eminently true of gonorrhœa. I have observed cases of married men whose urethral discharges always showed gonococci, but whose wives remained healthy and gave birth to children showing no sign of ophthalmic blennorrhœa.

But it is also true that men with a minimum of discharge containing gonococci have communicated the disease to others. I have never known a case in which infection resulted in the absence of gonococci. And again I have seen a few cases in which all the clinical symptoms of gonorrhœa were present, but in which the abundant creamy discharge contained no gonorrhœal microbes. In these cases recovery resulted in from two to six days, by letting things alone and ordering a placebo. These are doubtless the cases that appear in literature as "cured" by some "original" or novel plan of treatment. A systematic microscopic examination of all suspected secretions will soon dispel all such illusions. True gonorrhœa is never "cured" in less than four weeks. In many cases the process is of much longer duration. At least this has been my experience with the disease. But true gonorrhœa is not a benign urethral catarrh, it is a virulent inflammation due to bacterial invasion. This should be generally recognized by the profession, for there still prevails in our ranks much looseness of conception regarding the true nature of the disease, coupled with a disposition to shirk the responsibility which modern methods of bacterioscopy have entailed upon every earnest, honest, and well-meaning practitioner.

[1] See Sternberg's articles in The Medical News, of January 29, 1883, and October 18, 1884.

712 Madison Avenue.

REPORT OF A CASE OF IMPERFORATE HYMEN,

WITH SEPTICÆMIA BEFORE AND AFTER THE OPERATION FOR ITS RELIEF.[1]

By C. O'DONOVAN, Jr., M.D., of Baltimore, Md.

In reporting this case, from the service of Prof. Wm. L. Howard at the Hospital for the Women of Maryland, I wish to call the attention of the Society to the pulse and temperature range of the patient, rather than to the operation itself for the removal of the imperforate hymen, as it shows that for an indefinite time before and for a period of more than six weeks after, this girl suffered from the septic influence of chronic blood-poisoning; and that it was only by very careful nursing combined with the assiduous administration of remedies to meet the recurring elevation of temperature and frequency of pulse, that she eventually emerged from her dangerous situation. This will become more apparent as I read the history of the case.

C. S., aged fifteen, white, entered the Hospital for the Women of Maryland, on November 19, 1886. She came from Harford Co., Maryland; and had been seen by physicians before leaving home, who had correctly made the diagnosis of imperforate hymen with retained menstrual blood. She was very pale and anæmic in appearance, miserably thin, and showed no external evidence of the development usual at puberty. She was extremely nervous and irritable, so much so that no satisfactory examination could be made until chloroform had been administered. Her temperature was not taken before the operation, but her pulse was always frequent, varying between 96 and 120, and changing markedly during any prolonged observation, due most likely to her nervous irritability. She had never seen any external sign of menstruation, but at irregular intervals, of late more frequent and more regular, she had felt severe pains in her abdomen and back, at which times her condition would become much more serious. When she was thoroughly relaxed by chloroform, a tense cystic tumor could be felt above the

[1] Read before the Baltimore Gynecological and Obstetrical Society.

symphysis pubis, reaching probably three inches above the symphysis, and easily identified as the uterus, distended by fluid. The external genitals were perfect, but the hymen formed at the mouth of the vagina an absolute barrier to the egress of menstrual blood. The examining finger in the rectum appreciated the presence in the vagina of sufficient fluid to distend it to its fullest capacity, so much so that the uterus was pushed up completely out of reach.

On November 22d, following the method of Emmet, Dr. Howard punctured the vaginal cyst and let out a pint or more of thick chocolate-colored fluid, after which he washed out the vagina thoroughly with hot carbolized water, until the water returned clear. He then cut out with a pair of curved scissors the remnants of the hymen, so that there could be no impediment to the flow. After the operation it was noticed that the lump formed by the distended uterus was still quite apparent above the symphysis, though it seemed not so high in the abdomen. The finger introduced into the vagina could not make out the cervix, on account of the greatly thickened condition of the vaginal walls, which seemed, from the boggy feel they imparted, to be infiltrated with serum. On this account the cavity of the uterus could not be explored.

The treatment after the operation consisted only of rest in bed, and a copious vaginal douche morning and night of hot carbolized water. Her pulse continued frequent, from 100 to 110; but otherwise she progressed satisfactorily until November 26th, four days after the operation, when she complained about midday of a slight chill. At 1 P.M., her pulse was 138, her temperature 98.6°. She was ordered quiniæ sulph. gr. iij every three hours; but at 8.30 P.M. her pulse was 108, her temperature 100°. From this she developed quite a severe attack of septicæmia, with the following daily range of pulse and temperature:

				Pulse.	Temperature
November	25, 10.30	P. M.		142	1[illegible]
"	25, [illegible]	"		144	1[illegible]
"	28, [illegible]	"		120	1[illegible]
"	29, 7.	"		138	100
"	29, [illegible]	A. M.		1[illegible]	99.[illegible]
"	[illegible]	"		1[illegible]	1[illegible]
December	1, 2.30	"		162	102.6
"	1, [illegible]	"		1[illegible]	1[illegible]
"	1, 11.	A. M.		1[illegible]	99.4
"	2, [illegible]	P. M.		1[illegible]	1[illegible]
"	[illegible]	"		1[illegible]	99.
"	4, 11.	A. M.		1[illegible]	99.4
"	5, 2.	P. M.		137	100
"	6, 1.	"		125	99.5
"	7, 9.	"		125	101

This will show the extent of her attack and its subsidence, much more gradual than appears from the table, for at the last rate of pulse and temperature she continued for about three weeks longer, by which time she had gathered sufficient strength to be able to be up and about the Hospital. Her treatment during the elevation of temperature was moderate doses of quinine and of syr. ferri, with forced feeding, principally milk, and some alcoholic stimulation. The vaginal douche was continued throughout convalescence. When her condition was worst, with a pulse of 162 and temperature of 102.6°, on December 1st, the advisability of making an abdominal incision and washing out the pelvic cavity was considered, but postponed; meanwhile her symptoms became much more favorable, rendering operation unnecessary.

On December 22d she was thoroughly examined, and the cervix could readily be felt, but the vaginal walls were still so thick and infiltrated that little definite could be said of the condition of the pelvic organs. Dr. Howard announced his belief that she had a retrouterine hæmatocele, which had existed for an indefinite time, and that her septic symptoms arose from the absorption of material from this mass. This was conjectural, for nothing definite could be felt. She was ordered two of Blaud's pills after each meal, and gradually improved. On January 7, 1887, syr. ferri gtt. xv. t. i. d. was substituted. The cervix could then be felt, high up in the vagina, and soft. The anterior and posterior vaginal walls continued greatly thickened, and infiltrated with serum. Strange to say, she has not menstruated since the operation, although her general health has greatly improved, and her appearance is vastly better.

REMOVAL OF AN ENORMOUS CALCULUS FROM THE PELVIS OF THE KIDNEY BY LUMBAR INCISION, WITH REMARKS.[1]

By FRANCIS J. SHEPHERD, M.D.,

Professor of Anatomy in McGill University, Surgeon to the Montreal General Hospital.

The following case is of interest not only on account of the large size of the stone removed, but also because the question of the comparative merits of nephrotomy and nephrectomy is raised in such conditions of the kidney as existed in this case. The patient was sent to me by Dr. J. R. Johnston, of Spring Valley, Minnesota, with a letter stating he suspected the man was suffering from stone in the kidney.

The history of the case and condition on entrance I quote from the Hospital Report:

"W. C., aged twenty-six, was admitted into the Montreal General Hospital on the 18th of October, 1886, with a history of long-continued pain in the left lumbar region and pus in the urine.

"*History.*—Family and personal history good. Seven years ago he first noticed that small quantities of blood were passed in the urine at the end of micturition; four years ago blood was mixed with the urine, giving it a smoky appearance. Has seen no blood in his urine for two years. During the last seven years he has been troubled with continuous pain, not always very severe, in the left loin, occasionally radiating downward to the crest of the ilium. He occasionally has periods of very severe pain lasting for some two or three weeks, after which he is comparatively well; of late years these periods of pain have not been so frequent, and when they do occur the pain is of a sickening character and causes morning vomiting. Sudden movement, as sneezing and coughing, brings on an attack of pain. Five

[1] Read before the Montreal Medico-Chirurgical Society, March 25, 1887.

years ago first noticed a whitish deposit in urine; up to a few months ago this was quite small in amount, and was passed with the morning urine. No history of renal colic.

"*Present condition.*—Is a fairly well nourished young man, of medium size, and with an anxious expression of countenance; complains of dull, aching pain in left lumbar region, and immediately below the last rib, in the axillary line, is a very tender spot the size of a twenty-five cent piece. He says the pain radiates from this point. Urine has a specific gravity of 1.015, and contains 15–25 per cent. of pus. Some days there is only a trace of pus. At other times there is as much as 25 per cent. Urea, 7½ grains to an ounce. Amount of urine daily excreted, 40–50 ounces.

"By external examination no tumor or fulness can be detected on the left side."

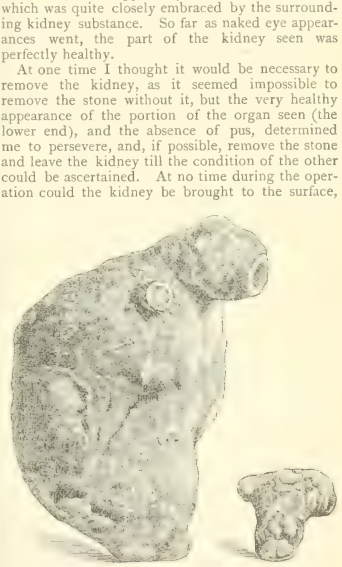
On the 28th of October he was put under ether and the abdomen thoroughly examined by both Dr. George Ross and myself, but no tumor could be made out. The left loin was carefully explored with the long needle of an aspirator, but failed to reach either pus or a calculus. It was concluded from the history of the case and the symptoms that a stone probably existed in the pelvis of the left kidney; so, after consultation with my colleagues, I decided to cut down on the left kidney by lumbar incision, and explore it.

Operation.—October 30th, the patient being under ether, was placed on his right side, with a hard pillow under the right lumbar region, and a horizontal incision was made close below the last rib of the left side, commencing at the edge of the erector spinæ muscles, and extending downward and forward for some five to six inches. After dividing the muscles of the abdomen, the quadratus lumborum was reached, the lumbar fascia divided, and the kidney searched for; the lower end was felt at a considerable depth, in fact, it could be barely reached with the fore and middle fingers of the right hand, so the opening in the loin was enlarged by an incision at right angles to the first, making the wound a crucial one. A long needle was introduced into the kidney and a calculus was immediately felt. The kidney being steadied by pressure from without, I made an incision down to the stone in the long axis of the organ, of some three inches. Through this incision an immense stone could be felt with the finger, but owing to its great fixity and large size it could not be dislodged. Whilst endeavoring to remove the stone, I accidentally ruptured a large artery, which ran to the lower end of the kidney, and was no doubt a supernumerary renal; the hemorrhage was profuse, and I immediately introduced one hand into the wound, and so prevented further bleeding, whilst with the other I managed to catch the bleeding vessel with a pair of long artery forceps.

The stone proved too large to be grasped by a lithotrite, and too hard to be broken by a cutting forceps. I attempted to break it with a chisel and mallet, but failed because of the difficulty of getting fixation of the kidney. The incision in the kidney was now further enlarged, and the stone gradually separated from the kidney tissue with the finger; even now, owing to the prolongations into the calices, the stone could not be removed. With considerable difficulty I managed to free the lower end of the stone which blocked the entrance of the ureter, and lifting it up, requested Dr. James Bell to grasp it with a pair of large lithotomy forceps; this was done, and the stone was brought away after the expenditure of considerable force. On examining the removed stone, it was seen that there were a couple of projections on it, one of which appeared to have been freshly broken off; so the hand was again introduced into the wound and a large fragment removed from a calyx; other smaller pieces were also removed. As the patient had been already an hour on the table, and was becoming weak from shock and loss of blood, no further exploration took place.

During the operation not a single drop of pus was seen; none apparently surrounded the stone, which was quite closely embraced by the surrounding kidney substance. So far as naked eye appearances went, the part of the kidney seen was perfectly healthy.

At one time I thought it would be necessary to remove the kidney, as it seemed impossible to remove the stone without it, but the very healthy appearance of the portion of the organ seen (the lower end), and the absence of pus, determined me to persevere, and, if possible, remove the stone and leave the kidney till the condition of the other could be ascertained. At no time during the operation could the kidney be brought to the surface,



Stone, one-half natural size.

and the operation had to be performed by feeling more than by sight.

After washing out the wound thoroughly with a 1:2000 solution of corrosive sublimate, and introducing a large drainage tube, the wound was brought together with silk sutures and dressed with sublimate jute pads. At the close of the operation the

patient was in a fairly good condition, and did not show much evidence of shock; and, although he had lost a considerable amount of blood, his pulse was full and strong, and not more than 80.

The weight of the removed stone and fragments immediately after the operation was 4 oz. 7 drachms. It measured 3½ inches in length, and 9 inches in circumference, and consisted entirely of triple phosphate.

After the operation, which took place at 2 P.M., the patient did not pass any urine till noon next day, when he voided 7½ oz. As there had been a great deal of oozing, the wound was dressed next day. Temperature 101°. Pulse 120. He still had vomiting from the ether.

Nov. 1. He passed 32 oz. of urine which was free from pus and blood.

For some time the patient progressed slowly toward recovery; his temperature ranged between 98° and 100°, and the amount of urine from 25 oz. to 50 oz. daily. The wound, which was not very sweet, and from which came large quantities of urine, gradually healed, and the tube was removed in the early part of December. He now began to have high and irregular temperature, with some sweating; from the 10th to the 25th of December his temperature ranged from 98° to 102°, and for several days after reached, in the afternoon, as high as 104°–105°. Fearing that some collection of pus was forming about the kidney, I reopened the wound, introduced my fingers, and explored the pelvis of the kidney, but without result, except that a few flakes of calcareous matter were brought away. It was now decided to cut down and remove the kidney, but the patient quite unexpectedly took a turn for the better, and improved so much that, in the early part of January, he was able to go about the ward, enjoy his meals, and gain flesh. The sinus in his right loin never healed, but continued to discharge large quantities of urine with a small amount of pus. At this time my service at the hospital having expired, I only saw my patient occasionally. His temperature was for several days quite normal, and then for a time would range as high as 101°. The amount of urine varied from 30 oz. to 40 oz. daily. I saw him early in February, going about, and apparently in fair condition. On the 10th of February he suddenly became jaundiced, his temperature rose to 102°, and he had severe sweatings. I saw him, and examined his side carefully, but could discover no evidence of any collection of pus about the wound, and the amount of urine reached 40 oz. daily. The fistulous opening in his side discharged urine freely, and a very small amount of pus stained the dressings. He gradually became worse, and died comatose on the 14th of February, three and a half months after the operation.

The autopsy was performed by Dr. Wyatt Johnston, pathologist to the hospital, and the following is taken from his report: "Body jaundiced. In left lumbar region a depressed cicatrix about two inches long is seen with a sinus toward the centre, from which fetid pus can be squeezed out. On opening the abdomen a large oval mass is seen in left lumbar and extending up into the left hypochondriac region. This mass has a quantity of fibrous exudation surrounding it and is very difficult to remove, being firmly attached to the lumbar muscles, spleen, and vault of the diaphragm. The retro-peritoneal glands are acutely swollen, but show no signs of suppuration. The aorta and vena cava are not directly involved in the mass and can be readily dissected off. Near the inferior extremity of kidney, two inches above the crest of the ilium, a small artery one and a half inches long running directly from aorta to kidney, is seen; it is obliterated, apparently from a ligature. The fatty capsule of the kidney is densely infiltrated with fibrous tissue and cannot be removed without tearing the kidney substance; the left kidney itself is greatly enlarged and forms a fluctuating mass weighing nearly 1000 grammes. On opening the pelvis a little fetid pus escapes and the sinus in the loin is seen to open into it. On palpation a small calculus mass can be felt toward the cortex in one of the calices of the kidney, the calculus is the size of a hazelnut and appears to be broken off in one spot. It is enclosed in a small pocket of pus. The ureter immediately below the pelvis of the kidney is completely obstructed and its walls are much thickened. On incising the kidney along its convexity it is found to consist in the upper portion of a series of large communicating sacs containing over ten ounces of fetid pus. These cavities do not communicate with the sinus or the pelvis of the kidney, but are completely shut off from the rest of the kidney by thick fibrous walls, showing that the disease is of long standing. Within these sacs lie five or six irregular branched calculi, varying in size from a bean to a walnut. The lower fourth of the kidney contains a considerable quantity of healthy renal structure. Bladder and lower part of ureter normal. Right kidney double normal size and looks to be perfectly healthy. Liver shows numerous enlarged lymph glands lying beside the bile ducts, but bile can be easily expressed. Other organs healthy."

There is not the slightest doubt that this patient died of septicæmia due to the fetid abscesses in the upper end of the kidney. These could not be diagnosticated by external manipulation, and from the fact that the part of the kidney seen at the operation was healthy in appearance and contained no pus, the condition of its upper end was not suspected.

So far as the operation itself went, it was successful, but one lesson may be learned from this case, viz.: that with a large stone in the pelvis it is almost impossible to have a kidney which has not undergone grave changes, and its thorough exploration by incision is indicated. Had there been pus around the stone and the kidney tissue not looked so healthy, I should have attempted to remove the kidney, but I had in my mind a specimen in the Museum of the Medical Faculty of McGill University, where the pelvis of each kidney, in a man, is filled by an enormous stone whilst the surrounding kidney structure is comparatively healthy and where there was not a drop of pus[1] or the sign of disor-

[1] This specimen is described by Dr. J. A. McDonald in Vol. XII. of Canada Medical and Surgical Journal.

ganization. In my case, however, although in the immediate neighborhood of the large calculus the kidney was healthy, yet the greater portion was composed of pus cavities containing stones unconnected with that in the pelvis.

The kidney was placed so deeply and situated so high up that, with even the very extensive lumbar incision which was made, it could not be properly explored, and I very much doubt if it could have been successfully removed by the loin. Its removal, owing to the numerous adhesions to important organs and its location, would have been a matter of serious difficulty, if not an impossibility, even by abdominal incision, for at the autopsy by the combined abdominal and lumbar incision it was only by cutting freely the surrounding parts that its excision was accomplished.

In such a case incising the kidney in every part, evacuating the pus, and removing the calculi would be the proper procedure. Diseased kidneys which enlarge downward are much easier to remove by lumbar and also abdominal incision, than those which enlarge upward and are wholly under cover of the ribs.

There is another point about this case which is worthy of notice and it is this: When a kidney is highly placed it may be enlarged so as to form a considerably sized tumor which cannot be detected by the most careful palpation even when the patient is placed under ether. The failure to find the stone by needle exploration, before the operation, was due to the same cause—the high position of the tumor and its great depth.

In connection with this case I might mention one reported by Prof. Guyon, of Paris,[1] which is very similar to the one narrated above. In Guyon's case, however, a distinct tumor could be felt externally. After cutting down on the tumor and incising it he found the pelvis of the kidney completely filled by an enormous stone with processes extending into the calices, these processes were cut off with forceps and the large calculus extracted with difficulty; after the removal of the smaller pieces, the pelvis of the kidney was explored with the finger and sound and no more stones could be felt. The patient died some two weeks after from hæmoptysis, and at the autopsy it was found that the kidney was so adherent to the surrounding parts that it probably could not have been extirpated. Several more stones were found in the upper end of the kidney in cavities separated from the pelvis by connective tissue. Prof. Guyon, in the course of his remarks on this case, states that here nephrotomy was preferable to nephrectomy, and that had the kidney been properly incised the other stones would have been found, that in such cases the kidney should be freely incised and every nook and cranny explored; he holds that if this were done in cases of calculous pyelitis nephrectomy would never be called for.

Formerly it was feared that free incision of the kidney would cause severe and dangerous hemorrhages, but experience has taught surgeons that the danger is an imaginary one, and that kidneys which are much disorganized may be incised without fear of bleeding, and that even in healthy kidneys the hemorrhage from incisions is easily and permanently controlled by pressure.

In such cases as the one above narrated, where the stone is of great size and the kidney is enlarged, the mere extraction of the stone in the pelvis should not satisfy the operator; he should thoroughly examine the kidney in every part by free incisions so as to be sure no calculus is left behind. External manipulation of the kidney is not sufficient to detect stone, and in such cases as my own, even exploration through the kidney pelvis would fail, without further incision, to detect calculi unconnected with that in the pelvis.

Up to a short time ago the largest stone removed by lumbar incision was under two ounces in weight. Lauenstein[1] reports a successful case of removal of a large calculus (weighing 25 grammes and composed of the triple phosphates) from the pelvis of the kidney. He had to break the stone with a lithotrite before he could extract it. In his paper he states that it was the largest stone removed up to that time, though not the heaviest. Three months after the operation the sinus in the loin had completely healed and when the article was written the patient was perfectly well.

Dr. John Neill,[2] after relating a case of large renal calculus found after death, quotes from *Cyclop. Pract. Med.* the following case: "A remarkable instance of such calculus occurred in the person of a natural daughter of Sir Richard Steele. No nephritic symptoms took place until shortly before death, when severe pain was felt in the region of the right kidney, fever followed and speedily proved fatal. A calculus of oxalate of lime weighing 7½ ounces was found in the right kidney which was so thin by absorption as to be reduced to a mere membrane. In this instance the stone could be felt, during life through the loins, inducing a belief that the kidney had become ossified (Catal. Museum of Royal Coll. Surg., London. Note by John Hunter)." In this case there was evidently but little suppuration, or the stone could not have been so easily recognized.

Mr. Victor Horsley[3] on Sept. 16, 1885, removed a stone weighing 2¼ ounces from the pelvis of the kidney of a middle aged woman; ten days after she was doing well. It was the largest stone removed from the kidney up to that time.

Mr. W. L. Brown[4] reported a case before the Birmingham and Midland Counties Branch of the British Medical Association, in May last, where he had removed from the kidney by abdominal section a stone weighing 11 ounces. The kidney tumor occupied the right half of the abdomen and contained three pints of pus. The cut edges of the cyst were stitched to the abdominal walls and the cavity drained. The patient died suddenly eleven days after the operation from heart clot. So far as I know, the stone in my case is the largest ever removed by lumbar incision.

ELEPHANTIASIS ARABUM OF THE EXTERNAL GENITALS OF A NEGRESS.

BY WILLIAM E. MOSELEY, M.D.,

AND

ROBERT B. MORISON, M.D.,

OF BALTIMORE.

MRS. G., a large, powerfully built, dark negro woman, apparently between forty and fifty years of age, first presented herself at my private dispensary July 15, 1886. Although a fairly intelligent woman for one of her class, it was difficult to get anything like an exact history of her case. So far as I could find out, her family history was good, as had also been her own general health previous to the first appearance of her present trouble. Her early menstrual history was normal, and since her marriage, whenever she was neither pregnant nor nursing, the flow has recurred regularly and normally, except for an occasional menorrhagia, which, together with a free leucorrhœa (both vaginal and cervical), can be accounted for by the lacerated cervix and perineum and subinvoluted uterus which exist. She has had fourteen living children and several abortions. The last child was born four years ago, and the last abortion (at about one or two months) occurred in April, 1886, only three months before I first saw her.

Some eight or nine years ago she first noticed a decided itching and burning about the vulva and extending into the vagina, which condition was soon followed by what she called "blood boils" about the vulva, and which were accompanied by a great deal of pain and discharge. Following this there was general enlargement of the right *labium major*, and about the same time itching and burning in the fold under each mammary gland, and a thickened condition of the skin in that location.

From that time the disease steadily increased until, when I first saw her, her condition was as follows: The skin in each axilla and in the fold directly under each mamma was much thickened and lying in folds. The skin over the mons veneris was thick, hard, and nodulated, as was also much of that over the nates and around the anus. The right labium major was a large pendulous mass, measuring fully 7 inches in length, 4 inches in breadth, and 2½ inches in thickness. [The exact measurements of the growth, after being in alcohol for nearly five months, are, length 14 cm. (5½ inches), breadth 7.5 cm. (3 inches), thickness 5 cm. (2 inches).] The mass had a hard but rather boggy feel, the skin thickened, and in the lower portion it had a peculiar warty appearance, due to the enormously enlarged papillæ. The left labium major was about one-third the size of the right, was softer and more elastic, and the skin less thickened. The diseased parts were constantly moist, and the only complaint of the patient, aside from the inconvenience of having so large a mass hanging down between her thighs, was the intolerable itching and burning wherever the diseased condition showed itself, together with certain "hot spells and pricking and crawling in the flesh all over." She is able to do considerable work, but is not as strong a woman as one would expect to find in a person of her age and build. Neither the nymphæ nor clitoris were at all involved.

As the weather was very warm, and any prolonged stay in bed would be most uncomfortable, I postponed surgical interference until the fall, giving her a saturated solution of boracic acid for local application, and from the use of which she obtained great relief.

On October 21st, under ether, I removed the right labium major, by means of a Paquelin knife, kept at the lowest possible cutting heat. In spite of every precaution, there was very free hemorrhage, the bloodvessels, especially the veins, being enormously dilated. Bleeding points were tied, and the line of incision sustained by a number of silver sutures. The wound was washed out daily, and dressed with iodoform and tarred jute. Healing took place very promptly, considering the method of operating, and the unavoidable sources of irritation. About half the diseased tissue over the mons veneris was dissected off with a knife, and the edges brought together. This portion healed by first intention. It was thought best to leave the left labium major for a second operation; and as it is the cause of a good deal of discomfort, and is increasing very perceptibly in size, it will be removed at an early date. At this writing there is no sign of any return of the disease on the right side of the vulva.

An item of some interest, as showing an anatomical peculiarity of the male negro, is developed by recalling the fact that in spite of the decided obstruction to coitus offered by the enlarged external lips, this woman aborted only three months previous to my first seeing her.

MICROSCOPICAL EXAMINATION.[1]—The horny layer of the epidermis was normal in its thickness, nor was it changed in its general characteristics. It was intact and the flattened cells, of which it is composed, were unaltered in their relative position or their size. Where in the papillæ the lymph vessels had become so much dilated as to occupy the entire papilla, and lower layer of epidermis, the horny layer stretched across the space forming its upper boundary.

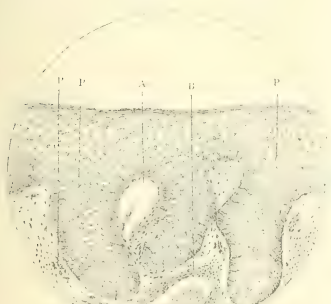
In the rete Malpighii the epidermic cells, especially those in the lowest layer which joins the connective tissue of the corium, were larger than normal. They were swollen, their outer membrane more than usually distinct, and their nucleus or nuclei also enlarged, while the nucleolus was small, and pushed apparently to one side in the nucleus. The peculiar arrangement of pigment in this layer, which is to be described later on, was its most striking feature.

The papillæ were abnormally irregular in length and breadth. Here and there, owing to the dilatation of the lymph-vessels, they were entirely absorbed, and a thin layer of epidermis was all that held their portion of the skin intact. In many places where the vessels of the papillæ were visible, the lymph-vessels were dilated and their contour uneven; no hair follicles were found in any of the sections

[1] The [illegible] examination was made by Dr. Morison in the Johns Hopkins Laboratory.

examined. The sweat glands were the seat of a well-defined round cell infiltration, and their bloodvessels were enlarged, but their usual glandular appearance was not obliterated or altered.

The vessels of the corium were somewhat dilated and were surrounded with round cell infiltration, which, however, affected more intensely the lymph-vessels. The latter vessels were dilated, uneven in outline, or completely filled with lymphoid cells. Their endothelial lining was thickened, and in the tissues around them there was an infiltration of lymphoid cells. The thickening of the endothelium in the smaller lymph-vessels was sufficient to render them impassable. All through the connective tissue of the corium, small and large dilatations of the lymph-vessels were seen. Many of these were lined with endothelium and filled with fibrin. The endothelium was thickened, the nuclei could be beautifully stained, while here and there it was torn away from the surrounding tissue, and lay with one free end within the space itself. See A and B.



A. Dilated lymph-vessel with the endothelium torn.
B. Dilated lymph space containing fibrin, and surrounded by wandering lymph corpuscles.
P. Pigment granules, which are seen in clusters at various points in the corium and as ramifying lines in the epidermis.

(We wish to acknowledge our obligation to Dr. A. C. Abbot, of the Pathological Laboratory, Johns Hopkins University, for this drawing.)

The connective tissue fibres were thickened. The smooth muscular fibres of the skin were enlarged and increased in number.

The nerves, as far as an examination of them was possible, seemed to be unchanged.

All the microscopical appearances here described point this specimen out as coming from a typical case of E. Arabum. The changes in the size and the contour of the lymph-vessels and spaces, the increase in the size and number of the smooth muscular fibres, and the swollen appearance of the epidermis are all characteristics of this disease.

Allusion was made above to the remarkable arrangement of pigment seen in this specimen. In the corium, underneath the line of the papillæ, a comparatively large quantity of pigment granules was visible. It was collected together in small heaps within round and branching cells, and also apparently scattered about in fine granules without them. In the epidermis, besides the ordinary collection of pigment in the lower layers of the rete Malpighii, it was seen to run upward from these layers in chains of very fine granules, so that it made a network of dark lines, which surrounded the epidermic cells as far up as the horny layer. It gave the sections the appearance of having been stained with gold. (See P.)

As this is a most unusual appearance in the skin, even of a negro, where the pigment is so profuse, the question of how it happened to be thus arranged is an interesting one.

Experiments by Key, Retzius and by Unna tend to prove the fact that the lymph circulates in the epidermis between the epidermic cells. Injections of the lymphatics of an œdematous skin with gold have shown that the gold will sometimes penetrate between the epidermic cells, as far as the horny layer. Unna supposes that, in an œdematous skin where the lymph spaces are enlarged, the pigment, if present in the lower layers, is taken up by the lymph-bodies and deposited between the cells of the epidermis.

In the specimen here described, although in places the pigment was seen to be within cells, it was apparently for the most part without them. The fine network of dark lines was probably made by the lymph bodies, which deposited the pigment as they circulated between the epidermic cells.

MEDICAL PROGRESS.

The Use of Iodoform Gauze in Gynecology.—Fritsch writes, in the *Centralblatt für Gynäkologie* of March 12, 1887, as follows regarding the uses of this material in gynecology; he uses it principally for tampons, choosing gauze containing ten per cent. of iodoform, the drug being in the form of powder or suspended in glycerine. The tampons used are made of pledgets three-fourths of an inch long and about two inches wide, combined as occasion demands. They remain longer antiseptic than material dipped in five per cent. solution of carbolic acid, they can be left *in situ* from four to six days, and can be removed without pain and often by the patient herself. These advantages find excellent illustration in the palliative treatment of carcinoma; Fritsch calls his method of treating this affection by this means the "dry" treatment of carcinoma. The secretion, hemorrhage, decomposition, and pain are lessened, so that the patient is able to go about with comfort; cases of cancer have been kept without odor until death by this means. In a number of cases the uterus was reduced to a mere shell, the inner surface of which presented a mass of anæmic granulation tissue. Fritsch has, in many cases, curetted away the cancerous tissue and cauterized its site with the Paquelin thermo-cautery; the uterine cavity has then been thoroughly powdered with iodoform and

tannin, and to stop bleeding and favor uterine contraction a tampon is placed in the uterine cavity which may remain there five or six days. The after-treatment consists in the insertion twice weekly of iodoform and tannin or iodoform and glycerine tampons; they may be most easily inserted by curved dressing forceps.

Iodoform gauze is also used with good results as a tampon after the removal of placentæ and the remnants of ova left after abortion; the uterus should be first gently curetted, washed out with an antiseptic fluid, and then tamponed with gauze.

The cervix may also be tamponed to advantage after the various operations which are there performed.

After removal of cancer of the uterus and pelvic sarcomata, where the peritoneum cannot be united over the stump, iodoform gauze should be packed into the wound; by virtue of its absorbent powers it will serve as a most efficient means of drainage and disinfection.

After laparotomies, in which the tissues are so diseased that it is impossible to unite by means of suture, the tissues should be powdered with iodoform, and brought together by gauze compresses, and from the lower end of the wound a strip of gauze should emerge for drainage. The so-called "capillary drainage" of serum and other fluids of the wound effected by the gauze is very marked; iodoform poisoning was never observed.

The writer cites 6 complicated cases—3 ovarian tumors, one of which had suppurated; 2 extrauterine pregnancies; and 1 carcinoma of the body of the uterus which healed promptly after operation by the method described.

ON THE DIFFERENT MODES OF ADMINISTERING MERCURY IN SYPHILIS, AND THE INDICATIONS FOR THEIR APPLICATION.—At the meeting of the Medical Society of London, held February 21, 1887, DR. E. MILNER stated that he believed that mercurial preparations might be administered somewhat as follows: Green iodide of mercury with Donovan's solution in large doses in light-haired people, especially wine-drinking females who suffer from an obstinate vesicular eruption. German blue ointment in the incipient tubercular syphilide occurring in dark-haired beer-drinkers. In drunkards with a severe and angry-looking rash, green iodide of mercury, Donovan's solution, and iodide of sodium. Calomel vapor in the treatment of indurated local sores and ulceration of the extremities. DR. DRYSDALE thought that when the use of mercury itself was questioned, the differences between its compounds need not be discussed. He considered potassium iodide the proper remedy in the tertiary stages. DR. LAUDER BRUNTON thought it a question whether mercury is most injurious to the germs of the disease or to the tissues. Potassium iodide is not a germicide, and possibly its action is on the tissues. DR. J. ALTHAUS has found blue ointment, with as much lanoline, excellent, also tannate of mercury internally.—*Provincial Medical Journal*, April 1, 1887.

A SIMPLE METHOD OF PREVENTING ARTERIAL HEMORRHAGE.—DR. MUSCROFT, of Cincinnati, described in the *Lancet-Clinic* of April 2, 1887, the following method of preventing arterial hemorrhage, which was entirely satisfactory in a successful amputation at the hip-joint, and a high amputation of the arm for elephantiasis:

"He proposed to pass a strong pin or needle under the femoral vessels *en masse*, high up in Scarpa's triangle, and then, by winding a cord around the exposed ends of the needle, protected by corks, in a figure-of-eight turn, to secure sufficient pressure to occlude the artery completely. This method of compression before the operation could not possibly do any harm, and if properly applied there could be no danger of hemorrhage. The additional advantage would be secured that there were no tourniquets or bandages to slip when their point of resistance was removed by the disarticulation of the head of the femur, and the apparatus for controlling the hemorrhage was not at all in the way of the operator or his assistants."

As soon as the patient was fully under the influence of the anæsthetic, a needle one-eighth of an inch wide, slightly bent at the point, about the thickness of a dime, and four inches long, was introduced perpendicularly into the front of the thigh, about an inch and a half below Poupart's ligament. The exact point of entrance was one-fourth inch internal to the combined sheaths of the vein, artery, and nerves. The point was pushed beyond the vessels, then turned outward until the needle had passed beyond them; the point was then pushed out through the integument. The needle was then behind the vessels and nerve. A piece of cord was passed under the heel and point of the needle, forming a figure-of-eight ligature. Before the ligature was applied the femoral artery could be felt pulsating strongly, but when it was tightened the pulsation below the needle had ceased entirely.

The compression with the needle and figure-of-eight ligature was entirely successful in preventing any bleeding from the brachial artery. The needle was introduced from before backward, and parallel to the borders of the axilla. The point and heel of the needle were protected, as on the former occasion, by corks.

AMMONIUM PICRONITRICUM.—The following is a formula for the administration of this substance, which has been used in the treatment of malaria:

R.—Ammonii picronitrici . gr. 4½ to gr. 24.
Pulv. rad. glycyrrhizæ gr. 24.
Syrupi glycyrrhizæ . m 24.
M. div. in pil. 30 in num.

It should be observed that the salts of picric acid, when mixed with dry substances, form explosive compounds, and a liquid should always be used in their combinations.—*Therapeutische Monatshefte*, March, 1887.

A METHOD OF PREPARING CARBOLIZED GAUZE.—The following is the method described by ENGLAND in the *Journal of Pharmacy* for April, 1887: This is by far the most important and the most in demand of all the gauzes and enters into medical practice whenever the Lister dressings are employed. It is very apt to deterioration on keeping from the volatilization of its contained carbolic acid, but this can, in a very large measure, be prevented if the finished product be wrapped in paraffin paper. The formula employed is based to a certain extent upon that of Von Brun's (carbolic acid 10 parts, resin 40 parts, castor-oil 8 parts, and alcohol 200 parts), but it varies in containing glycerine in the place of the

oil, and, in addition, petroleum benzin. The following formula contains ten per cent. in weight of carbolic acid, in the finished product:

Carbolic acid . .	239 gm. (8 oz. av., 188 gr.)
Alcohol . . .	1200 gm. (42 oz. av., 144 gr.)
Glycerine . . .	150 gm. (5 oz. av., 127 gr.)
Resin . . .	300 gm. (10 oz. av., 255 gr.)
Benzin . . .	1400 gm. (49 oz. av., 168 gr.)
Gauze . . .	1700 gm. (59 oz. av., 423 gr.)

Triturate the resin in a mortar with the benzin, add the alcohol, in which has been dissolved the carbolic acid, and then add the glycerine. Lastly, soak the gauze in 3- or 6-yard pieces, in this mixture, kneading well, to secure uniform diffusion; express and hang the gauze on frames to dry. It dries very quickly, after which, fold in rolls and wrap up in paraffin paper. In order to increase the efficiency of the gauze, it has been recommended that the layers of gauze, prior to application, be dipped into a 1 to 40 aqueous solution of carbolic acid.

In this gauze the acid is, of course, the active ingredient. The resin is used to prevent the washing away of the acid by the discharges from the wound, while the glycerine is employed to make the resin less brittle, and help, also, the retention of the acid in a more than ordinarily soluble form. Benzin is used to reduce the cost.

Disinfection of Dwellings and of Inhabited Rooms.—Drs. Guttmann and Merke, of the City Hospital Moabit, in Berlin, have made an investigation as to the relative value of various methods of disinfecting inhabited rooms, and have published the results in a paper in *Virchow's Archiv* of March 2, 1887. The main points kept in view in the inquiry were that a satisfactory method should destroy the vitality of the bacteria, should not injure the house or furniture, should not be dangerous to the health of the person in the house or of the person applying it, should involve the least possible labor in its use, and be as cheap as possible. The bacillus anthrax was taken as the test organism, and was dried in silk fibres and scattered through the room, on rugs, etc. Disinfection was attempted by rubbing the floors, ceilings, and walls with disinfectant fluids and by spraying the same on the rugs, etc. The solutions experimented with were a five per cent. solution of carbolic acid, and solutions of bichloride of mercury of various strengths. Their conclusion is that a solution of bichloride of mercury, 1 to 1000, used as a wash and a spray, is the most certain, the cheapest, and in all respects the best for disinfecting inhabited rooms.—*Sanitary Engineer*, April 9, 1887.

Treatment of Phosphaturia.—Cantani is quoted as prescribing as follows in the *Centralblatt für klinische Medicin* of March 26, 1887:

℞.—Acid. lactic. . . . . ♏ 45.
Aq. fontis . . . . ℥ 6½.
Aq. menth. piper. . . . ad ℥ 8.—M.

Sig.—Two or three tablespoonfuls in half a glass of soda water every two hours.

Bacteria in Ice.—Fränkel, of Berlin, has examined ice for bacteria, and has found them present in considerable numbers. Ice from the water of springs showed bacteria, as did the ice of river water. Bacteria, however, were not found in ice made from distilled water, and ice intended for direct application to wounds and other portions of the organism exposed to direct contagion should be made from distilled water. Ice from ordinary sources of supply may be used to preserve foods, as meats, if the food be thoroughly cooked at high temperature before it is eaten. Of course, when ice is not brought in contact with food, but is packed about vessels, it need not be carefully selected.—*Centralblatt für klinische Medicin*, March 26, 1887.

The Results of Pasteur's Treatment.—Lutaud, of Paris, editor of the *Journal de Medecine*, has written as follows regarding the results of Pasteur's method:

In answering the objections of M. Peter, Vulpian replied at the Institute, on January 24th, and gave the statistical statements which the Institute immediately sent out all over France. He said: "We have inoculated 3000 persons: the death-rate from rabid bites was formerly 160 per 1000. Without M. Pasteur, then, 320 persons would have died in 1886 from hydrophobia; as only 22 died, we have saved 300 lives."

The arithmetic seems correct; but what is no less evident is that, by M. Pasteur's novelty, the number of persons attacked by hydrophobia is suddenly increased to an extraordinary extent. It must be ascertained how many deaths occurred before M. Pasteur. If the number in 1886 is as high as it was before, it follows that the new treatment is without effect.

What was the death-rate before 1885? An eminent professor, Tardieu, found 25 deaths annually during a period of thirteen years. Professor Brouardel lately, during a period of twenty-three years, has found 30 cases yearly. Tardieu said that nearly all the departments answered his circular. M. Brouardel states that only two-thirds gave him the information that he required. Admitting this statement, if 30 is the number of deaths for two-thirds of the departments, 45 will be the number for the whole of France.

Now, in 1886, 39 deaths have occurred. Where, then, are the advantages of the new method?

With regard to the terrible charge brought against M. Pasteur by M. Peter of causing paralytic hydrophobia by his inoculations, M. Vulpian says that the disease is not so rare as is generally believed, and M. Brouardel has recalled one instance spoken of by Van Swieten.

Meanwhile, until M. Vulpian's assertions as to the infallibility of M. Pasteur's method are confirmed by new facts, I advise my professional brethren to keep to the old method of cauterizing the wounds. The statistical accounts prove that out of the 25 fatal cases of hydrophobia in 1886, only 3 had been previously cauterized. This neglect arises from the blind faith in M. Pasteur's treatment which is at present so prevalent.

I may add, that nine persons have died during the last two months with strange symptoms of paralysis (paralytic hydrophobia) after having been submitted to the new intensive method. These facts are perfectly conclusive. If M. Pasteur cures hydrophobia, the cure is not a certainty as affirmed by M. Vulpian, and the new intensive method is far from being harmless.—*British Medical Journal*, April 2, 1887.

Formulæ Successfully Used in a Case of Severe Croup.—Lewentaner, of Constantinople, successfully

treated a case of severe croup in which suffocation was imminent by a large dose of turpentine, as described in THE MEDICAL NEWS of March 12, 1887; he used in addition the following formula in spray, which we take from the *Centralblatt für klinische Medicin* of March 26, 1887:

℞.—Tinct. eucalypt. glob. . . . ℥ ss.
Acid. carbolic. cryst. . . . gr. 75.
Ol. terebinth. rect. . . . ʒ ij.
Alcohol . . . . . ad ʒ iv.—M.

The following was given internally:

℞.—Hydrarg. [illegible] . . . gr. ½.
Tinct. aconiti . . . . ♏ x.
Aq. destillat. . . . . ad ℥ 4.—M.
Sig.—To be taken *during twenty-four hours.*

TURPENTINE IN IMPETIGO.—DR. SAERBS recommends essence of turpentine as a local application in impetigo of the scalp or other hairy part. The preparation should be well rubbed into the skin and the roots of the hair with the fingers. After about five minutes it should be washed off with carbolic soap, and afterward with warm water. Tincture of iodine should be next applied. This treatment should be carried out once or twice a day; it causes slight itching, but is not painful. The author has found it successful where other modes of treatment have failed.—*British Medical Journal*, April 2, 1887.

THE TONIC TREATMENT OF THE HAIR.—DR. FOLEY, of Boston, writes as follows in the *New York Medical Journal* of April 9th, on this subject:

A wineglassful of aromatic spirits of ammonia added to a basinful of water is very cleansing and refreshing. Care should be taken that it does not get into the eyes. The shampoo as given by the barber is too rough and vigorous, and the conglomeration he puts on the head afterward is anything but beneficial. While one performs daily ablutions of the face, hands, and body, the head is generally left out. This should not be; it is as necessary to wash the scalp as any other portion of the body. The hair should be brushed daily. Too much violence must be guarded against. It should be brushed gently in the direction in which it lies. A harsh brush should be used to cleanse the scalp of dust and dandruff, and then the hair-shafts should be smoothed and polished by means of a softer brush. The scalp should receive a roseate glow. This insures quicker circulation in the follicle about the hair-papilla, and hence the growth is invigorated. Hair-tonics have the same effect upon the skin—viz., a stimulating effect upon the skin capillaries. Morning and night, before retiring, is the best time for brushing the hair. Too hard brushing tends to produce dandruff. In brushing, the object is to cleanse it from extraneous materials, such as feathers, dust, dandruff, and concrete sebaceous material, which often oozes out upon the scalp, to make it smooth, and to bring truant hairs into the right place, and set at harmony discordant filaments.

Friction polishes the hair as well as bandoline or ointment. The end we seek in building up a scanty hair crop is a proper amount of blood-supply, through friction and hair-tonics. The appended is an excellent hair-tonic:

℞.—Acid. carbolic . . . . . ʒ ss.
Tr. nucis vom. . . . . ʒ ij.
Tr. cinchonæ rubræ . . . . . ℥ j.
Tr. cantharidis . . . . . ʒ ss.
Aq. [illegible] . . . . . ad ℥ iv.—M.
Ol. cocois

Apply once or twice a day to the scalp by means of a soft sponge. This will prevent the hair from falling out if it does not produce a luxuriant crop.

NEW FORMULÆ FOR HYPODERMATIC INJECTIONS OF SUBSTANCES COMBINED WITH LIQUID VASELINE.—MEUNIER, of Lyons, continues his series of formulæ of combinations with liquid vaseline as follows:

℞.—Eugenol . . . . . 3 parts.
Liquid vaseline . . . . 100 parts.—M.
Filter twice.

Eugenol, active principle of essence of cloves, is considered a very powerful microbicide.

℞.—Helenine . . . . . 1 part.
Liquid vaseline . . . . 100 parts.

Triturate together while cold; heat over a water bath until solution occurs; filter through double paper.

Helenine is the active principle of the essence of elecampane root, and is regarded as a microbicide.

The greater number of alkaloids are very soluble in vaseline, but, by adding an intermediate dissolvant, the quantity of alkaloid dissolved can be greatly increased. Injections should be made immediately after their preparation, to avoid precipitation of a portion of the solid.

℞.—Cocaine . . . . . 2 parts.
Liquid vaseline . . . . 100 "

Triturate; heat over a water bath, filter through two papers.

This solution is employed for local anæsthesia upon the skin; in the eye; in the larynx, and about the teeth; its action is more prolonged and sure than that of a watery solution, because of the penetration of the vaseline beneath the skin:

℞.—Chloroform . . . . . 20 parts.
Liquid vaseline . . . . 80 "

This injection is without pain, and is very useful in sciatica and neuralgia:

℞.—Crystal. aconitine (Duquesnel) gr. $\frac{3}{200}$.
Chloroform . . . . ♏ 15.
Liquid vaseline . . . ʒ 1.

Dissolve the aconitine in chloroform, mix with the vaseline and filter.

The contents of Pravaz's syringe, containing $\frac{3}{100}$ of a grain of aconitine, may be given for intercostal neuralgia:

℞.—Crystallized digitaline . . gr. $\frac{1}{200}$.
Chloroform . . . . ♏ 15.
Liquid vaseline . . . ♏ 75.

Dissolve the digitaline in the chloroform and add the vaseline.

This may be injected for cardiac asystolia, when caffeine and digitalis are not tolerated by the stomach, in doses of sixteen minims:

℞.—Quinine . . . . . gr. 3.
Absolute alcohol . . . gtt. 10 to 15.
Ether . . . . . gtt. 10 to 15.
Liquid vaseline . . . ʒ 5.

Triturate the quinine in alcohol until completely dissolved, add the ether and then the vaseline, and filter.

Meunier, discussing Bouchard's experiments in producing cataract in the eyes of animals by naphthaline, has injected vaseline into the eyes of sheep and rabbits, a third or a fourth the volume of the eye, with perfect diffusion and no irritation.

He finds that cholesterine is soluble in vaseline in proportion of 1 to 100 at the temperature of the human body. It seems rational to suppose that hepatic calculi may be dissolved by injections of vaseline.

It may be also given in capsules in typhoid fever and diseases of the digestive tract, as it is inoffensive and digestible. Substances intended to disinfect the intestines, as iodoform, thymol, and eucalyptol, can be thus injected easily and harmlessly.

Meunier, however, considers *pure* liquid vaseline the most satisfactory medium for the hypodermatic injection of the remedial agents mentioned.—*Bulletin de Thérapeutique*, February 28, 1887.

Splenectomy for Wandering Spleen.—Dr. W. H. Myers, of Fort Wayne, Indiana, reports the following case in the *Journal of the American Medical Association* of April 2, 1887:

Upon making an examination I discovered that the tumor was then resting on the brim of the pelvis, and extending above the umbilicus. It had suppurated, and three sinuses existed, communicating with the abscess. The discharges were offensive, almost intolerable. The patient was emaciated, had chills with profuse perspiration at night, and great loss of appetite. Her surroundings deterred me from venturing to relieve her by any surgical procedure at her home. By agreement she was brought to Fort Wayne and placed in St. Joseph's Hospital.

The cleansing of the skin over the tumor, and for some distance around, was carried out by washing it with a carbolic acid solution, 1–20, after which stimulants were administered, when she was placed under the influence of ether and removed to the operating table. The line of incision was six inches in length, extending two inches above the umbilicus and made in the *linea alba*. During the progress of the operation the strictest antiseptic precautions were observed. Silk ligatures, previously carbolized, were applied to the bleeding vessels and then cut short; the hemorrhage was thus arrested completely before dividing the peritoneum. The peritoneum was caught up with forceps, and incised with a knife sufficiently to admit the completion of the incision with scissors. This was followed by a free discharge of sero-purulent fluid, received upon the towels and sponges conveniently placed for this purpose. The tumor was now freely exposed, and proved to be a displaced and wandering spleen, indurated, and greatly enlarged, lying in a peritoneal abscess. I succeeded in lifting the spleen from its resting place, the brim of the pelvis, and in securing the pedicle, composed of the vessels and fibrous tissue, much elongated. While the tumor was partially lifted from its bed, I succeeded in transfixing the pedicle with a needle, armed with a double thread of silk, and ligated it in two portions. The pedicle was then cut short and dropped back into the cavity occupied by the spleen; so also were the ligatures. Into the cavity occupied by the spleen carbolized sponges were introduced repeatedly until the hemorrhage was entirely arrested. This was followed by the insertion into the lower angle of the wound of a large size glass drainage-tube, and I proceeded to close the wound with stitches of silk thread, including the peritoneum. After the edges of the wound were carefully approximated, and the surface washed with carbolized water, protective gauze was placed over the line of incision, and over it a layer of carbolized cotton and antiseptic gauze; and over these a firm snug-fitting flannel bandage; over the mouth of the glass tube, carbolized gauze. The spleen weighed seven pounds.

The patient was now removed and placed in bed, wrapped in warm blankets, and bottles of hot water placed about her. The evidence of shock disappeared in a few hours. The after-treatment consisted in the administration of tonics, stimulants, and food, washing out the abscess cavity daily with carbolized water, 1–20, until the removal of the drainage-tube; this occurred on the twelfth day.

On the ninth day the first dressing was removed and union was found to be almost complete; the deep stitches were removed, and the superficial stitches allowed to remain until the fourteenth day.

Her pulse never exceeded 110, and her temperature never exceeded 102°. Her appetite improved rapidly, and her previous bad symptoms disappeared, so that in twenty-one days she was enabled to leave the hospital, and her recovery at the present time is complete.

Operation for Post-nasal Sarcomatous Tumor.—Dr. S. P. Duffield writes as follows in the *American Lancet* of April, 1887, of a visit paid by him to von Wahl, of Dorpat, Russia, an eminent surgeon, who succeeded Bergmann in the professorship of surgery:

"An operation I saw him perform for post-nasal sarcomatous tumor was as follows: Instead of the old-fashioned Mott way of splitting the nose, he made an incision across the nose, following the line of the articulation of the ossa nasi with the os frontis, and then down the right side in the line of the articulation with the maxillaris; breaking through the articulation of the os frontis with chisel and mallet, he turned the nose over upon the cheek and had a good, unobstructed opening through which to work, and with a curette removed the tumor piecemeal, replaced the nose, fastened with sutures, dusted with iodoform, and dressed as usual. Two days after the patient came into the clinic, and the nose looked as natural almost as ever."

Infantile Constipation.—A very successful remedy for this is podophyllin, in small doses; iridin may be combined with it with good effect. Make a tincture of the following:

Podophyllin resin.	gr. viij.
Iridin	gr. v.
Spt. ammon. arom.	℥j.

Digest for several days, and filter.

One or two drops of this may be given at bedtime on a small piece of loaf sugar, or the dose may be combined in mixture along with syrup of orange. This is the dose for a child of one year and under.—*The Chemist and Druggist*, March 19, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

THREE DOLLARS PER YEAR . . . . .

SINGLE COPIES, ... TEN CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, APRIL 23, 1887.

ETHER OR CHLOROFORM?

THE *vexata questio* of a suitable anæsthetic continues to be far from a unanimous decision. The increasing employment of ether, and the corresponding disuse of chloroform during several years past, are the result of a conviction that the former is far safer. No attentive observer, however, can fail to see the evidences of a beginning reaction in favor of chloroform. The opinions expressed by members of the New York Academy of Medicine during a recent discussion, a report of which appeared in our last issue, indicate that the superiority of ether is not admitted by some of our New York colleagues as an article of medical faith. It is obvious enough that the facts brought forward by Dr. Gerster are of a character to disturb the confidence of the ether partisan, and will do so unless an erroneous interpretation has been given to the fatal cases.

During this discussion, the belief was expressed that ether owed the immunity from accidents, which had hitherto attended its administration, to the comparatively small number of inhalations formerly practised, and that chloroform had got its evil repute from its indiscriminate use in a vast number of cases. It was, also, intimated that deaths from ether have been increasing with an increasing number of inhalations. In respect to the character of their comparative danger, it appears to be the consensus of opinion that chloroform is more apt to kill during the inhalation, whilst ether induces morbid states of the respiratory organs which prove fatal subsequently.

If the experiences of our New York colleagues are confirmed by general observation, the questions will be—When ether? When chloroform? and the decision will rest on the provisions which can be made use of, to render one or the other safer under the existing conditions. The immediate and remote dangers being known, how can we best avoid their occurrence by modes of practice now available or to be hereafter discovered?

That the condition of anæsthesia as now produced, must inevitably be a condition of danger, can hardly be disputed, since it consists in an entire suspension of the functions of animal life. The way to safety consists in maintaining the organic functions of circulation and respiration, for the failure of one is of necessity fatal to life. That anæsthetic which least endangers these functions, or whose injurious action is most easily obviated, is best, provided that it has no after-effects, which, if slower, are equally fatal.

We do not find in the discussion under consideration an adequate statement of the means to prevent or to remove dangerous indications. That does not appear to have been Dr. Gerster's intention, and in the course of the discussion this subject was only incidentally mentioned. This, however, is an important part of the subject, since the decision of the question may be much influenced by the readiness with which danger-symptoms may be prevented.

"Mixed anæsthesia," as it has been designated with little felicity, has paramount importance in this connection. By this term is meant the suggestion made, originally, by Bernard, and afterward practised and strongly advocated by Nussbaum, that morphine be administered subcutaneously before commencing the inhalation. Of late the combination of morphine and atropine has been advantageously substituted. The good effects of this practice are these:

It facilitates the inhalation by allaying the irritability of the broncho-pulmonary mucous membrane; it prevents that tetanic condition of the muscles, especially those of respiration, called "the stage of rigidity;" it prolongs the insensibility with a less quantity of the anæsthetic; it diminishes the shock of the surgical procedure; it serves to maintain the functions of respiration and circulation; it relieves much of the after-pain, and it prevents the inflammatory reaction which arises after the immediate effects of the anæsthetic are spent.

We know that it has been asserted by the opponents of this practice, that the hypodermatic injection is only an addition to the dangers of the anæsthesia. It may be replied, that any misadventure properly attributed to the injection was due to the careless use of too large a dose—for the amount necessary will rarely exceed $\frac{1}{6}$ of a grain, and often not more than $\frac{1}{12}$ grain of morphine, and $\frac{1}{150}$ grain or even $\frac{1}{200}$ grain of atropine.

To inefficient, negligent, even bad modes of administration, may often be referred the unpleasant

action, or the fatal result. Inattention to the high density of chloroform vapor, and to the proportion of air necessary to carry on the function of the red globules of the blood, are two common causes of accident from the inhalation of chloroform. Then it is we hear of a mysterious idiosyncrasy—that a few whiffs of vapor caused death because some inexplicable condition existed—when the real truth is that those few "whiffs" consisted of chloroform vapor and that the red globules were suddenly deprived of their oxygen, and the motor ganglia of the heart immediately ceased to functionate. On the other hand, in giving ether, so much air is admitted that the stage of excitement is greatly lengthened, the rigidity becomes extreme, and the respiratory organs are irritated by the prolonged contact of the ether vapor. If ether is properly administered and insensibility is promptly produced, fewer examples of pulmonary inflammation may be expected to occur, if any were ever due to this cause.

As between ether and chloroform, the suddenness with which the latter acts, and still more the character of the action, when it causes danger-symptoms, makes it by comparison far less suitable as a general anæsthetic than the former, and as the untoward effects of ether are much more amenable to treatment by the usual restorative measures, its advantages are still more conspicuous. If, however, the after-results of ether administration are so serious as the recent experience seems to indicate, the choice between them must be decided by other considerations than those of safety. It may, indeed, finally appear that the choice between them is to be determined by the character of the case in which anæsthesia becomes necessary. In that event, the mode of administration will be the chief object of attention. It is surely not flattering to the professional vanity, as it is rather derogatory to the professional humanity, that so many fatal cases are attributable to carelessness, to ignorance, and to mere accident that might have been avoided.

THE TREATMENT OF BACKWARD DISPLACEMENTS OF THE UTERUS.

Amid the animated discussions that have been provoked by the procedures advocated by the bolder surgeons of the present day, for whom the peritoneal cavity has none of those terrors that it once inspired, some minor problems in gynecology have suffered comparative neglect. What gynecologist, what general practitioner, indeed, is there to whom the treatment of backward displacement of the uterus is not a problem presented constantly for solution? And yet it is a problem still unsolved. Shall he use mechanical supports? shall he employ electricity? shall he perform a plastic operation in the vagina? or must he accept the teachings of those who look to laparotomy as the panacea for all the ills that female flesh is heir to?

The inquirer may obtain a variety of answers to these questions in the report of the discussion of a paper by Frankel, of Breslau, read before the Gynecological Section of the last Congress of Scientists and Physicians in Berlin. Fränkel found that among more than five thousand gynecological cases eighteen per cent. had backward displacements of the uterus, and about seventy per cent. of this number admitted of mechanical treatment; for which purpose, after the uterus has been replaced, he prefers above all others the Thomas pessary, having with it in about eight per cent. of his cases effected a permanent cure; but the treatment was a tedious one, pessaries being used, on an average, one year, and in one case more than two years. This length of time might easily exhaust a physician's patience, and this explains the eagerness with which Alexander's operation for the radical and rapid cure of retroversion was at first adopted, but Fränkel takes occasion to condemn the operation, and his condemnation was endorsed by the majority of the Society.

In the discussion that followed the paper Küstner also recommended the Thomas pessary, while Martin and Veit expressed a decided preference for the Hodge pessary. Sänger spoke strongly in favor of the prophylactic treatment of uterine displacements. He made it a rule, he said, to examine every patient during the first few weeks after confinement, in order to correct any tendency to a retro-deviation, for, in his opinion, these displacements most frequently occurred during the puerperium. Czerny spoke of having sewed the fundus of a uterus to the abdominal wall at the close of an operation for the removal of diseased tubes and ovaries, and Veit related a similar experience, but said that he had little reason to be satisfied with the position of the uterus a year and a half after the operation.

Frank described an operation that he performed in order to dispense with pessaries altogether. The peritoneum was loosened from the uterus and bladder and passed upward in a fold, and was fastened by catgut stitches, which, at the same time, brought the raw anterior surface of the uterus in contact with the denuded surface of the posterior wall of the bladder. Schwarz, on the other hand, recommended the simplest mechanical contrivances, and used, he said, the ordinary Mayer's ring in connection with injections of astringent solutions, while Martin expressed his belief that all treatment of backward displacements of the uterus was unnecessary, unless the displacement was associated with disagreeable symptoms or sterility.

This wide diversity of opinion indicates how unsatisfactory, after all, are the means at our command

for the treatment of retroversions and flexions of the uterus, but it seems to us that a sound judgment would dictate the exercise of some patience in the application of mechanical means of support, and that operative procedures, often difficult of execution and unsatisfactory, even sometimes dangerous in results, will not find a permanent place among the remedies for this condition.

OSTEOPLASTIC RESECTION OF THE FOOT.

IN THE MEDICAL NEWS for January 29, 1887, we called attention to the operation of resection of the foot and leg, known by the names of Wladimiroff and Mikulicz. One such operation has recently been performed in this country, by FENGER, of Chicago, and is reported in *The Journal of the American Medical Association* for January 29, 1887. Another, as yet unreported, was performed a few weeks ago by HOPKINS, of Philadelphia.

The operation of Hopkins was done for an ulcer involving the entire heel and more. Six months before, a car-wheel had carried away all the tissues down to the bone, leaving an isthmus of skin, an inch and a half wide, on the dorsum of the foot. The operation was modified, according to the suggestion made in our editorial of January 27, by suturing the tendo Achillis to the tissues of the foot, Hopkins choosing for this purpose, the plantar fascia, instead of the periosteum of the scaphoid and cuboid bones. He also sutured the retrenched tendon of the peroneus longus muscle, and the posterior tibial nerve, and pegged the tarsus of the leg bone with sterilized bone dowels. So far, the patient has done very well.

In connection with these two operations we would call attention to an interesting enlargement of the scope of this method, as illustrated by a case reported by GUTSCH, in the *Archiv für klinische Chirurgie*, Bd. xxxiv. Heft 3. The patient, a boy twelve years old, had previously undergone a resection by the method of König, but had had a recurrence of tuberculous degeneration. A month after the former operation Gutsch did another resection by the Wladimiroff-Mikulicz method. The circumstances of the case compelled him to make his incision in the foot pass through the cuboid bone and the three cuneiform bones, while that through the tibia and fibula was situated seven centimetres above the point of the internal malleolus. The result was excellent. The bones consolidated perfectly, and with a properly constructed shoe the patient was able to walk without a cane, and even to indulge in snowball fights with his comrades.

TRUTHFULNESS OF SURGICAL REPORTS.

AN old proverb says that "truth is golden," and this should apply in a special manner to reports of successes and failures in surgical work, for the reason that the prognosis in cases of like character must very largely depend upon what is believed to have been the results under former operations, whether fatal or curative. If we cannot trust the statements of the remarkable successes of well-known operators, we are forced to base our prognosis upon doubtful records.

Exaggerations are certain, sooner or later, to be detected through some want of correspondence with previous statements. Investigators who do not confine their observations to printed records will occasionally trace up a long-believed rumor to its sophistical origin. A few years ago a well-known surgeon visiting this city, stated in the course of conversation that he had twice performed the Cæsarean operation with entire success. Inquiry proved the claim to be groundless, and the medical neighbors of the boaster gave him a low status for veracity. The unwritten records of surgical work contain many such statements, and some have only been set aside many years after they were started.

Fabrications of cases are much less commonly published than orally given. Marvels of history, like that of the Princess of Schwarzenberg, said to have been delivered of a living fœtus some hours after she was burned to death, she being in fact but four months pregnant, are so much beyond belief that few give them any credence in this age. As a rule, we are apt to credit the statements of hospital reports, but even in them we may detect exceptionally some boastful swindle. One was exposed not many years since in a general hospital in the Orient, where the chief was absent from his post for several years. His temporary successor made it appear by his reports that he had removed more than the average number of vesical calculi, and with the best results. But not satisfied with this, the young man deliberately fabricated six cases of ovariotomy, giving the names and ages of the women, with accompanying details. On the return of the chief there was a resumption in the former lower average of lithotomies, and the ovariotomy cases were erased from the hospital record as fabulous.

When a surgical operator makes the impression that the number of his cases and the proportion of his cures are to be received *cum grano salis*, he will soon find his statements discredited when perfectly true, because of the bad name which he has acquired for himself in the past. Men of real merit and large experience, should be content to report only what legitimately belongs to them.

PREGNANCY AND ITS SYNONYMS.

IT certainly is remarkable that the terms used synonymously with pregnancy, as a rule, merely express some one of the more obvious phenomena,

and not the essential condition. Thus, the Romans, though they had the word *prægnatio*, spoke of *graviditas*, the increased weight being the origin of the term applied to pregnancy; in like manner, the Italians use the word *gravidanza*. The French express not greater weight, but greater size, in the word *grossesse*. The German *Schwangerschaft* gives the idea of carrying, an idea which has evidently come from the *gestatio* of the Romans, the κύησις of the Greeks, the root of the former being *gesto*, and of the latter κύτος, each meaning to carry. "To be with child," is an English expression which evidently corresponds with the Greek ἐν γαστρὶ ἐχούσας, a circumlocution found in the New Testament.

Turning from these words, so superficial in significance, and indicating merely phenomena, we find that pregnancy in its etymology expresses the essential condition. The derivation of the word clearly signifies reproduction, the root-verb being *gigno*; and this in turn takes us back to the Greek γενναω, from which we have genesis, genus, generic, genitor, etc. But we must go to the Sanscrit to find the origin of the Greek verb in *zan* or *gan*: this common verb appears in our language in the word beget. There is, therefore, not only a more profound, but a more appropriate meaning in the word pregnancy than in any of its substitutes.

In honor of the Queen's jubilee, Sir Donald Smith, member of the Canadian Parliament, and Sir George Stephen, President of the Canadian Pacific Railway, have offered to give $500,000 each for a new hospital at Montreal, to be named, with the permission of her Majesty, the Royal Victoria Hospital. The city is asked to give a site on Mount Royal, adjoining the estate of the late Sir Hugh Allen. The building is to cost $250,000, which would leave an endowment of $750,000. This, it is estimated, would bring in about half the necessary revenue for the maintenance of the 200 patients for whom accommodation is to be provided. The site asked for is ten acres in extent, and is valued at $40,000.

Sir William Jenner has, for the seventh time, been elected President of the Royal College of Physicians of London.

At the Eightieth Annual Commencement of the University of Maryland, held in March last, the degree of M.D., was conferred on ninety graduates.

The Imperial Institute at Tokio, Japan, is said to be the only college in the world which has a professorship of sanitary engineering. The position is filled by an Englishman.

A correspondent of the London *Lancet* "thinks that if the American railway companies could be induced to grant free passes over their lines to foreign medical men attending the International Medical Congress in September, it would result in largely increasing the attendance, and would be an immense boon to many doctors of limited means, who otherwise would be debarred from visiting America." Unfortunately for this suggestion, the issuing of free passes is strictly prohibited by the Inter-State Commerce Act.

REVIEWS.

Clinical Manual for the Study of Medical Cases. Edited by James Finlayson, Professor and Lecturer on Clinical Medicine in the Glasgow Western Infirmary. Second edition, revised and enlarged. 12mo. pp. 683. Philadelphia: Lea Brothers & Co., 1886.

The profession cannot but welcome the second edition of this very valuable work of Finlayson and his collaborators. The size of the book has been increased and the number of illustrations nearly doubled. The manner in which the subject is treated is a most practical one. Symptoms alone and their diagnostic indications form the basis of discussion, there being no description of any *disease*.

The first chapter, by Gairdner, on the physiognomy of disease is of interest and value. In the portion following, written chiefly by Finlayson himself, we notice particularly the important chapter on case-taking and that on temperature, with illustrative charts, and the articles on vomiting and vomited matter, dropsy and its causes, and on the use of electrical instruments in diagnosis, with diagrams of the motor points.

The parts devoted respectively to the study of the organs of special sense, and to the examination of the urine, deserve especial mention. The former is, we think, one of the most useful features of the book; the latter contains among other things the qualitative and quantitative processes for the analysis of urea and sugar, with the best tests for albumen, besides a series of very satisfactory illustrations of the microscopical appearances of urinary sediment. The last chapter, by Gemmell, on the physical examination of the chest and abdomen, is by no means the least important. Among the numerous illustrations which it contains are a series of sphygmographic tracings of different pulse types and a set of diagrams representing the rhythm of the cardiac murmurs. The text explains clearly and thoroughly the methods of examination and the conclusions to be drawn from the physical signs.

A bibliography of works bearing upon the subject is appended to nearly every chapter, and a good index ends the volume.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, April 5, 1887.

The President, C. L. Dana, M.D., in the Chair.

Dr. W. R. Birdsall and Dr. R. F. Weir presented a

Report of a case of sarcoma of the brain, occipital lobe, causing hemianopsia, removed by operation.

(See The Medical News for April 16, page 421.)

DR. GRAEME M. HAMMOND presented the following

REPORT OF A CASE OF CYST OF THE BRAIN, WITH OPERATION.

The patient, a married woman, complained of a severe pain an inch above the right ear, and had left hemiplegia. At the time her symptoms began she was about twenty-nine years of age; she had had four children; during the progress of her disease she had a fifth child. All were strong and well. Her sickness lasted about two years and a half. It commenced by sudden loss of consciousness, and convulsions limited to the left side. The left side of the face became, and remained, paralyzed. About a year later she noticed gradual loss of power in the left arm; things dropped from the hand. At the end of another year the left arm was completely paralyzed. She then noticed increasing weakness in the left leg. When Dr. Hammond first saw her she was able to stand and walk slowly. While the paralysis was extending she had four or five epileptic seizures. Confined to the left side, headache developed about the time the legs became affected, grew more constant, and was described as agonizing.

She denied syphilis. Physical examination showed loss of motion on the left side of the face, tongue, and soft velum; of the left arm, and partial loss of motion in the left leg. There was no disturbance of sensibility of any kind. The reflexes were exaggerated on both sides. Sight, hearing, smell, and taste were normal. Choked disk on both sides was observed at a subsequent examination.

Under treatment, the headache was controlled to a considerable extent. Dr. Hammond's diagnosis was probable cerebral tumor involving the cortical or subcortical substance of the motor centres. An operation was refused. The patient grew worse until the 20th of March, 1887, when her husband asked that the operation be performed. Dr. Spitzka then saw the patient with him, and made two examinations. He coincided in the diagnosis. The operation was performed in the hospital March 30th; Dr. M. Josiah Roberts assisted at the operation, removing the portion of skull by his electro-osteotome. Four buttons were removed by the electro-trephine. These were connected by straight lines made with the circular saw. The diameter of the opening was over two inches. A crucial incision was made through the dura. A hypodermatic needle was introduced in different directions, but no fluid was withdrawn. The dura was closed, a drainage tube was introduced, the skin flaps were sewed up. The patient was put to bed. She lived only twenty-one hours, remaining unconscious after the operation. Prior to the operation she had become completely paralyzed in the left lower limb, she had delusions and hallucinations, she talked incoherently, bedsores developed.

The autopsy showed little hernial protrusion at the wound; the cortical substance here was thin. Incision through the motor region revealed three cysts in a line deep in the white substance. The fluid in the cysts had been only partially examined; it was serum, and contained broken-down brain substance. The cysts were close together, and in a position to affect the face, arm, and leg centres. He could not explain why the syringe failed to bring forth fluid, unless it was that the cysts were too deeply situated or the needle passed between them. He added to the clinical history that the head was drawn to the right side the last three days of life.

DR. E. C. SEGUIN said he was partly responsible for the operation in the case reported by Drs. Birdsall and Wier, but it seemed that the patient would not live more than two or three months without it. He expected to find a large tumor, but was somewhat surprised to see it encapsulated and non-parenchymatous. During the early history of the case the symptoms pointed to destruction of brain tissue. He asked Dr. Hammond whether the sensory or motor symptoms determined the seat of his operation.

DR. HAMMOND replied that the headache corresponded to the centres for the motor symptoms, and the seat of the operation.

DR. SEGUIN added that the seat of the pain would be a very uncertain indication for the seat of the operation. In some cases of cerebellar tumor, for instance, the pain had been mostly frontal.

DR. E. C. SPITZKA, referring to the case reported by Drs. Birdsall and Wier, said that an artery, large enough to cause fatal hemorrhage, entered the gray and white substance of the right occipital lobe. It had been overlooked in many text-books.

DR. ROBERTS explained how the circular saw could be used without injury to the brain, and the operation of the electro-osteotome.

DR. STARR suggested the desirability of an analysis of reported cases of cerebral tumors for the purpose of determining their rapidity of growth and size.

DR. R. L. PARSONS read a paper entitled

NOMENCLATURE IN PSYCHIATRY. MONOMANIA OR OLIGOMANIA, WHICH? PARONOIA, WHAT?

An examination of the reports of fifty-one asylums for the insane, taken at random, showed that of the whole number of patients enumerated, less than two per cent. were classified as cases of monomania, while in twenty-four of these reports the term did not appear. But, however much systematic writers on the subject of insanity deprecated the use of the term monomania, they rarely succeeded. There are manifestations of insanity which are neither melancholia nor dementia, but which differ so much from mania that another designation is required for them, and the objectionable term monomania is the only one generally employed. Dr. Parsons thought a suitable substitute could be found. Paranoia had been used to a considerable extent, but if the meaning of the term monomania is too narrow for the purpose required, that of paranoia is too broad. In conclusion, then, with the assumption that monomania, as defined and explained by certain writers on psychiatry, designates phases of insanity of sufficient importance and well enough differentiated to require a place in the general classification of mental diseases; and with the further assumption that the reasons adduced in this paper are sufficient to justify the substitution of the term oligomania for monomania, it only remains to apply the proper meaning of the latter term to the former, to wit, a form of insanity which, although potentially affecting all the mental faculties and operations, apparently involves only a part, as the intellect, the emotions, or the will, or certain manifestations only of a faculty of the mind; which originates in the intel-

lectual faculties rather than in the feelings; and the manifestations of which are well defined, persistent, dominant, and systematic in character.

CORRESPONDENCE.

THE PAY OF ARMY AND NAVY SURGEONS.

To the Editor of THE MEDICAL NEWS,

SIR: A comparison of the pay of the medical officers of the army and navy, which appears in one of your recent issues, while in the main correct, so far as direct pay is concerned, conveys an altogether false impression of equality of compensation of the two branches of the service. Leaving out of consideration the question of "actual" and "relative" rank, the significance of which no one not in a military service can fully comprehend, it is not at all a matter of doubt that the army medical officer receives, at least, one-third more than his naval *confrère*, if not in actual cash, in its equivalent.

The writer of the above-mentioned comparison fails to make any allusion to the important consideration of "allowances," which, indeed, in the case of naval officers, do not exist, with the one exception of a ration, rated at thirty cents a day, allowed only when at sea. Those of the army officers, however, constitute a large and important item, and relieve them of many of the expenses of bare living, which tax the officers of the navy so heavily. All army officers, including those of the medical department, are allowed quarters at all times, or commutation for them at the rate of twelve dollars per month per room, for from two to five rooms, according to rank (*Army Regulations*, p. 316), and are thus relieved of the burden of rent, that presses so heavily on naval officers, who rarely obtain quarters, and never commutation for them. Of course, the latter are provided with their little shelves on the side of their ships, when they are at sea, but the rent for their families, when they have families, must come out of their own slender purses. When the naval officer is compelled to move under orders, from one station to another, the cost of transportation of all his possessions must be borne by himself; the army officer is allowed from 1000 to 2000 pounds of extra baggage, which is moved for him at the expense of the government. (*Army Regulations*, p. 214.) From the army commissary department, officers of that service can obtain all the necessaries, for themselves and their families, at little above, and, in many cases, below actual cost. (*Army Regulations*, pp. 317, 241.) Coal, for instance, at the uniform rate of three dollars per ton. No such provision is made for naval officers.

On shore duty, and at least half the time of medical officers of the navy is spent on such duty, the pay is reduced, and when on leave or waiting orders, his pay is still further cut down, his expenses continuing the same, while army officers, whatever their duty, receive their pay and allowances, without reduction.

This is not all. Every five years, the pay of army medical officers, of all grades, is increased ten per cent. Passed Assistant Surgeons in the navy, and in that grade from ten to fifteen years are passed, at the present rate of promotion, receive only one increment of pay, at the end of the first five years.

It is true that there are more medical officers in the navy, holding ranks above that of major, than in the army, but of the full surgeons in the navy, only twenty-seven rank above captain—equivalent to lieutenant in the navy—and a further increase in rank does not entitle them to greater compensation, as it does in the army, length of service only brings an increase every five years after the grade of surgeon is reached, for twenty years beyond which no further increment is allowed. With every successive step in rank, the medical officer of the army receives an increase of pay, upon which his longevity pay is based.

These facts are so well understood outside of the services, that, while it is impossible to supply the natural waste of the medical corps of the navy with properly qualified men, no such difficulty exists in the army, the supply always being in excess of the demand.

P. A. SURGEON.

THE MATERNITY HOSPITAL.

To the Editor of the THE MEDICAL NEWS,

SIR: The Board of Governors of the Maternity Hospital have unanimously determined that the vacancy now existing in the visiting obstetrical staff of the hospital should be filled by a competitive examination.

Dr. Edward L. Duer, Dr. Wm. Goodell, and Dr. W. H. Parish have consented to conduct the examination.

Those desiring the position must apply by letter before the 1st of May to Dr. Edward L. Duer, 1704 Arch Street, Chairman of the Committee, and soon after that date the applicant will be notified of the place where, and time when the examination will be held.

Yours, very truly,

J. V. INGHAM, M.D.,
Chairman of Executive Committee.

714 South Tenth St., Philadelphia,
April 18, 1887.

NEWS ITEMS.

PARIS.

From our Special Correspondent.

ACUTE POISONING BY CARBOLIZED COTTON-WOOL.—In a recent clinical lecture at the Hôpital des Enfants Malades, M. SIMON described an interesting case of acute poisoning by carbolized cotton-wool in a girl patient, aged twenty-two months. On the 6th of January M. Simon was called in consultation to examine a little girl, aged twenty-two months, who had the evening before presented a series of nervous accidents (prostration, vomiting, cold extremities). The patient had been affected with submaxillary adenitis, and tincture of iodine had been applied. The tincture being very much concentrated an ulceration of five to six centimetres in length was the result of its application. The family doctor was now called in, and iodoform gauze and carbolized cotton-wool were applied to the ulceration. The first dressing was made on the 3d of February. The next morning the wound presented a much better appearance, but the general state of the patient left much to be desired. The mouth was dry, tears flowed, and there was evident coryza. The child was very excitable and complained of pain in the head. Temperature 101.8° F., pulse frequent. February 5th

the child was taken with vomiting, which medication failed to arrest. The face became pale and the extremities cold, while the temperature rose to 103° F., prostration was extreme, and the urine suppressed. The carbolized cotton-wool was abandoned, the patient recovering entirely from the toxic symptoms at the end of thirty-six hours.

Specimens of the urine passed during the attack and which were as black as ink did not give the characteristic blue color when treated with nitric acid and starch, making it evident that the iodine had played no part in the intoxication. According to M. Simon, the elimination of the urine having been arrested at the first moment, the carbolic acid was accumulated in the nervous centres, and afterward came away, on the suppression of the carbolized dressing, in the black urine characteristic of the poison.

Considering the great susceptibility of children to the toxic action of carbolic acid, M. Simon thinks that this medicament should never be used in children under two years of age.

DIASTASIZED WINE.—It is generally admitted in the present day that vegetable diastase considerably aids digestion, and the assimilation of farinaceous substances. Dr. Coutaret first indicated a practical process for extracting the diastase from sprouting barley.

MM. Gruber and Musculus demonstrated the identity of vegetable diastase with the salivary diastase of the superior animals, and proved that the ferments of this diastase acted in a similar manner upon glycogen and upon starch.

In Dr. Durand's diastasized wine the tonic substances (cinchonium and manganese), though their proportion is but slight, produce a most remarkable therapeutical effect.

Dr. Delmis describes the case of a woman who had suffered from dyspepsia for fifteen years. Obstinate constipation was the principal symptom. The use of this diastasized wine was followed by a sensible amelioration in her condition. Constipation entirely disappeared.

The beneficial effects of Dr. Durand's diastasized wine have been seen in many cases of dyspepsia, gastralgia, persistent vomiting, anæmia, prolonged and trying convalescence. The ordinary dose prescribed is a wineglassful after meals.

THE AMERICAN SURGICAL ASSOCIATION will hold its annual meeting at Washington, on May 11th, 12th, 13th, and 14th. The preliminary programme, just issued, announces the following papers:

Dr. F. S. Dennis, on "The Exploration of the Bladder by the Suprapubic Method."

Dr. John H. Packard, on "Suprapubic Cystotomy for other purposes than the Removal of Calculi."

Dr. A. Vanderveer, "To what extent can we classify our cases of Vesical Calculi for operation, with report of cases?"

Dr. J. Collins Warren, on "Resection of the Intestines; with Specimens."

Dr. C. B. Nancrede, on "Should Laparotomy be done for Penetrating Wounds of the Abdomen involving Viscera?"

Dr. T. A. McGraw, on "Laparotomy for Injuries of the Abdominal Viscera."

Dr. C. H. Mastin, on "Hernia; its Treatment, etc."

Dr. J. E. Michael, on "Report of a Case of Ventral Hernia successfully treated by operation; with a suggestion as to the method of operating."

Dr. Samuel W. Gross, on "The Prognosis of Sarcomata of the Breast."

Dr. D. Hayes Agnew, on "The Medico-Legal Aspect of Cranial and Thoracic Wounds (suicidal)."

Dr. L. McLane Tiffany, on "Surgical Diseases of the White and Colored Races compared; preliminary observations."

Dr. B. A. Watson, on "An Experimental Study of the Effects of Puncture of the Heart in cases of Chloroform Narcosis."

Dr. J. Ford Thompson, on "Case of Vaginal Hysterectomy."

Dr. W. F. Westmoreland, on "Fibro-cystic Tumor of the Jaw."

Dr. T. J. Dunott, on "Some Remarks on Hypertrophy of the Tongue, and the History of a Case."

Dr. J. A. Comingor, on "A Case of Varix of the Jugular Vein."

Dr. William A. Byrd, on "Excision of the Ankle-Joint."

Dr. David Prince, on "Wounds; their Aseptic and Antiseptic Management."

Dr. J. Ewing Mears, on "The Study of the Methods of Operation Practised, and of the Results Obtained in the Treatment of Cleft of the Hard and Soft Palate, Illustrated by a Record of Fifty Cases."

THE SOUTH CAROLINA MEDICAL ASSOCIATION held its thirty-seventh annual meeting at Aiken, on the 12th and 13th of April, under the presidency of Dr. Cornelius Kollock, of Cheraw. A number of interesting papers were read, and the Society recommended the establishment of a State Medical Examining Board, the members of which should be appointed by the Governor, from nominees presented by the South Carolina Medical Association.

The following officers were elected for the ensuing year:

President—T. Grange Simons, M.D., of Charleston.

Vice-Presidents—James Evans, M.D., of Florence; Thomas Legare, M.D., of Charleston; and D. S. Pope, M.D., of Columbia.

Secretary—W. P. Porcher, M.D., of Charleston.

Treasurer—H. W. De Saussure, Jr., M.D., of Charleston.

The next meeting will be held at Columbia, on the second Wednesday in April, 1888.

MEDICAL DEPARTMENT OF WESTERN RESERVE UNIVERSITY.—A very elegant and complete new building for the Medical Department of Western Reserve University, in Cleveland, Ohio, has been completed, and was formally dedicated on the evening of March 8, 1887. The entire cost, about $175,000, was the donation of Mr. John L. Woods, a wealthy and liberal citizen of that city.—*Maryland Med. Journal*, April 2, 1887.

MALPRACTICE SUIT FOR SKIN GRAFTING.—A case has been recently decided in Atlanta, Ga., which offers

some points of interest. Dr. Henry Wile, of that city, proposed to a boy of thirteen years old to submit to the removal of some small skin grafts from his arm to be placed upon an extensive ulcerated surface on the head of his cousin, a little girl somewhat younger, whom he accompanied to Dr. Wile's office. The boy readily consented, and minute grafts were excised without causing him any inconvenience. The father of the boy subsequently swore out a warrant against Dr. Wile, charging him with assault and battery. Upon trial Dr. Wile was promptly acquitted.—*Maryland Med. Journal*, April 2, 1887.

Smallpox and Rags.—Two cases of smallpox were lately reported from Huntington, among employés of the Chester Paper Company. An investigation of the circumstances by the Secretary of the State Board of Health, showed that rags were the probable medium of contagion, but whether domestic or foreign rags, it was impossible to determine definitely. A portion of the domestic rags were from New York, where smallpox has been prevalent of late, and the probability seemed to Dr. Abbott to be in favor of these rags as being the medium of contagion.—*Boston Med. and Surg. Journal*, April 14, 1887.

Professor Adam Politzer.—The old pupils and friends of Professor Adam Politzer have arranged to present him with his portrait by an eminent artist of Vienna as a token of appreciation of the great service he has rendered to aural surgery during the twenty-five years he has been teaching in the University of Vienna. The presentation will take place at Easter, at the meeting of the Otological Association, at Vienna.

Efficiency of Filters.—An interesting paper was recently read by Dr. Plagge, of Berlin, on the relative efficiency of the different forms of filters in removing bacteria from water, in the Public Health Section of the German Association of Naturalists and Physicians. The experiments were made with water from the River Spree.

The results from Bischoff's spongy iron method were disappointing, from 18,000 to 24,000 bacteria remaining in the filtrate of water which contained 38,000 per cubic centimetre previous to filtering.

Carbon filters proved entirely inoperative.

Sand filters were found to be utterly worthless.

Filters of compressed cellulose were not satisfactory.

The earthenware filters, on Pasteur's principle, gave, in nearly every instance, a filtrate practically free from germs.

Asbestos filters gave an apparently free filtrate, but germs developed later on.

His experiments point in the desirability of using filtered water soon after it is filtered.—*Sanitary News*, April 9, 1887.

Vitiation of the Atmosphere by Gas and Kerosene Stoves.—Dr. D. F. Lincoln, of Savannah, Ga., writes to the *Boston Medical and Surgical Journal*, of March 31, 1887, as follows upon this subject:

"Occupying, for a part of the day, a small room, containing 1100 cubic feet of air, I introduced a small kerosene stove for warmth. The heat yielded was sufficient to raise the temperature of the room about eighteen degrees, which served my purpose sufficiently well. I had to stand some odor; but otherwise, I did not experience any personal discomfort from the peculiar atmosphere. One evening, however, I saw that the reading-lamp was dim; the flame had shrunk to one-half its usual size; thinking that the housekeeper had neglected it, I carried it into the entry, but was surprised to find it burning brightly. Placed in the room, it again burnt low; opening the window relieved the difficulty. The same thing occurred on another evening, when, having with me Wolpert's air-testing apparatus, I found that the amount of carbonic acid in the air had reached sixty-seven parts per ten thousand, the normal amount being three or four parts.

"This numerical statement is only a fair approximation to the truth; but may be regarded as near enough to be of practical importance. It is not at all surprising that such an effect is produced by a pair of burners, each four inches long, generating as much CO_2 as eight or ten common lamps. In a well-built house with tight doors the effect might be doubled."

Schedule of Study Advised in the Berlin University.—The Faculty of Medicine in Berlin has issued a schedule of studies for its students, in which the latter are strongly advised to follow courses in meteorology, mineralogy, geology, anthropology, psychology, and logic. The plan, of course, is not obligatory; but while the Faculty uses no compulsion upon its students in this matter, it holds itself competent to give them good advice.

Prizes for Essays Regarding the Effects of the Use of Tobacco.—The French Society for the Suppression of the Abuse of Tobacco, offers the following prizes, competition for which will remain open until 1888:

A prize of 600 francs for the best essay upon the cachexia caused by nicotine; its symptoms, cause, effects, proven by at least eight clinical observations made in either hospital, private, or military practice.

A prize of 1000 francs upon the effects of tobacco upon men of letters, and its influence upon the development of French literature.

A prize of books worth 200 francs and a medal are offered to any medical man for the best description of four typical cases of affections exclusively attributable to the abuse of tobacco. Communications may be in French, German, English, Italian, or Spanish.

Education of Women in Germany.—Of late the Prussian Minister of Education has had several applications made to him to admit women as students at the universities. His reply is, that women are not to be admitted as regular students at any Prussian university, nor at any of the medical schools.—*Nature*, March 18, 1887.

Acuteness of the Sense of Smell.—Messrs. Nicholls and Bailey recently contributed to *Nature* the results of a series of observations made by them to test the acuteness of smell in the different sexes and in different individuals. The sense of smell in the male was found to be more acute, on the average, than in the female sex. In some individuals it was so keen as to detect one part of prussic acid in two million parts of water. Several

substances were experimented with, and the following is a summary of the results, the figures indicating the average limit of delicacy of perception: Cloves: males, 1 in 88,128; females, 1 in 50,667. Nitrate of amyl: males, 1 in 783,370; females, 1 in 311,330. Extract of garlic: males, 1 in 57,927; females, 1 in 43,900. Bromine: males, 1 in 49,254; females, 1 in 16,244. Prussic acid: males, 1 in 112,000; females, 1 in 18,000.—*Science*, March 25, 1887.

THE TENNESSEE STATE MEDICAL SOCIETY held its 54th Annual Meeting at Nashville on the 13th, 14th, and 15th inst. The following officers were elected for the ensuing year:

President.—P. D. Sims, M.D., of Chattanooga.

Vice-Presidents—Drs. J. M. Masters, of Knoxville; T. J. Happel, of Newton; and Richard Douglas, of Nashville.

Secretary.—Ambrose Morrison, M.D., of Nashville.

Treasurer.—Richard Cheatham, M.D., of Nashville.

FATALITY OF THE SWORD AS A WEAPON.—Lord Lytton need not have restricted his celebrated aphorism regarding the comparative might of the pen and the sword as he did. Even outside "the rule of men entirely great," the sword has become, in these latter days, quite a feeble and useless thing. Colonel Paul Methuen stated recently, in the course of an address which he gave at Toynbe Hall, in London, that in the Franco-German war, only six Germans owed their death to the sword, and that the total number wounded with this weapon, with which the Romans conquered the world, was only two hundred and twelve. But all this is saying nothing about the rifle, the revolver, or even the toy-pistol. The average boy finds the latter weapon more effective, and infinitely easier to wield, than the pen; while the daily records of the press show that a considerable portion of the community put their trust, in times of storm and stress, upon the seven-shooter, rather than upon the stylographic pen.—*Boston Med.* [illegible]

OBITUARY RECORD.—Died, at Chicago, on April 18th, JAMES STEWART JEWELL, M.D., a distinguished writer on nervous and mental diseases. Dr. Jewell had been in poor health for a considerable time, and although not so ill as to be compelled to relinquish his practice entirely, his condition was such as to cause grave apprehensions among his friends. He began to break down in health about five years ago, and a complication of disorders set in which he was never able to overcome. Dr. Jewell was born Sept. 8, 1837, at Galena, Ill. He was graduated at the Chicago Medical College in 1860, and two years later he settled in Chicago, where he remained in active practice till the time of his death. From 1864 to 1869 he was Professor of Anatomy in the Chicago college, and since 1872 has held the chair of Nervous and Mental Diseases. In 1874 he started the *Journal of Nervous and Mental Diseases*, the columns of which were devoted to the discussion of these disorders.

———At Providence, on April 17, EDWARD T. CASWELL, M.D., in the fifty-fourth year of his age. Dr. Caswell was the son of the Rev. Alexis Caswell, D.D. formerly President of Brown University. He received a liberal education at the Brown University, and was graduated in medicine at the Jefferson Medical College, Philadelphia, in 1859. After a few years of study in Europe, he settled in practice at Providence, where he soon won a high professional position. He made a number of valuable contributions to medical literature, and in 1866 translated Semeleder on *Laryngoscopy and Rhinoscopy*. He was Surgeon to the Rhode Island Hospital, and from time to time has occupied many positions of professional honor.

NOTES AND QUERIES.

CASTRATION OF CRIMINALS.

To the Editor of THE MEDICAL NEWS.

SIR: In THE MEDICAL NEWS of March 26, page 363, I read with interest the News Item "Castration of Criminals." It is an epitome of a paper which I read before the Maine Medical Association, June 11, 1878—"The Eradication of Syphilis and Crime by the Extirpation, in that class, of the Procreative Power." The paper was widely commented upon at that time, and I supposed the suggestions entirely new. I subsequently learned that an [illegible] supported [illegible] in the *Medical Times and Gazette* of May 25, 1872, in which corresponding "proposals" were cited as far back as 1731. So the idea is ripening, and I have no doubt that in future crime will meet, in this form, its most powerful suppressor. This method of treating criminals would not only exert an incalculable moral influence, but eradicate much of that incurable disease which, under the present system, is propagated and transmitted. Yours, most respectfully,

GEORGE F. FRENCH.

MINNEAPOLIS, April [illegible], 1887.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 12 TO APRIL 18, 1887.

[illegible] Chief [illegible] and Assistant Surgeon. Granted two months leave of absence on surgeon's certificate of disability.—*S. O. 82, A. G. O.*, April 9, 1887.

KANE, JOHN J., *Captain and Assistant Surgeon.*—Resigned April 13, 1887.—*S. O. 85, A. G. O.*, April 13, 1887.

FREEMAN, V. WALKER, *First Lieutenant and Assistant Surgeon.*—Ordered from Fort McIntosh, Texas, to Post of San [illegible] Department of Texas, April 11, 1887.

[illegible] Medical [illegible]

WOODRUFF, CHARLES E.—To be Assistant Surgeon with the rank of First Lieutenant, to date from April 14, 1887.

CABELL, JULIAN M.—To be Assistant Surgeon with the rank of [illegible] from April 14, 1887.

[illegible] Medical Purveyor, New York, City, N. Y., to [illegible], April [illegible], 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING APRIL 16, 1887.

GRIFFITHS, S. H., *Passed Assistant Surgeon.*—Detached from the U. S. S. "Lancaster," and waiting orders.

HIBBETT, C. T., *Passed Assistant Surgeon.*—Detached from duty on Iron Clads, City Point, Va., and waiting orders.

MARSTELLER, E. H., *Passed Assistant Surgeon.*—Ordered to duty on Iron Clads, City Point, Va., the 20th instant.

ORIGINAL LECTURES.

CARDIAC LESIONS FROM EXCESSIVE MUSCULAR EXERTION.

An Address delivered before the Alumni Association of the Medical College of Ohio, March 8, 1887.

BY WILLIAM H. KELLY, M.D.,

OF COVINGTON, KY.

IN 1865, in the Croonian Lectures, Dr. Peacock, of London, first called attention to the cardiac lesions dependent upon severe and protracted muscular exertion. His observations were made among the miners of Cornwall, and convinced him that the cardiac dilatation and hypertrophy so common among such workmen were dependent upon two factors: the muscular strain and the impure air in the mining shaft.

Shortly after the civil war in our own country, Da Costa, after a large experience in the hospital practice of that time, called attention to what he termed "irritable heart." In some of these cases hypertrophy, and in rare cases dilatation, was found. As a rule, the symptoms were subjective, rather than objective. Those most subjective to this trouble were soldiers who, being somewhat out of health, underwent long and severe marches, hard fighting, with the accompanying mental anxiety, protracted sieges, building fortifications, etc.

After the Franco-Prussian war of 1870–71, Fräntzel was able to confirm Da Costa's observations, and in addition to the causes above mentioned, laid special stress on the pressure on the thorax of the uniform and other military accoutrements. Quain, Fothergill, Morgan, Flint, Seitz, Leyden, and others have drawn attention to the causation of cardiac lesions by excessive muscular effort. The literature of this subject is fairly developed, but as a clinical feature it has not yet obtained the general attention the subject demands. Many cases, affected with obscure and indistinct cardiac symptoms, took origin in this way, and cannot be relieved unless the treatment is conducted with this view in mind.

In 1871 Dr. Clifford Allbutt published a paper, "The Effect of Overwork and Strain on the Heart and Great Bloodvessels," giving a personal experience during an Alpine pedestrian tour. It was in the afternoon, the morning having been spent in mountain climbing, when he determined to reach a still higher peak than the one on which he then stood. During the ascent, which was very difficult and laborious, he suddenly became conscious of "a strange and peculiar *besoin de respirer*, accompanied by a very distressing sense of distention and pulsation in the epigastrium." Placing his hand over the cardiac region, he felt a labored, diffused beat over the epigastrium. Ceasing further attempts at ascending the mountain, and remaining quiet, these unpleasant symptoms disappeared, but another attempt to continue the ascent caused a return of the symptoms. As soon as he reached level ground he was perfectly easy, and felt none of the symptoms above mentioned. This continued until the next morning about three o'clock, when he was awakened by a recurrence of the symptoms. These uncomfortable sensations finally disappeared, to return no more. Such is a brief clinical history of a case of the affection under discussion by an accurate and skilled clinician. It is true, we lack the results of a physical examination, but these would probably have been almost negative, serving only to exclude any chronic organic change; possibly dilatation might have been demonstrated.

Dr. Brunson, of New York, quoted by Fothergill, had a similar experience during a pedestrian tour in Tyrol, and by questioning the guides found that such occurrences among tourists were not infrequent, and usually occurred when the individuals were out of sorts, or had undergone severe and long sustained efforts. When these attacks occurred, the victim being on lofty peaks or dangerous passes, the guides were compelled to carry him down as best they could.

Such is a brief reference to the literature of the subject of this paper. As yet the lesion has no universal cognomen: cardiac overexertion (Seitz), heart strain (Allbutt), muscular subparalysis of the heart (Fothergill), irritable heart (Da Costa).

This paper is based upon two cases believed to be cardiac lesions dependent upon excessive muscular effort; one case seen in the Vienna General Hospital, and the other in private practice. Full notes of the history and physical examination were taken, but unfortunately have been misplaced, and this report is from notes taken at the lecture.

Patient, æt. nineteen, was an apprentice to a wagon-maker, and was compelled to work diligently from 4 A. M. to 9 P. M.; strongly built, with good muscular development. Eight months ago had a slight attack of sickness, lasting only a few days, but from patient's account it was impossible to form a definite opinion as to its nature. Close questioning seemed to exclude the probability of its having been rheumatism. Perfectly well until six days ago, when, engaged in pushing a wagon out of the shop, he felt an acute pain at a point, according to the patient's statement, corresponding to the fourth intercostal space, and outside of the left mammillary line; also marked dyspnœa and palpitation. At the time of examination all these symptoms, except the pain, have disappeared, and this is very slight, except during exertion. Evening temperature, 37.6°; respiration 18; pulse 70, regular, and fairly strong. At this time the patient has been in bed for five days. Urine normal.

Physical examination gave very interesting results. Inspection showed the heart beat diffused over the fourth and fifth intercostal spaces and under the nipple. Palpation showed it to be weak and flapping. On tapping over the cardiac region with the tips of the finger sev-

eral times, the area of cardiac dulness could be changed. At first this line of dulness extended from the third rib to the sixth rib below, and from the left mammillary line to the right parasternal line. By striking the chest wall over the heart with the finger tips, the upper and right borders of the cardiac dulness became normal, but the lower and left lines remained as above mentioned. In a few minutes the area of dulness became as before. Auscultation gave no demonstration of murmurs; the sounds were weak and flapping.

The lungs were normal; the liver and spleen were somewhat enlarged. No œdema or anasarca.

As I left Vienna shortly after this, I was unable to follow the case, and hence do not know the final issue. Dr. Heitler, Prof. Drasche's assistant, who showed the case to us, told us that such cases were not infrequent, and that the majority of these cases, under proper management, recovered perfectly, with no permanent cardiac lesion. The treatment in this case consisted in rest in bed, concentrated and nutritious food, with infusion of convallaria.

My own case was seen last October, and I have had it under observation since that time.

October 25, about 6 P. M., I was called to see J. S., laborer, aged eighteen, who had been sick only a few hours; stout and well developed. During childhood had the usual children's diseases; considered himself perfectly well until the commencement of the attack in which I saw him. He was addicted to the excessive use of both tobacco and liquor. He had been engaged for some time in digging trenches, and in loosening and throwing out the dirt he was compelled to subject himself to violent muscular exertion. That afternoon, while thus engaged, he suddenly felt a sharp pain in the cardiac region, accompanied by distressing dyspnœa and palpitation. He also felt faint, and was scarcely able to get out of the trench. He was finally taken home, and about two hours after I first saw him. I found him in bed, propped up with pillows, face somewhat cyanotic, and the breathing slightly labored and increased in rapidity. Temperature 99°, respiration 24, pulse 108, weak, compressible, and irregular. The sensation imparted to the finger by the pulse reminded one of the flight of birds as they endeavor to lead an intruder from their nests. Moving along evenly for a few seconds, then apparently falling or fluttering along, then again the even, regular flight. In this case the pulse for several beats would be regular, then the irregular laboring effort, and again the regular beat. With the hand over the heart this was even more distinct.

Physical examination showed lungs normal. Area of cardiac dulness extending above to fourth intercostal space, to right parasternal line, below to sixth rib and to left mammillary line. Apex beat diffused, but strongest in sixth intercostal space below the nipple. Auscultation showed no murmurs; heart sounds not perfectly clear; somewhat muffled and flapping.

Liver enlarged, but I could not demonstrate any splenic enlargement. Urine passed the next morning examined and found apparently normal. I saw him again the next morning, and his condition was about the same; the pulse had decreased in frequency, 96, but was still irregular and weak. His condition remained about the same for eight days before any decided improvement occurred. The dyspnœa disappeared, and the cardiac action was slower, 84, stronger, and more regular; the cardiac pain disappeared on the fourth day. His sleep, which had been disturbed by the irregular heart action, now became sound and refreshing. Area of heart dulness still enlarged. He was kept in bed until the twenty-first day, when he was allowed to set up for awhile; then, by gradual increase in the amount of exercise, he was at last allowed to go out. At this time, thirty days after the attack, the area of dulness was almost normal; still extending a little too much to the left. The apex beat was localized and strong. Since that I have examined his heart several times and have found about the same conditions.

At my first visit I ordered as nearly as possible absolute rest in bed, milk, and underdone beef and mutton, no tea, no coffee, and absolute quiet in the room; in addition to this, cit. caffein and fl. ext. coca, every four hours. His digestion was good, and there were no gastric disturbances of any kind. He had some bronchitis, but it needed no treatment, and the only indication was to aid the exhausted and laboring heart.

On the twelfth day iron and digitalis were ordered for him, and this combination he continued to take for a month. He was directed to give up all manual labor, and to avoid any violent muscular effort. He obtained a position as a clerk, and has so far had no return of the old symptoms. He has decided to go to Alabama to settle, but does not expect to do any heavy work, so that the probability is that there will be no excessive muscular effort to impair the present integrity of his heart.

Such is a brief clinical history of a case that to me was very interesting. Previous to seeing the first case I had paid no attention to the subject; in fact, had never heard of it except as a clinical curiosity. What was my diagnosis? "Dilatation of the heart from muscular exertion." Voltaire says "Only the charlatan is always certain," so I do not claim an absolutely positive diagnosis, but post-mortem examinations of cases presenting similar clinical aspects have demonstrated the lesion claimed.

Thompson reports the case of a man, aged twenty-eight, who, after raising a heavy burden, was taken with symptoms of heart-failure; he gradually grew worse, and after fourteen days died. Post-mortem examination showed a dilated heart with thin yielding walls, but no valvular disease. From the present condition of my patient's heart, as shown by physical examination, I am inclined to believe that a slight compensatory hypertrophy has taken place.

To propel properly the blood through the body the heart must act with force enough to overcome all resistance to the blood flow. Many arteries are crossed by muscles or tendons, or lie between two planes of muscular tissue. When these muscles are contracted the lumen of the bloodvessels is diminished, and the blood-pressure between the heart and the constriction is increased. To overcome this the heart must contract with increased power and energy. In violent muscular effort, especially when the muscles of the upper body are in action, we hold the breath in order to give them a firmer point of support and increase the efficiency of the effort. The temporary cessation of respiration stops the pulmonary circulation; this acting through the right heart stops the venous circulation,

and thus in the capillaries and arterioles directly opposes the propulsive power of the heart. During the straining the nerve-centres are supplied with imperfectly oxygenated blood, the vasomotor nerves are irritated, and thus blood-pressure is increased. Violent muscular action produces dyspnœa and increased heart-action, dependent upon the inability of the heart to overcome the increased resistance, and force the blood into the arterioles; the heart laboring to overcome the obstacle receives into its cavities more blood than it can force out, and then as evidence of failing heart's action the dyspnœa and palpitation appear. By regular and gradual exercise the heart accustoms itself to this increased resistance, and overcomes it without disturbance. Such is the process of "training," and to persons who have undergone this, feats of effort and endurance, impossible to the untrained, become easy. In many cases this training produces an evident increase in the size and capacity of the heart. Eclipse, the noted race-horse, had an unusually large heart. If this training be too severe, the heart is over-strained, and unable to do the required work; the individual is said to be broken-winded. In such cases even slight exertion produces dyspnœa and irregular heart action; this condition may be permanent, or, under proper management, only temporary.

Persons engaged in severe physical labor in constrained and awkward positions—coal-miners, for example—are especially prone to cardiac changes. The hands and arms are, of course, used mostly, and to increase the efficiency of the effort, the muscles of the entire body, especially the trunk, are called into action, thus affording the muscles of the arm a fixed point of support, and increasing their power. In rowing the feet are firmly fixed, and then the muscles of the arm and trunk are exerted to make the stroke of the oar. As before stated, in addition to the resistance of the muscular action to the blood-current comes increased resistance from holding the breath, and thus impeding the pulmonary circulation. We are all familiar with the so-called "striker's" heart; in these cases, by the excessive muscular effort in hammering the heated metal, and in the workman's endeavor to do as much as possible in the limited time during which the metal is hot enough to be worked, increased work is thrown upon the heart, and at the end of the shift the workmen are found in a state of intense vascular excitement, dyspnœa, and excited cardiac action. Eventually, in a large number of these cases, hypertrophy of the heart occurs, and for the time being this enables the heart to overcome the increased resistance. The aortic valves, however, become affected from the force with which they are closed by the excessive intravascular pressure, increased as it is both by the cardiac hypertrophy and the atheromatous changes in the aorta, and thus serious cardiac lesions are produced.

Persons engaged in violent gymnastics or athletic sport often suffer with extreme dyspnœa and palpitation. This may disappear entirely, or may return whenever the exercise is attempted. On entirely ceasing the violent muscular exercise no further symptoms follow, but the workman, compelled, in order to be self-supporting, to continue his work, prolongs the action of the efficient cause, and finally becomes a victim of serious cardiac disease.

Among mountain-tourists, most of whom at home lead lives comparatively free from active muscular exercise, heart strain might be expected to occur frequently. They seem to think that the more violent exercise they take the more benefit they will derive from their summer outing. In their rivalry to make the highest and most dangerous ascents they undergo violent and prolonged muscular efforts, necessarily producing intense physical exhaustion; and it is not strange that in some of these cases the heart must become unable to meet the increased demands upon it. Involved in the general muscular exhaustion, dilatation may occur, or, more often, dyspnœa, cardiac distress, and palpitation betray the failing heart.

So far we have discussed the question as relating to the heart which was assumed to be of normal nervous, and muscular power. We must now take up those cases in which, while there is normal muscular power, the heart lacks the proper nervous stimulus, and without which it cannot functionate properly. Muscular tissue, in order to retain its tonicity and elasticity, these being necessary to its proper action, must be supplied with active and abundant nerve force. Lacking this, the muscle acts slowly and laboriously, and is easily wearied and exhausted. The wearied heart muscle shows itself in palpitation and dyspnœa. Having lost its tonicity and elasticity, it may be dilated by the increased blood-pressure; or, what is more usually the case, cardiac distress and dyspnœa; the so-called cardiac asthma is an evidence of the strain to which the heart is subjected.

The causes of this defective nerve-supply are such as depress the general nervous strength: anxiety, grief, late hours, dissipation, severe and prolonged mental labor, the abuse of tea, coffee, alcohol, previous sickness. Impure air also indirectly affects the integrity of the heart. By forcing serum charged with carbonic acid through a frog's heart Cyon caused stoppage of the pulsation; within a short time after the carbonic acid gas was removed, and pure serum was forced through, the pulsations again commenced. Impure air means imperfectly oxygenated blood; such blood sent to the brain means the evolution of defective nerve force; this insufficient nerve stimulus supplied to the heart causes weakened cardiac action, and loss of tonicity and elasticity in the the heart substance. In addition, we have the direct depressant effect of the impure blood on the heart itself, affecting the ganglia in the cardiac tissue.

Taking into consideration the causes enumerated, the number of individuals exposed to these causes, and the comparative infrequency of the occurrence of heart-strain, we must take refuge in personal idiosyncrasy. In these cases of heart-strain there must be, in addition to the efficient cause, a predisposing cause beyond demonstration. "Personal equation" is an explanation that, in our lack of knowledge, we must frequently employ, and with our present means of investigation, will probably remain, like the "x" in algebra, an unknown quantity.

We have now discussed the direct relation of muscular exertion to cardiac lesion, and also some causes influencing the heart, weakening and depressing its power, thus rendering it more liable to injury from the muscular effort. We have shown the possible direct effect on the normal heart of severe muscular exertion; then how

much more probable is this effect when promoted by loss of nervous power, and personal idiosyncrasy?

What is the pathology of this lesion? In some cases no physical change whatever; in others, simple dilatation; in some, hypertrophy, sometimes fatty degeneration, but, according to Leyden, never sufficient to account for the dilatation which he believes to be due to a true stretching of the muscular tissue. The heart, in order to meet the increased demands upon it, may add to the dilatation a hypertrophy that maintains the integrity of the cardiac function for years, and the patient be entirely free from cardiac symptoms. If then, from any cause, the hypertrophy yields, we have a case of organic heart trouble dependent upon the over-strain years before, and not, as might be supposed, upon some recent cause. In cases of long standing, or unusual severity, marked œdema may be present; Leyden, in all his autopsies on cases of this kind found dilatation, but, of course, this dilatation and consequent cardiac failure were the causes of death, and as some cases recover, apparently completely, we must suppose that in cases in which recovery had occurred there was either originally no anatomical change in the heart tissue, or the dilatation disappeared, and there was a restitutio ad integrum.

From the foregoing, we think the following conclusions justifiable:

1. The heart-muscle, like other muscles, is subject to injury from overwork.

2. Like other muscles, it may be weakened by unusual and excessive work, and losing its tonicity and elasticity, may, by the dilating force of the increased blood-pressure, be dilated.

3. Like other muscles, it may accustom itself to the increased exercise and become hypertrophied.

4. Like other muscles, it may not exhibit any physical change as the result of overwork, yet be exhausted, and give evidence of it by weakened and irregular (spasmodic) action.

The heart may show the evidences of strain and overwork in two ways:

1. By weakened and irregular action without any demonstrable physical change.

2. In addition to the irregular action of the heart there may be physical changes, as dilatation or hypertrophy.

Of course, such symptoms as characterize the first condition, also accompany the second, and, in addition, physical examination gives evidence of cardiac enlargement. When compensatory hypertrophy has occurred, except the increased cardiac volume, there may be no other evidence of the preceding heart-strain.

In these cases a previous history of excessive muscular effort will serve to attract special attention to the cardiac symptoms. The symptoms may occur suddenly, as the result of a severe and prolonged effort, or may appear gradually; in the latter cases the predisposing causes, loss of nervous power, impure air, etc., are the most important factors.

The immediate symptoms are included in the term cardiac asthma; labored and irregular action of the heart, distressing dyspnœa, and pain in the cardiac region. Dependent upon the severity of the strain, these symptoms vary in intensity; sometimes slight, and again counterfeiting approaching dissolution. Cerebral anæmia from imperfect cardiac action causes faintness and vertigo. When the heart has undergone dilatation we have proof of this as the result of physical examination; that is, of course, if sufficiently dilated to be detected. In most of the first class of cases there is slight dilatation, but which cannot be detected. The increased area of cardiac dulness, assuming a globular form, is evidence of general dilatation; if dulness increased toward the right, the right ventricle is involved; if downward and to the left, the left. The apex beat is usually the best criterion of the condition of the left ventricle (Leyden). Auscultation usually reveals clear, but weak, or flapping heart-sounds. Occasionally a systolic murmur at the apex is heard, due, as is claimed, to a relative insufficiency of the mitral valves. Nothnagel, in opposition to most authorities, denies the origin of a murmur from such a cause.

In cases that go from bad to worse, the dyspnœa becomes very severe and distressing; the cardiac pain becomes worse, resembling true angina pectoris; incapacity for mental or bodily effort; attacks of vertigo and faintness; disturbances of the digestive tract; disturbances of the circulation producing œdema.

Finally, the heart-muscle becomes greatly exhausted, and we have extreme cardiac weakness; the heart lacks force to propel the blood, and cyanosis, suppression of urine, collapse, etc., appear. At last coma ensues, and the patient dies. The last stage is similar to the last stage of valvular disease; in fact, so far as cause and effect are concerned, is identical, as it is the asystolia or cardiac insufficiency that causes death.

ORIGINAL ARTICLES.

ABDOMINAL SECTION FOR TRAUMATISM; INTESTINES SUTURED: RECOVERY.

BY CORNELIUS KOLLOCK, A.M., M.D.,

OF CHICAGO, ILL. (LOS ANGELES)

On the 19th of December, 1886, Samuel Gaines, colored, aged fifteen years and seven months, was shot through the abdomen with a Smith & Wesson pistol, ball 38 calibre, distance six feet. At the time of the accident the patient was standing, and his comrade, from whose hands the pistol was discharged, was sitting on a low stool at his left side. The ball entered the left inguinal region, passed obliquely upward, and emerged in the right umbilical, about one and a half inches from the median line.

I saw the case about six hours after the accident, when the following features were presented. The patient was very restless, had an anxious expression

of countenance, much thirst, and a weak pulse; also a deep-seated, emphysematous, crackling sound around the borders of the external opening. There was hepatic resonance, which, though generally regarded as pathognomonic, is not an unerring sign, for it may be caused by the transverse colon being placed between the liver and the walls of the abdomen. A slight displacement of the liver might also give rise to resonance. The rectal temperature was decidedly subnormal.

These signs, especially when considered with reference to the course of the ball, which had been explored with Nélaton's flexible spiral probe, clearly indicated intestinal perforation, at one or more points. Laparotomy was decided upon, and while preparations were being made for the operation, there was a movement of the bowels, and blood was passed per anum; small particles of fecal matter were also observed escaping through one of the external openings. This settled the question of intestinal perforation beyond all cavil.

The operation was performed under some difficulties, as is often the case in surgical practice out of town, where intelligent assistance cannot always be obtained. The patient resided on a plantation, remote from any settlement; the nearest physician being eight or nine miles distant, much time must elapse before his aid could be procured. The earlier an operation is done in a case of this kind the better; every hour's delay adds to the danger of peritonitis and septicæmia. The peristaltic motion of the bowels was evidently recovering from the paralysis imparted by the shock, and blood and fecal matter were already being extravasated into the cavity. I therefore determined to proceed with such help as I had. An intelligent white man, and two or three negroes constituted my corps of assistants.

I administered the chloroform, and when anæsthesia was fully established, gave the towel to the white man, with instructions to withhold it when directed. The patient had been previously troubled with diarrhœa, had eaten nothing since dinner of the previous day, and very little then. This was in some respects an advantage, and in some a disadvantage. He was very gaunt, and the abdominal walls were relaxed, and the bowels flat and flabby. This somewhat embarrassed the operation, but proved in the end a fortunate circumstance.

By an incision of three inches in the median line, below the umbilicus, the peritoneum was reached. The edges of the opening were thoroughly mopped with sponges wrung out of hot water before the peritoneum was opened; consequently very little blood, if any, escaped into the cavity. When the cavity was reached, every precaution was taken to prevent the bowels from becoming chilled, by enveloping them in hot cloths. Search was then made along the track of the ball, and three intestinal openings were found—two in the descending colon, the ball having entered a little above the sigmoid flexure and passed through; a third opening was found at the point where the ball emerged from the cavity, it having cut through a knuckle of the small bowel. An appendix epiploicæ, which was found lacerated and bleeding freely, was tied with catgut at the base and cut off. The discharge of blood from a small vessel on the inner side of the colon was so free that it was necessary to throw a small ligature around it. There was considerable oozing from a number of smaller vessels which was readily checked by sponges soaked in hot water. The edges of the intestinal openings were now pared and drawn together by Lembert's suture, the stitches being placed only a line apart. Care was taken in putting in the stitches to introduce the needle more than a quarter of an inch from the opening, causing it to penetrate to the submucous tissue, and then bring it out again about an eighth of an inch from the edge of the wound on the same side. On the opposite side it was introduced about one-sixth of an inch from the opening, and brought out a quarter of an inch from it. The advantage from this precaution is that, when the sutures were tightened, the mucous membrane was inverted, and the serous surfaces were brought in contact. Serous surfaces unite readily when brought in apposition; but no union can possibly be effected between two mucous surfaces, or between a mucous and a serous surface.

The peritoneal cavity contained a considerable quantity of blood and fecal matter. The cavity was thoroughly mopped with hot sponges. The nozzle of a fountain syringe was introduced—the patient being turned a little to one side—and a steady stream of hot carbolized water kept up till the water came out clear.

All blood and fecal matter being removed from the cavity, the incision was closed by five white silk sutures, supported by adhesive strips, the whole enclosed in a gauze dressing and an elastic flannel bandage. The bowels were kept locked by repeated doses of morphia for eight days, during which time not a particle of food was allowed, except occasionally a small glass of fresh milk. The sutures were removed on the eighth day, when the parts were firmly united by first intention. All dressing, except the adhesive strips and flannel bandage, was now removed, and the patient was allowed a light diet of peaches and milk and mush and milk for a few days, when he resumed his regular habits. On the morning of the ninth day there was a healthy natural action of the bowels, accompanied by no pain or inconvenience. The operation was in all respects very satisfactory. The patient recovered without a bad symptom, and is now, more than three months since the accident, perfectly well, and attends regularly to the duties of a farm hand.

Although the profession is now much interested in abdominal section for any purpose, more especially for traumatism and suturing the intestines, the literature on the subject is yet very meagre. Dr. T. S. K. Morton, of Philadelphia, in an able and interesting paper, published in THE MEDICAL NEWS of February 19th, furnishes considerable valuable information on the subject, more than can be found elsewhere. He also makes some excellent suggestions as to the manner of diagnosticating the existence of intra-peritoneal injury; also the circumstances under which abdominal section would be proper. But Dr. Morton is not correct in all his

statements. He says the first recorded case of gun-shot wound treated by abdominal section is that of Dr. Kinloch, of South Carolina, in 1881, and that the first recovery is that of Kocher, of Switzerland, in 1883. Dr. Kinloch's operation was done in 1862, on a soldier in the Confederate army. The operation was successful, and the patient lived a number of years afterward. This case is reported in the *Medical and Surgical History of the War of the Rebellion*.

BACTERIOLOGICAL NOTES.

BY GEORGE M. STERNBERG, M.D.,

The Bacillus of Typhoid Fever.

IN a paper read before the Association of American Physicians in June last, and published in THE MEDICAL NEWS of August 21, 1886, the writer has reviewed the evidence relating to the etiological import of the bacillus of Eberth, up to the date at which this paper was written. Since that time several important papers have been published, in which detailed accounts are given of extended experimental investigations relating to the biological characters of this bacillus and its relation to the disease with which it is associated. My object at present is to consider briefly this recent experimental evidence, and this I can best do under several distinct heads.

(*a*) *Typhoid bacilli in the blood.*—Almquist,[1] in 1882, reported that he had occasionally found in the blood of typhoid patients during the second or third week of the disease short rods. In the same year Dr. Moxon, of London, in a paper contributed to *The Lancet*, says,

"During last winter's clinical session, some of my most acute and intelligent friends searched carefully for germs in the blood of several severe typhoid cases. The result was that one bacterium was seen, only one, but I was told that it was a very active one."[2]

Cornil and Babes (1885) say that the bacilli are sometimes found in the blood.

Meisels (1886)[3] claims to have found the bacillus nineteen times out of twenty in blood drawn from the finger.

Neuhauss (1886)[4] states that he has found the bacillus nine times out of fifteen in blood drawn from the rose spots in cases of typhoid fever. Opposed to these claims we have the negative results reported by several very careful observers, and especially those recently published by Seitz.[5] This author examined blood drawn from the finger and from roseolous spots in eleven cases. Seven times the blood was drawn from the finger and fourteen times from the rose spots. This blood was examined both by culture-methods, and by staining and direct microscopical examination. Forty-five cover-glass preparations stained with an alkaline solution of methylene-blue gave a negative result. Thirty-seven gelatine plates, and thirty-five *Gläsern*, prepared according to the method from which Neuhauss had previously reported successful results, gave an absolutely negative result.

Gaffky,[1] in his elaborate and conscientious experimental research upon the etiology of "abdominal typhus," also gave his attention to this point. He examined blood drawn from the rose-colored spots, from the skin over the liver, and from the forearm, in every case without result.

Fränkel and Simmonds,[2] in a recent publication, have also reported their failure to find the bacillus in six cases, in the second and third week of sickness, in which they have examined blood drawn from the index finger by the method of cultivation.

Pfuhl,[3] in 1886, also reports his failure to find the bacillus in blood drawn from typhoid patients.

In view of all this negative evidence from observers of recognized skill in bacteriological investigation, it seems to me that the positive results reported by Almquist, Meisels, and Neuhauss, must be considered with scientific scepticism, unless they receive further confirmation from a source which inspires confidence.

(*b*) *Examination of spleen-pulp.*—Maragliano,[4] in 1882, and Klein,[5] in 1884, have reported their success in finding the bacillus of Eberth in spleen-pulp extracted during life by means of a hypodermatic syringe. Quite recently (1886) Philipowicz[6] has given confirmatory evidence upon this point. The bacillus was found in four cases, and its presence further demonstrated by culture experiments with material withdrawn from the spleen.

Seitz has not ventured to repeat these experiments, as he considers puncture of the spleen to be a dangerous procedure. In a case in which a puncture was made immediately after death, for the purpose of obtaining a little splenic pulp, he has seen, when the cavity of the abdomen was subsequently opened, a long rent in the capsule of the spleen, and a considerable escape of blood into the peritoneal cavity.

The examinations made by Seitz, of splenic tissue obtained post-mortem, fully confirm those of Koch, Eberth, Gaffky, Meyer, Fränkel, Simmonds, and many other observers, as to the presence of Eberth's bacillus in this organ in a large majority—and presumably in all—of the cases of typhoid fever. Seitz made plate cultures from the spleen in 22 cases, with a successful result in every instance. In 14 of these cases the typhoid bacillus was obtained in pure cultures—that is, no other microörganisms appeared upon the plates.

(*c*) *Typhoid bacilli in the dejections.*—Gaffky (op. cit.) and Pfuhl (op. cit.) failed to obtain the bacillus from the dejections of typhoid patients, but later investigators have been more successful. Thus, Fränkel and Simmonds, in 1885, were successful in

3 cases out of 11. Pfeiffer[1] also was able to obtain the bacillus from perfectly fresh discharges obtained from patients during the epidemic at Wiesbaden in 1885.

Seitz (op. cit.) examined, by the plate method, 19 dejections from 6 different cases, and obtained a positive result 8 times.

(*d*) *Typhoid bacilli in the urine.*—Seitz made careful researches by the plate method in 7 cases, with a negative result in 5. In 2 cases, however, the typhoid bacillus was found in great numbers. Sixty plates made from the 5 cases remained sterile. On the other hand, the plates from the remaining 2 cases furnished a multitude of colonies, which, by the characteristic growth on potato, were demonstrated to consist of typhoid bacilli. In these 2 cases alone the urine was found to be albuminous. Seitz supposes that in these cases there was preëxisting disease of the kidneys, as the urine was found to be albuminous when they were first admitted to hospital. He remarks that these results give support to the view of Wyssokowitsch,[2] who arrives at the conclusion that a filtering membrane in normal condition is impenetrable for bacteria, and that it is only when the normal separation walls are injured that bacteria which have accumulated can escape at the point of injury.

In sections made from the kidney in 7 cases of typhoid fever, Seitz failed to find colonies of the bacillus, as Gaffky had previously done in 3 cases out of 7.

(*e*) *Experiments upon animals.*—The earlier investigators—Murchison (1857), Birch-Hirschfeld (1874), Klein (1875), Bahrdt (1876), Von Motschukoffsky (1876), Walder (1879)—in their experiments with the discharges of typhoid patients, and with blood, failed to obtain any satisfactory evidence that the disease may be transmitted to the lower animals. Gaffky (1884), operating with pure cultures of the bacillus, also failed to obtain any positive results in experiments upon rabbits, guinea-pigs, rats, mice, and Java apes. Fränkel and Simmonds, on the other hand, have shown that such cultures, when injected in *considerable quantity* into the circulation of a rabbit, or into the peritoneal cavity of a mouse, may cause death after an interval varying from *a few hours to two or three days*. These experimenters report a positive result—*i. e.*, death of the animal—in 2 cases out of 20 in which the injection was made into the peritoneal cavity, and in 20 cases out of 46 in which the culture was injected into the circulation of rabbits through the large vein of the ear.

In the fatal cases the presence of the bacilli in the spleen was demonstrated by microscopical examination and by culture experiments. The more recent (1886) experiments of Seitz were made upon guinea-pigs and rabbits. The general result of these experiments is to confirm Fränkel and Simmonds as to the pathogenic power of *cultures* of the typhoid bacillus when injected in sufficient quantity into the circulation, or when introduced into the alimentary canal. But these cultures contain both the bacillus and the ptomaine produced during its active growth, which was made the subject of experiment by Brieger[1] in 1885. The more recent experiments of Sirotinin,[2] of A. Fränkel,[3] and of Beumer and Peiper,[4] show very clearly that the pathogenic power of the cultures cannot properly be ascribed to the direct action of the bacillus, and that there is nothing specific or characteristic in the effects produced.

In the experiments of A. Fränkel upon guinea-pigs the method of Nicati and Rietsch was followed—that is to say, cultures were injected into the duodenum, either with or without previous ligation of the common bile duct. In fourteen experiments a positive result was obtained seven times. The animal died at the end of three to seven days. The post-mortem appearances consisted in swelling of the spleen, swelling of Peyer's patches both in the small and large intestine, and, in a single case, a fresh ulcer one-half of a centimetre in diameter. The intestinal contents were fluid. The mesenteric glands were swollen, of grayish-red color, and partly studded with hemorrhagic foci. The experiments of Beumer and Peiper show very clearly that these appearances cannot be taken as evidence that the animals died from a specific typhoid process, for similar results were obtained by them from the injection of cultures of five other microörganisms; viz., (1) a greenish-yellow bacillus which does not liquefy gelatine; (2) Bacillus subtilis; (3) a white bacillus; (4) Micrococcus prodigiosus; (5) a yellowish-green bacillus which liquefies gelatine.

The authors referred to sum up their results in the following language.

"When for the decision of this question we consider the above recorded experiments, there can be no doubt that they give concordant evidence in favor of the view that the typhoid bacillus has no specific characteristic action upon the lower animals experimented upon. All of the anatomical changes, such as swelling of the spleen, of the mesenteric glands, of Peyer's patches, the evident inflammation of the upper portion of the small intestine with the watery overflow into the lumen of the gut, which leave us in doubt whether we have before us a disease process similar to that of typhoid, all of these we see in equal degree, with almost the same regularity, resulting from the intravenous or intraperitoneal introduction of the five named species of bacilli. Everywhere the same disease-picture, the same pathological lesions."

The result which Beumer and Peiper have reached after a protracted and painstaking series of experiments is in accord with that which Sirotinin has attained by a more direct method. This author injected cultures which had been subjected to a temperature which insured the destruction of the bacillus, and of spores, if present, in quantities corresponding with the amount of non-sterilized cultures which had given positive results in the experiments of Fränkel and Simmonds, and of

Seitz. Sterilization was effected by exposing his cultures to steam at a temperature of 100° C.

Injections were made into the circulation of rabbits, through the ear-vein, into the peritoneal cavity and beneath the skin of mice, and were administered to guinea-pigs *per os*, and by injection into the peritoneal cavity. The dose employed corresponded with that used in the experiments of Fränkel and Simmonds, and of Seitz.

Experiments were also made with culture fluids from which the bacilli had been removed by means of the Chamberlain filter.

The general result may be briefly stated in the language of the experimenter:

"These experiments show in a definite manner that in fact, culture-solutions from which the typhoid bacillus has been destroyed by sterilization or removed by filtration, induce exactly the same morbid phenomena [illegible] as cultures containing living bacilli; that they cause death in the same time, and that they induce similar pathological changes.

"As in the experiments of Fränkel and Simmonds, so also in my own, the result depended, in general, upon the quantity of the culture injected."

Sirotinin has observed a difference in the poisonous properties of cultures in different media. According to his experiments, more of the poisonous ptomaine—typhotoxin of Brieger—is present in gelatine cultures than in those in agar, or on potato. The age of the culture also is a matter of importance. At the expiration of three days but little ptomaine is found, and he found it best to use old cultures, and states that the poisonous qualities are not diminished even when the cultures have been kept for weeks. The question whether the typhoid bacillus multiplies in the body of the animal in inoculation experiments is answered in the negative both by Sirotinin and by Beumer and Peiler. The last-named authors have made extended experiments with reference to this point, and find that instead of an increase, such as occurs when a microörganism which is pathogenic *per se* is introduced into a susceptible animal, the typhoid bacillus quickly dies out and disappears from the body of an animal into which it has been introduced in enormous numbers by one of the methods employed in their experiments.

(*f*) *The question of spores.*—Since the publication of Gaffky's memoir, in the second volume of the *Mittheilungen aus dem Kaiserlichen Gesundheitsamte*, his statements with reference to the formation of spores by the typhoid bacillus have been generally accepted, and have been confirmed by most of the observers who have followed him. Seitz, however, has not been able to convince himself of the presence of spores in his cultures. Buchner[1] and Michael[2] also report their failure to find spores.

According to Gaffky, spores are not formed at the room temperature. He has repeatedly searched for spores in gelatine and potato cultures grown at the room temperature, but without success. On the other hand, in cultures kept in the incubator at 37° C., spores were constantly found on the third and fourth day, in unstained preparations, and also in stained cover-glass preparations. These spores were shining, round bodies, occupying the whole width of the bacilli, and situated at the ends of the rods. Only a single well-developed spore was observed in a single rod. At the opposite end of such a rod, however, one sometimes observes an indication of the formation of a second spore. But Gaffky says that he has never seen two perfectly developed spores in a single rod. When two rods are joined, no spores are found at ends which are coupled together, while each rod may have a spore at its free extremity.

The same thing is seen in the filaments (scheinfäden), which are made up of separate bacilli, each of which may contain a single spore. When a culture has been kept for a considerable time, one finds near the bacilli containing spores, free round spores, which show themselves to be such through their uniform size and refractive power, as well as through the fact that they do not take the aniline colors. Gaffky says:

"As the question of the formation of spores is one of high importance for the etiology of the disease, I have sought to clear up this point. I used for this purpose the excellent thermostat of d'Arsonval, by which it is possible to maintain precisely the same temperature for weeks at a time. The result of this research is that growth and spore formation undoubtedly occur at 42° C. (107.6°), although, perhaps, somewhat less vigorously than at the body temperature. From 30° to 40° appears to be the most suitable temperature for the development of spores. They are also formed at 25° although somewhat later, 20° C. appears to be the lowest point at which they form; at least I have at this temperature only found a few, not very well developed spores, at the end of eight days. Two days later the process was not much further advanced."

Gaffky also states that spores form in gelatine cultures, and upon blood-serum when kept in the incubating oven at a temperature of 30° to 40° C. Blood-serum containing spores, dried in a thin layer, was kept for three months, and then inoculated into flesh-peptone-gelatine with success.

I may say here that I have started fresh cultures of the typhoid bacillus from a liquid culture in veal broth which has been kept in a hermetically sealed glass tube for four months. I have not, however, been able to detect the presence of spores in this material. Seitz has started fresh cultures from a dried-up gelatine culture which had been kept for nearly eight months.

Bacilli dried upon silk threads were found by the author last mentioned to grow at the end of three weeks.

The interesting results obtained by Seitz in the cultivation of this bacillus at a low temperature may be mentioned here. Gelatine cultures placed in an ice-chest had, at the end of three weeks, a development about equal to that of a similar culture kept at the room temperature for four or five days. Gelatine plates kept at a constant temperature of 3° C. above the freezing-point, showed a decided growth at the end of forty-eight hours.

(*g*) *The thermal death point of the typhoid bacillus.*—Some three months since the writer commenced a series of experiments intended to fix in a definite

way the exact degree of heat which is required to destroy each of the pathogenic microörganisms at present known to us. A detailed account of the results obtained will be given in a paper to be published in the July number of *The American Journal of the Medical Sciences*. I shall give at present, however, an account of these experiments so far as they relate to the typhoid bacillus.

In all of these experiments I have adopted ten minutes as the standard time of exposure to a given degree of temperature, which, in a series of experiments, is, of course, changed according as it is found to be too high or too low.

A fresh culture of the organism to be tested is introduced into capillary glass-tubes having an expanded extremity to serve as an air-cavity, by means of which the culture-fluid is drawn into or forced out of the capillary tube. This is readily accomplished by means of heat.

The glass tubes, hermetically sealed, are introduced into a vessel containing water, which is kept at a constant temperature by personal supervision, a Bunsen burner being the source of heat. A standard thermometer is placed in the vessel, and this and the capillary tubes are protected from the bottom of the vessel containing them by a thick plate of non-conducting material. A uniform temperature throughout the fluid is maintained by constant stirring.

After exposure for ten minutes to a given temperature the sealed extremity of the capillary tube is broken off with sterilized forceps and the contents are forced, by heating the air in the expanded extremity, into a test-tube containing sterile fleshpeptone-gelatine, which has been liquefied by exposure in a water bath to a temperature of 40° C., or below. The cotton plug is only removed for a moment in order to introduce the contents of the capillary tube, and in my extended experiments I have very rarely seen any accidental contamination. A rubber cap is next placed upon the open end of the test-tube, and the gelatine is spread in a uniform manner over the interior of the tube by the method of Esmarch.[1] This is accomplished by rolling the tube in iced water until the gelatine hardens. These tubes are then placed in a room or incubating oven, having a suitable temperature—20° to 22° C.—and are left until the question is determined as to the destruction of the vitality of the organism which has been introduced into them.

A control experiment is made in every case with material from the same culture which has not been subjected to heat. The control usually shows numerous colonies within twenty-four to forty-eight hours, but in the case of certain pathogenic organisms the development of colonies which can be recognized by the naked eye takes a longer time—*e. g.*, erysipelas, mouse septicæmia; others, such as the tubercle bacillus and the gonococcus of Neisser, will not grow at all under these conditions.

As growth is, as a general rule, retarded by temperatures approaching that at which it is entirely prevented, it is necessary, when no evidence of growth is seen sooner, to keep the tubes for at least a week. A negative result at the end of this time may be taken as evidence that the organism introduced into the tube was killed by the temperature to which it had been subjected.

I come now to speak more specifically of my experiments upon the typhoid bacillus.

As authors generally agree in the statement that the typhoid bacillus forms spores, and as my own previous experiments upon spore-bearing bacilli, and those of others, indicated that spores are only killed at a comparatively high temperature, I made first the following experiment, in which material from a pure culture in veal broth was exposed for the time adopted as a standard (ten minutes) as follows:

Exp. of Nov. 10. **50°**, 60°, 70°, **cont.** In this and all subsequent records of experiments made, the figures in heavy type indicate that growth occurred; the figures in light type indicate the absence of any growth—*i. e.*, the killing of the organism at the temperature indicated by the figures. It will be seen that at 60° or at 70° C. no growth occurred, while in the control tube, and in that at 50° C. (= 122° Fahr.) the typhoid bacillus grew abundantly. I may say here that my object has been to determine the lowest temperature which will insure the destruction of all germs of each species tested. I have not, therefore, considered it worth while in those cases in which only a few colonies have grown out, after some days, to count the number of colonies and record the same. This would involve a vast amount of work, and from my point of view such a record would have no special advantage over the simple record of growth or failure to grow. In the practical application of data of this kind in the disinfection of typhoid excreta, etc., it is evident that a few colonies, representing a few bacilli or spores, which have survived the temperature tested, are as potent for mischief as a larger number.

My stock for these experiments is from cultures brought from Europe by Dr. Bolton, and obtained by him in the laboratory of Professor Koch. I have repeatedly tested this stock by means of potato cultures, stained cover-glass preparations, etc., and it presents all of the characters assigned to the typhoid bacillus by Gaffky, by Eisenberg in his *Bakteriologische Diagnostik*, and by Flügge in his recent work, *Die Mikroörganismen*.

In fluid cultures and in potato cultures kept at the room temperature I have not been able to discover any spores, but in potato cultures kept in the incubating oven at 38° C. I have repeatedly seen spherical, highly refractive bodies at the ends of the rods, which appear to be spores, and no doubt correspond with the bodies which have been called spores by Gaffky and others. My only reason for hesitation in concurring in this opinion is based upon the fact that my frequently repeated experiments show that potato cultures containing these refractive bodies are killed by a temperature of 60° C. I have in no instance had any growth from potato cultures exposed to this temperature for ten minutes. At first I was disposed to think that this fact is fatal to the view that these refractive bodies at the ends of the typhoid bacilli are reproductive spores, for all spores which I had previously met with resist a much higher

[1] Zeitschrift für Hygiene, Bd. 1, Heft 2, S. 293

temperature than this. But, on second thought, I am not inclined to accept this inference without further investigation. It does not follow that, because the spores of several well-known bacilli resist a temperature of 100° for some minutes, all spores have a like resisting power. Indeed, we have heretofore recognized differences in the resisting power of those spores which are only killed at a comparatively high temperature, and it is quite possible that some spores are killed at a comparatively low temperature. My investigations, which are not yet completed, favor the view that this is the case, and that these refractive bodies are reproductive spores, notwithstanding the fact that their resisting power for heat is not greater than that of the bacilli themselves. I shall consider this question *in extenso* when my experiments upon the thermal death-point of other bacilli have been completed.

The experiments which I have made upon the typhoid bacillus up to the present date are recorded in the following table:

TYPHOID BACILLUS.

(Ten minutes exposure.)

Date.	Culture.	Experiments.	Remarks.
Nov. 10.	Veal broth.	50°, **cont.**	[illegible] hours.
Nov. 1[illegible]	Veal broth.	50°, 52°, 54°, 56°, 58°, 60°, **cont.**	Fluid culture of November 1st.
Nov. 30.	Potato culture.	50°, 55°, 80°, **cont.**	Culture at room temperature.
Dec. [illegible]	Potato culture.	60°, **cont.**	Culture in oven at 38° [illegible] C.
Dec. 24.	Potato culture.	60°, 70°, 80°, **cont.**	Culture in oven for 10 days, then kept at room temperature [illegible] days.
Jan. [illegible]	Potato culture.	55°, 60°, 70°, 80°, **cont.**	Culture in oven at 38° for 7 days.
Jan. [illegible]	Potato culture.	48°, 50°, 52°, 60°, **cont.**	Potato in oven at 38° [illegible]
Jan. [illegible]	[illegible]	50°, 60°, **cont.**	Potato in oven 7 days, [illegible]

An inspection of this table shows that no development occurred in any instance after exposure to a temperature of 56° C. and above. In one experiment (Nov. 30) growth occurred after exposure to 55° C., but in this case it was very much delayed; in the experiment of January 15, no development occurred after exposure to 55°. Differences of this kind, when we are on the border-line, are to be expected.

We may then safely say that the thermal death-point of the typhoid bacillus is 56° C. (= 132.8° F.).

A CASE OF POISONING BY THE HYPODERMATIC USE OF COCAINE MURIATE.

BY E. HOWELL WAY, M.D.
[illegible]

On March 15th, having been for some time engaged in studying the physiological and therapeutical effects of cocaine on human beings, I concluded to make a personal experiment with cocaine administered hypodermatically—an experiment which proved a very dangerous one, and which came very near terminating fatally.

Without presuming to add anything to the already voluminous papers which have thronged the journals during the past two years, on the action of cocaine and its salts, I submit a report of my case, believing it may be of interest as the personal experience of a physician.

At 6 P.M. I injected a quarter of a grain of Squibb's hydrochlorate of cocaine into the dorsal aspect of the left forearm. In three minutes this was followed by a limited degree of anæsthesia in the integument for about two inches in each direction from the point of injection.

Notwithstanding the very superficial nature of this and of subsequent injections, the local anæsthesia was at no time marked—never becoming developed sufficiently to prevent a sensation of pain on puncturing or pricking the integument with the point of a needle.

No constitutional symptoms were manifest at the expiration of fifteen minutes. I now made another injection of a quarter of a grain of the salt at a point a few lines removed from the site of the former injection. Again fifteen minutes elapsed without there being any apparent increase in the degree of local anæsthesia present or the appearance of any visible constitutional effects.

After debating the question as to whether or not the dangers of cocaine-poisoning had been overrated, and a query as to the purity of the salt used, I, emboldened by the apparent inertness of the drug, at 6.30 P.M. injected near the same points as before, half a grain more, making one grain taken in half an hour hypodermatically. In ten minutes from the time of the last injection constitutional symptoms began to be manifest. I became restless and disinclined to remain quiet, my respirations increased to thirty per minute, and grew shallow and sighing in character, while my pulse rose from normal (72) to 120.

Five minutes later I became convinced that I was poisoned, and perhaps might need assistance. I arose, and buttoning my coat about me, walked down a flight of stairs and a distance of two hundred yards to a drug-store. On walking in I endeavored to tell the druggist what I wanted, but was unable to collect words to express my ideas for about one minute, during which he had me sit down. The aphasia disappearing, I told him to bring ammonia and digitalis, and accompany me to my office. I then returned, walking along without any difficulty, greeting friends I met as usual, and experiencing only a sense of slight dizziness and some precordial oppression, which continued to increase.

It was now 6.50 P.M. Twenty minutes had elapsed since taking the half grain injection. My pupils were dilating slowly; mental faculties perfectly clear and collected; no pain in head or other part of body; respirations reduced to normal frequency, but very shallow and sighing; pulse 140, quick, feeble, and barely perceptible at wrist. I walked about the room for three or four minutes,

when I grew weak and exhausted, and was compelled to lie down on a lounge.

At 7.20 P.M. my condition was almost that of collapse. Mental faculties perfectly clear and natural; pupils widely dilated; mouth dry, and a sensation as of the presence of a foreign body in the pharynx; respirations shallow, sighing, and reduced to 11 per minute; pulse elevated to 180, very feeble, fluttering, and extinct at wrist; extremities cold; body was warm to the touch, but my own sensations were those of intense cold. I was placed in front of a large fire and my body enveloped in heavy woollen blankets while my feet and hands were briskly rubbed.

A sense of impending dissolution came over me—not a feeling of fear, but a conviction that my physical condition was such that death was almost inevitable. My mind remained perfectly clear, and I gave my attendants all directions as to my care. I took frequent doses of ammonia and digitalis—the former seemed to be of very great advantage.

At 7.30 P.M. my condition was worse, and myself and attendants were momentarily expecting my death. My extremities seemed to lose all power of either motion or sensation. I struggled against this with all my will-power, and would call for frequent doses of ammonia, which would give me (so it seemed) sufficient strength to move. Painful emesis occurred twice, each time being attended with the ejection of about f℥ij of white, frothy matter which soon evaporated, leaving only a faint white residuum. Respirations were now only 9 per minute, and exceedingly shallow; carotid pulse faintly beating at 200; radial pulse entirely imperceptible; and no impulse of heart-beat felt on palpation. Mind still clear. Suffered no pain.

I remained in this state for about half an hour, during which, in addition to frequent small doses of ammonia and digitalis, I inhaled three drops of nitrite of amyl. A slight improvement in the cardiac action was now noted. Respirations increased to fourteen per minute, pupils contracted to normal, and skin became moist and warm. At 10 P.M. the radial pulse returned, was full, and reduced to 140. Respirations were of normal frequency, and of almost normal vigor. Improvement continued. At 11 P.M. respirations normal, pulse 120. Suffered at this time from a dull, aching pain in lumbar region of spine and sense of great weakness and prostration. Half an hour later very copious diuresis took place.

At 1 A.M. was entirely well save the feeling of exhaustion naturally following so great a derangement of the vital functions. Was now removed to my room, and slept soundly until 8 A.M. During the day I suffered much annoyance from the very dry state of my pharynx and also from muscular weakness. Both these inconveniences disappeared during the following night, and since then my health has been most excellent.

MEDICAL PROGRESS.

Subiodide of Bismuth in the Treatment of Wounds.—Dr. Sweetman reports, in the *Canadian Practitioner* for April, 1887, his results obtained in the use of subiodide of bismuth, as originally brought to the notice of the profession in an article by Dr. A. S. Reynolds, of Philadelphia, published in The Medical News of October 9, 1886.

Its advantages as a dressing are:

1. That it is a reliable antiseptic.

2. That it is not easily evolatilized, and when properly applied the dressing may remain untouched for several days.

3. That it has no objectionable odor.

4. That it produces no irritation.

5. That there is no danger from absorption, and is harmless even when taken by the mouth.

6. That if the subiodide of bismuth is used properly, the prognosis in every case may be certain cure in half the time, and with far better results than can be maintained by any other treatment he has seen employed.

Iodol in Diphtheria.—In order to test the statements of Dr. Mazzoni, Dr. L. L. Stembo, of Vilna, tried (*Proceedings of the Vilna Medical Society*, No. v., 1887, p. 114) the local use of iodol in seven cases of diphtheria, two of which were severe. The drug was applied either alone, in powder, or in the form of a solution (℞ Iodoli, ℈ss; liq. vini, ℥ss; glycerini, ℥iijs). All the patients recovered after treatment lasting from four to six days. The advantages claimed by Dr. Stembo for iodol are its complete harmlessness, its freedom from unpleasant smell or taste, the painlessness of its application, and the absence of any untoward secondary effects, such as loss of appetite, nausea, vomiting, etc. —*British Medical Journal*, April 9, 1887.

Absorbent Canton Flannel.—England, in describing antiseptic dressings which he prepares for use in the Philadelphia Hospital, describes as follows his preparation of canton flannel:

Under this term we use, in the Philadelphia Hospital, a canton flannel rendered absorbent by boiling in a 3 per cent. solution of caustic soda for 1½ or 2 hours, until all the fatty matter in the fibres is decomposed, then washing in several portions of cold water, then macerating for 10 or 15 minutes the product in a 1.5 per cent. solution of hydrochloric acid, whereby any traces of free soda are neutralized, and the fibres of the goods are whitened; and, lastly, followed by several washings in water, wringing out with a machine and drying. This product has been found to be peculiarly serviceable in hospital practice as a cheap, efficient, and reliable substitute for all the minor cases for which at present the so-called patent lint is generally demanded; for example, in local applications of lotion of lead-water and laudanum, and as a dressing with various ointments upon chronic sores, ulcers, etc. The proof of its utility may be inferred from the fact that while we used, during 1886, 1500 yards of patent lint, we used, also, 2500 yards of this absorbent canton flannel. In cost it is almost one-half of that of patent lint.—*American Journal of Pharmacy*, April, 1887.

A Formula for the Use of Paraldehyde.—Dr. Eccles, of Brooklyn, in the *Reports of the New York State Pharmaceutical Association* for 1886, gives the following as a useful formula for administering paraldehyde:

The following is the formula that has so far given the

best results. If properly dispensed it will be perfectly transparent. To have it so care must be taken to see that the articles are pure and *the vials* into which they are put [illegible]:

R.—Ol. amygd. dulc., [illegible]
Paraldehyde . . . . . ʒss
Chloroformi . . . . . gtt. xij.
Ol. cinnam. . . . . gtt. iij.—M.

Sig.—One-half at bedtime, the rest during the night if required.

This, of course, is designed for an adult so far as the dose is concerned. Children can be given it in proportion to their ages. In cases of strychnine poisoning this whole amount or even more might be administered at a single dose. It is said to be the only reliable antidote to strychnine. According to late reports from some investigators rabbits have been saved by its use after the administration of one or more fatal doses of this poison.

HEART-STRAIN AND WEAK HEART.—DR. BEVERLEY ROBINSON states in the *Med. Record* of Feb. 26, 1887, that in these cases he has had the best results from the administration of tincture of the chloride of iron, in moderate and frequently repeated doses continued for weeks and months, while the liver was gently stimulated by tablet triturates of calomel, gr. ¼ to ½, morning and evening, or oftener. The usual heart-tonics have sometimes proved inefficient; again, they have been evidently useful. He does not approve of the use of digitalis in these cases, except in very moderate doses, combined or not with the iron tincture. If too much digitalis be given, instead of helping the patient it does him harm.

On several occasions, when digitalis had proved to be useless or injurious, he has had very excellent results from caffeine or convallaria. Certainly the latter drug is more easily tolerated by a sensitive stomach than digitalis is; and whenever the nervous supply of the heart is especially implicated, he believes that he secures more quieting effects from its employment. Among well-known cardiac tonics and stimulants for obtaining temporary good effects, at least, he knows of no drug quite equal to coca. Given in the form of wine or fluid extract, it does much at times to restore the heart-muscle to its former tone. He has obtained the best effects from the use of Mariani's wine. These results are attributable to the excellent quality of the coca-leaves and of the wine used in its manufacture. Of course, the good effects of any and all treatment will be closely allied with the stage of the disease when it first comes under observation. If the heart-muscle be healthy, with the exception of more or less loss of tonicity or contractile power, its complete integrity may be restored. If, on the contrary, the heart-fibres are already considerably stretched and the cavities dilated, while in some instances the patient may be restored to apparent health for a shorter or longer period, the probabilities are that ultimately renewed distress will be felt and further progress in the disease will take place.

MEANS TO DISGUISE THE ODOR OF IODOFORM.—*Pratique Medicale*, of March 1, 1887, gives the following various substances as useful in masking the odor of iodoform: 1. Several drops of the essence of bitter almonds; tannin; a small quantity of balsam of Peru; a mixture of iodoform and the above may be made.

2. An emulsion of iodoform and the oil of bitter almonds, equal parts.

3. Iodoform . . . . . 1 part.
Powdered charcoal . . . . 2 parts.
Sulphate of quinine . . . . ½ part.
Essence of mint . . . . . ½ part.

A DEVICE TO SECURE FIXATION OF FRAGMENTS IN COMPOUND FRACTURES.—DR. MOLLOY describes the following, as seen in Schede's wards at Hamburg:

The treatment of compound fractures presents some novel features. The wound or wounds are laid freely open, irrigated thoroughly with corrosive sublimate solution, 1:1000, all loose splinters of bone removed, fracture reduced, and fixation of the fragments secured by means of a little device of Dr. Hansmann, the first assistant surgeon. It consists of a small metal plate about half an inch wide and as long as is necessary, perforated with holes at short distances. It is laid upon the periosteum, and a screw inserted through one of the holes into the bone on each side of the point of fracture. Two of these little splints are usually employed in a fracture of a large bone, after which the immobility of the limb is secured in the usual way by splints; the wound being left open and treated antiseptically. The metal plate has the advantage over bone sutures in being much more easy and simple in its application as well as removal, and it secures and maintains the approximation and fixation of the fragments just as firmly.—*Lancet-Clinic*, April 16, 1887.

HYDRIODATE OF HYOSCINE IN KIDNEY DISEASES.—DR. TIRARD, in the *Practitioner* for February, 1887, reports his experiences with the following solution:

R.—Hyoscinæ hydriodatis . . . gr.j.
Aquæ destillatæ . . . . mxcc.

Hydriodate of hyoscine is a drug which can be used with perfect safety in cases of kidney disease where morphine is inadmissible. It is a drug which may give rest when other sedatives fail.

If used in two minim doses subcutaneously, it may give more satisfaction to the patient than to the attendants, since the unconsciousness may be accompanied by angry and combative delirium; should this occur it will probably be sufficient to diminish the amount employed.

It is very rapid in its action, unconsciousness following in from ten to twenty minutes, and the after-effects are of a soothing character.

Even when delirium is present in a violent form, it is followed by quiet sleep, and the patient, being unconscious, is much more refreshed than by a night of short snatches of sleep produced by chloral or bromide, and the result is a marked improvement in both aspect and temper. And lastly, no irritation is produced around the site of injection.

I believe that hydriodate of hyoscine will probably take a firmly established position as a sedative in cases where morphine cannot be employed.—*Medical Age*, March 25, 1887.

DISINFECTANTS AND THEIR USES.—DR. ALFRED CARPENTER delivered an address at the last monthly

meeting of the Association of Public Sanitary Inspectors, on "Theory and Practice as to Disinfection." He urged that sanitary inspectors, who have very great power if they use it carefully, should reason out the grounds of the application of any particular mode of disinfection, rather than give a blind obedience to a written order. With regard to smallpox, he pointed out that germs of living protoplasm in the breath of a patient will take root if immediately transplanted to the membrane of a susceptible person, but if floated about in the air for 100 yards they will lose their vitality. Isolation, with ventilation, as rapidly as possible, is necessary in such cases. For disinfecting the furniture of a house after infectious disease steam is preferable, and he advised all local authorities to provide themselves with the means of applying steam heat. Dr. Carpenter did not recommend carbolic acid as a disinfectant in cases of disease, for it has been found that the acid preserves the dormant germ from decay. This also hold goods of alcohol; the use of spirituous liquors as a protection against the evils of impure water is no protection at all. The same argument applies, though in a minor degree, to sulphurous acid. The best disinfectant is a solution of bichloride of mercury. It requires to be used with care, but it is rapid in its action, and so powerful that a solution of 1 part in 5000 of water will in fifteen minutes destroy every living germ, dormant or otherwise, with which it comes in contact. The best disinfectant for sewers is sulphate of iron. Dr. Carpenter concluded by saying that the lines on which disinfection should be carried out are: Ventilation, aërial disinfection by chlorine or steam, lime washing, washing floors and furniture with solutions of mercuric chloride; steam heat for clothing, furniture, etc.; and sulphate of iron or chloride of lime in adequate quantities for flushing. If these means are effectively applied infectious diseases will be completely banished from our midst, and any local authority which now allows of their continuance is doing defective work. —*British Medical Journal*, April 9, 1887.

Fatal Result of Large Doses of Thallin.—Professor Ehrlich, who has had very good results from thallin in typhoid fever, has had the candor to report a case (*Münchener med. Wochenschr.*, No. viii.) which ended fatally under repeated progressive doses —namely, 0.08 up to 0.58 gramme (one and a quarter grains to nine grains nearly)—of thallin tartrate. The necropsy showed the lesions of typhoid fever in the healing stage, cardiac hypertrophy and dilatation, fresh mitral endocarditis, and hemorrhagic infarcts in the renal papillæ, the last-mentioned being, as shown by experiment, a characteristic sign of thallin poisoning. Ehrlich assumes that the cardiac condition caused defective excretion and consequent accumulation of thallin. This danger may be completely avoided by fixing as the maximum dose for hourly administration 0.2 gramme of the tartrate (three grains). In the progressive administration of thallin very small doses are used at first—namely, 0.07 or 0.08 gramme—and this amount is increased daily by $\frac{1}{10}$ gramme. Heart-failure of any kind is a contraindication of thallin treatment; so are the various forms of kidney disease, and also cases which resist the influence of small doses. Professor Ehrlich deserves our sympathy and respect for his conduct in this case, which will have great influence upon the use of thallin in this country.—*British Medical Journal*, April 9, 1887.

Treatment of Acne.—Bulkley, as quoted by the *Monatshefte für Praktische Dermatologie*, No. 6, 1887, gives the following prescriptions:

For *sebacea oleosa* of the face the following lotion:

℞.—Potass. sulphat.,
Zinci sulphat. . . . . āā ʒ 1.
Aq. rosarum . . . . . ℥ 3¾.

Each of the salts used should be dissolved in half the fluid and the solutions mixed.

Repeated bathing with weak solutions of soda (1 or 2 to 600), followed by the application of an alcoholic solution of corrosive sublimate (1 to 200 water and 1000 alcohol) generally suffices to lessen the excessive formation of sebaceous matter.

Weak solutions of ergotin and belladonna or of atropia are useful when sublimate does not agree.

Seborrhœa of the scalp is treated by the following lotion:

℞.—Tinct. canthar. . . . . ʒ 2 to 5.
Tinct. capsic. . . . . ʒ 2 to 5.
Tinct. nuc. vomic. . . . . ℥ 3¾.
Olei ricin. . . . . ʒ 2.
Olei lavand. . . . . ♏ 30.
Spirit. dilut. . . . . ad ℥ 3¾ or 4.
M. Fiat lotion.
Sig. External use only.

Acne sebacea cerea of the face may be treated by this ointment:

℞.—Bismuth. subnit. . . . . ʒ 1.
Ung. hydrarg. oxyd. rubr. . . gr. 30.
Ung. hydrarg. præcip. alb. . . ʒ 2.
Ung. rosat. . . . . ʒ 6.
M. Fiat unguentum.

A New Method of Taking Temperature in Children.—Filatoff writes as follows in the *Archiv f. Kinderheilkunde* on this point:

The difficulties in taking the temperature in children are but too well known, and an important symptom often fails of accuracy of record, either because the child offers too much opposition, or because the mother cannot endure the crying of the child for the quarter of an hour during which the thermometer must remain in the axilla, or the five minutes during which it should be kept in the rectum. In cases of this kind the author recommends the use of a warmed thermometer which need be kept only for a moment in the axilla, and with which the fall and not the rise of the column of mercury is to be observed. The result will not vary by more than one or two-hundredths of a degree from that which is obtained by the ordinary method. The thermometer may be warmed either by rubbing the bulb in the bare hand, or in a handkerchief, and 42° to 43° C. may be quickly indicated. It should then be quickly placed in the axilla and allowed to remain one or two minutes. The author is satisfied with the experience which he has had with this plan up to the present time.

A Method of Preparing Borated and Salicylated Cotton.—In an article on "Antiseptic Cottons

and Gauzes," in the *American Journal of Pharmacy* for April, 1887, ENGLAND describes his methods as follows:

Borated Cotton.—Since, according to the Pharmacopœia, boric acid is readily soluble in 3 parts of boiling water and 25 parts of cold water, it is evident that hot water will readily dissolve 15 per cent. of boric acid, and precipitate a very large proportion on cooling, and, if purified cotton be treated with an equal weight of a hot aqueous solution of the acid of that strength and dried, it will, of necessity, contain 15 per cent. of the acid; a very desirable strength to insure its antiseptic properties. But in practice it will be found that cotton readily absorbs from about four to five times its weight of water; the exact proportions varying with the absorbency of the cotton, the quantities of antiseptic cotton made at a time, the manner of impregnating with the medicated solution, and the degree of subsequent expression. Hence it is better to make the water four or five times the weight of cotton used, impregnate in thin layers in a flat, open vessel, and express moderately, or in such a manner that after all the cotton has been treated there will be no medicating liquid left. Borated cotton thus prepared, has the acid intimately incorporated into its fibres, and is free from loose particles of crystals among its meshes.

Boric acid	. .	80 gm. (2 oz. av. and 360 grs.)
[illegible]	. .	[illegible]
Absorbent cotton	.	435.5 " (1 lb. av.)

Dissolve the acid in the boiling water, impregnate the cotton, express and dry by exposure to the air or slight heat. Borated cotton thus made contains exactly, in the finished product, 15 per cent. of its weight of acid. The use of a Trœmner solution balance will greatly facilitate the weighing of quantities in this, as well as in all other formulæ herein given.

Salicylated Cotton.—This is generally made 10 per cent. in strength, with water, alcohol, and a small proportion of glycerine to prevent the shaking out, after drying, of the crystals contained in the interstices of the fibres. The following is the formula used:

Salicylic acid	. .	57 gm. (2 oz. av.)
Alcohol	. . .	453.5 " (1 lb. ")
Hot water	. .	[illegible]
Glycerine	. .	[illegible]
Absorbent cotton	. .	453.5 " (1 lb. ")

Mix the acid, in a porcelain or Wedgewood mortar, with the glycerine, dissolve with added alcohol, place the solution in a large, flat, open vessel, and lay upon the surface of the liquid the cotton in thin layers. After standing for ten minutes in this liquid, and absorption is completed, remove, express, and lay aside to dry upon a frame. The method of expression may be with the use of the hands, but a better way is between the open rollers of a clothes-wringer so provided that they are not too tightly screwed together. Pilcher observes that the antiseptic qualities of this cotton may be still further enhanced if, before using, a thin layer of it be dipped in a 10 per cent. solution of the acid in glycerine, applying this to the wound first, and then following on top with a thick layer of dry salicylated cotton, sufficiently wide to extend beyond the outer limits of the wound on all sides.

PICRATE OF AMMONIA IN MALARIAL DISEASE.—DR. H. MARTYN CLARK, of the Amritsar Medical Mission, Punjaub, has treated no fewer than 10,000 cases of malarial diseases with picrate of ammonia, and in half the cases he has kept a record. In nine cases out of 5000 did the picrate fail, and in these quinine cured at once. The usual dose is from one-eighth of a grain to one and a half grains four or five times times a day in pill. Half a grain is a fair average dose. Thus given the result is soon visible. In the great majority of the cases treated, one-half grain doses in the interval prevented the recurrence of the next attack of the fever, while in about twenty per cent. of the patients two or three attacks followed before the fever ceased. In only one case of quartan ague, despite large doses of the salt, the fever recurred for six periods, gradually diminishing in intensity, and then yielded to it. It is equally successful in all the forms of ague, but it is a curious fact that the cases in which it failed to cure were all of the tertian variety. Dr. Clark has also employed this agent in the treatment of twenty-five cases of malarial neuralgia of various nerves, six cases of malarial headache, and one of malarial colic. In all these instances it cured completely and speedily. In addition to being cheaper and given in smaller doses, picrate of ammonia does not produce the unpleasant effects that quinine does, such as headache, deafness, tinnitus, etc.; nor does it, like quinine, disorder the digestion or cause nausea, as quinine does in India.—*Chemist and Druggist*, March 19, 1887.

THE MICROBE OF TYPHOID FEVER.—At a recent meeting of the Société des Hôpitaux, M. Chantemesse made an interesting communication concerning the morphological and biological characteristics of the typhoid microbe. The sporulation of this microbe takes place between 19° and 48° C. (67° to 104.4° F.). It develops in water, even if sterilized. At a temperature of 45° C. (113° F.) the cultivations live for several days; they are destroyed by boiling. This microbe retains its vitality in damp ground. Corrosive sublimate (1 : 20,000) and sulphate of quinine (1 : 800) destroy it. Carbolic acid (1 : 400) has no effect on it; hydrochloric acid is also inert; therefore, the acidity of the stomach is not inimical to this microbe.—*British Medical Journal*, April 9, 1887.

ORDINARY PRECAUTIONS IN THE CARE OF THE EARS.—HARTMANN, of Berlin, in a recent work on otology, gives the following advice:

Under ordinary conditions, the healthy ear does not need to be protected from cold; only during extreme cold or stormy or rainy weather ought cotton-wool to be inserted, into children's ears especially. The same precaution must be taken in the case of every ear predisposed to inflammation. All persons whose membranæ are perforated ought to protect their ears with cotton-wool. The entrance of cold fluids into any ear must always be prevented; and so, while bathing or diving, the ear ought to be plugged. Patients with perforations of the membrane should be very careful in this respect, as violent inflammation may be caused by the entrance of cold water.—*Bristol Medico-Chirurgical Journal*, March, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE. . . . . $5.00.

SINGLE COPIES. . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, APRIL 30, 1887.

CEREBRAL LOCALIZATION AND CRANIAL TOPOGRAPHY.

THAT the subject of cerebral localization is not only not exhausted, but that the threshold of its investigation has been scarcely more than passed, is indicated by the appearance of a paper of unusual interest, by VICTOR HORSLEY, in the current number of *The American Journal of the Medical Sciences*. This paper is modestly termed "A Note on the Means of Topographical Diagnosis of Focal Disease Affecting the so-called Motor Region of the Cerebral Cortex." It is a contribution which will prove equally valuable to the surgeon and to the neurologist, being a summary of the means adopted by the writer as topographical guides to definite portions of the brain. Its value consists largely in that it is not simply a review of the literature of the problem under discussion, but contains the results of experiment, observation, and of clinical and surgical experience.

Already to Horsley we owe not only valuable physiological and clinical work, particularly in connection with the subject of cerebral localization, but also to him, in large part, is due the credit of a few of the most brilliant operations that have been performed within the last few years, among which several cases of cerebral tumor successfully removed, after having been localized by the aid of the rules given in this paper, are notable.

Every one who has had to deal practically with the subject of cranio-cerebral topography knows something of the difficulties of exactly locating on the skull the relative position of the parts beneath, especially when those parts are of the dimensions of a fissure or of a single convolution. As useful as the older methods of Broca, Championnière, Seguin, and others have been, they have not fulfilled all the requirements of great exactness and easy adaptation. Horsley gives some new and valuable suggestions.

Taking up the surface markings of the head, he regards first the sutures, next the eminences, and lastly the temporal ridges, giving methods so simple and easy of application for recognizing and determining these landmarks that nothing is left to be desired. The importance of the temporal ridges is well shown. He recognizes two of these, the first or lower, marking the upper border of the attachment of the temporal muscle; the second or upper, marking the attachment of the temporal fascia. The ridge of the temporal muscle can be most readily determined by telling the patient to shut the mouth firmly. That of the fascia in the majority of instances can be felt by palpation. The methods of determining the coronal and parieto-squamal sutures as given are comparatively easy.

Horsley wisely, we think, adopts the plan of Thane, of University College, London, for locating the upper end of the fissure of Rolando. It consists in taking the length of the middle line of the head from the root of the nose to the occipital protuberance, and then by halving the result the centre of this line is obtained. The upper end of the fissure of Rolando will be found in adults to be situated half an inch behind this centre point. He describes a very simple instrument of soft iron, consisting of a ten-inch strip, one centimetre broad, from the middle of which branches off another strip about six inches long, the two making an angle in front of sixty-seven degrees. This instrument is used by placing the arm upon the middle line of the head, which has been previously marked; the angle between the arms is then made to coincide with the theoretical situation, according to Thane, of the upper end of the fissure of Rolando; and a line drawn from the anterior border of the short arm will give the situation of the fissure for the upper two-thirds of its course.

The limitation of the areas of the representation of movements of different parts of the body, in certain cerebral gyri, to which the paper of Horsley is confined, is very carefully described. The results of some new investigations by the author and several colleagues are given in various places.

An important fact and suggestion are contained in the following quotation: "It may be advisable, moreover, to point out that, as the representation of one and the same function may extend over and beyond this or that sulcus, as has been already mentioned, it is advantageous mentally to subdivide this region into horizontal levels, for the variation in the representation of the function will be found to be greatest in passing over the 'motor' area from above

down. In other words, the nature of the function of the convolution bordering the longitudinal fissure is more different from the function of the convolution forming the upper edge of the Sylvian fissure, than is the function of the anterior third of the so-called motor region from the posterior third."

The area of the cortex for the representation of the movements of the face and throat is first carefully given. Dividing the brain horizontally, as above indicated, a line drawn through the lower end of the intraparietal sulcus and the genu of the fissure of Rolando bounds this district above, the fissure of Sylvius limits it below, and it extends from the precentral sulcus in front to a theoretical extension of the intraparietal sulcus to the Sylvian fissure behind. In the upper part of this facial area the movements of all the groups of muscles of the lower face are represented. The anterior third of the lower portion of this facial area is the seat of representation of the movement of complete adduction of the vocal cords, together with the associated movements of other parts of the throat; the hinder two-thirds is the seat of the representation of the opening and shutting movements of the mouth, with protrusion and retraction of the tongue and the floor of the mouth. The seat of representation of movements of the upper limb is just above the facial area. In front the upper limb region extends into the middle frontal convolution for about its posterior fourth. Behind it extends across the ascending parietal convolution. The shoulder is centred in the upper part of the area, the elbow next below and posteriorly, the wrist next below and anteriorly; the fingers next below and anteriorly; the thumb lower and posteriorly. Above this region for the upper limb, which has for its upper boundary the superior frontal surface sulcus, is first an area where representation of the upper limb and that of the lower limb are absolutely blended, a most interesting zone. The seat of representation of the lower limb only, the primary movement of which part is that of the hallux or great toe, is immediately in front of the upper end of the fissure of Rolando, but it is also continued over the margin of the hemisphere into the paracentral lobule.

That the paper of Horsley is a distinct advance in the work done in cerebral localization and cranial cerebral topography is shown in many ways; for example, in the attention which he pays to the relations of certain parts which ordinarily have been neglected by those who have written upon this subject. Thus, he shows the importance of the precentral or vertical sulcus as a cortical landmark, as it divides two convolutions of very different functions, and as it has on either side of it convolutions in which most extensive representation of movement exists. This sulcus, as a rule, reaches to about the centre of the fissure of Rolando, and from it diverges forward about opposite the superior temporal ridge. Horsley also shows the topographical value of various other sulci and convolutions which have hitherto received but little attention—the superior frontal, the inferior frontal, and the intraparietal sulci, the various frontal convolutions, and the marginal convolutions, for example.

Valuable as is the paper of Horsley, here and there are points which may be criticised, but they are only minor points. In speaking of the intraparietal sulcus or interparietal fissure, he does not indicate very clearly the most usual direction of this fissure, as well as its variations. He speaks of it soon after its beginning as tending to leave the fissure of Rolando, thereby forming the ascending convolution, the summit of which is widened so as to become the superior parietal lobule. He pays no attention to the so-called retrocentral fissure, which is so very constant in the human brain, and which is regarded by some as a secondary extension upward of the beginning portion of the interparietal fissure, and by others, as Wilder for instance, as a distinct fissure. In a foot-note, however, he says that the commonest line of the intraparietal sulcus has yet to be determined, and the real breadth of the ascending parietal gyrus consequently remains also unknown. It is possible also, it appears to us, that he takes somewhat too strongly the position that the mapping out of the localities of function has nearly all been done by the accurate observations of experiments on the lower animals. It seems scarcely strictly true, in view of the labors of Jackson, Charcot, and others, to say that we owe nearly all we know of the functions of the different parts of the cortex cerebri to experiments upon the lower animals.

The paper is illustrated by numerous diagrams, and by two photographs from cadavers, the first of these showing a head from which the scalp has been removed opposite the so-called motor region of the brain; the second, with the convolutions of the same region exposed, and both so marked as to indicate clearly the relations of certain fixed and detectable points and lines of the skull surface to the fissures, sulci, and convolutions beneath. The whole paper is an admirable illustration of a combination of scientific investigation and the adaptation of such investigation to strictly practical purposes, and will form an indispensable aid to all laborers in the field of cerebral topography.

THE TECHNIQUE OF ANTISEPTIC MIDWIFERY.

When one recalls what Semmelweiss accomplished forty years ago in the Vienna Hospital, and when one reads of the condition of the Maternité before Tarnier was elected to its wards, and sees now the

wonderful immunity from disease of the puerperal patients in that institution, it is not surprising that the means by which these extraordinary results have been accomplished have excited such great enthusiasm that their application has been carried to immoderate lengths. It was at one time possible, in some of the large lying-in hospitals of Europe, to witness the strange spectacle of a woman in labor, shorn of her pudendal hair, douched from time to time with strong antiseptic solutions, until finally the child emerged from the vagina, its outlines dimly discernible through a mist of carbolized spray, while an assistant, robed from neck to heels in a linen gown, stood ready to clap an antiseptic dressing over the vulva, which yawned to admit the invading hosts of deadly parasites with which the atmosphere was everywhere impregnated.

It is little wonder that there was a tardy acceptance on the part of general practitioners of the doctrine of the causative relation of pathogenic microorganisms to puerperal fever, for the admission of such a theory seemed to demand the adoption of preventive measures which were impossible of general application in ordinary practice. The reaction from these extreme measures soon began, however, as the conviction dawned upon the professional mind that the greater part of this germicidal artillery should be turned upon the physician rather than upon the patient or the infant just emerging from what had been an air-tight sac. This conviction has been steadily gaining ground, until now the technique of antiseptic midwifery has been so simplified that its adoption is easy under any circumstances, either in private or hospital practice. More and more is the disinfection of the attendants becoming the cardinal point, while the advantages of non-interference with the parturient and puerperal female are becoming every day more evident, unless, indeed, there should be some special indication for the energetic disinfection of the parturient tract.

Szabó reports in the last number of the *Archiv für Gynäkologie* the results obtained in the Lying-in Hospital of Buda-Pesth, where, of 2629 confinements, the deaths from sepsis numbered only 8, or 0.3 per cent., with this simpler system of antisepsis in obstetrics. In this hospital vaginal injections are not employed at all in ordinary cases, but the hands of the attendants are thoroughly disinfected with a corrosive sublimate solution, 1 : 1000; while a solution of half that strength is used to cleanse the external genitals of the patients.

It is important to call attention to the possibility of attaining excellent results in obstetric practice with very simple precautions against puerperal infection, for such knowledge must hasten the universal adoption of antisepsis in general practice, even in the country, where the boasted purity of the air is yet supposed to give immunity from puerperal fever, although the fallacy of this supposition has been frequently demonstrated. Every rural physician must fully realize that he, as well as his city brother, may at any time have touched a few drops of pus or decomposing blood; that he may have placed his hand upon an erysipelatous skin; upon the dried sputum of diphtheria; or upon a few flakes of the desquamated skin of scarlet fever, and that the next woman in labor who is unfortunate enough to have him as an attendant, may easily fall a victim to his want, not of ordinary, but of absolute cleanliness. With a knowledge of the dangers that surround a parturient woman, and possessing the means of neutralizing them to a great extent, it surely cannot be long before there will be no one so indifferent to the welfare of his patients as to subject them to risks that might easily be avoided by using the few and simple precautions that constitute the most recent and admirable plan of antisepsis in obstetrics.

HOW EARLY IS THE FŒTUS VIABLE?

Hitherto obstetricians have generally agreed that the fœtus is first viable when seven months of intrauterine life have been completed. It is true that in rare instances a fœtus born in the seventh month has lived—that is, before the generally admitted time of viability—but these exceptions were so rare that they were not regarded as invalidating the rule; indeed, a child born even at the completion of seven months has only a relative viability, its chance of living being much less than if birth had been delayed. Tarnier, in the second part of his work upon obstetrics, asserts that as a certain number of children born at six months, or six months and a few days, can by means of the couveuse and gavage be raised, the time when the fœtus becomes viable should be fixed at six months.

The method of gavage consists in feeding the child through a urethral catheter of red rubber introduced into the stomach. The frequency with which the operation is repeated depends upon the quantity of food taken, but in general two drachms of milk every hour will be advisable, if the infant is very small and much premature.

AN OLD TREATMENT REVIVED.

In the March number of the *Revue Médico-Chirurgicale des Maladies des Femmes*, we find it stated that Coupey has recently used a crayon of nitrate of silver placed in the uterus, as a remedy for metrorrhagia. This treatment was successfully employed by him in two cases, but the editor of the journal regards the method as very painful, and liable to cause dangerous pelviperitonitis.

This practice is by no means new, for it was

employed twenty-five years ago, by the late Sir James Y. Simpson. Our own experience with it has been confined to a single case, in which its application was followed by such grave metroperitonitis that we never felt disposed to try it again. If the solid nitrate of silver thus left in the uterine cavity cures any cases of metrorrhagia, it is only one variety of the affection which is amenable to the remedy—that which is caused by fungoid disease of the endometrium, and surely there are other therapeutic plans less painful and perilous which may be followed.

THE President, in accordance with the provision made in the Sundry Civil Appropriation Bill, passed at the last session of Congress, has appointed Surgeon George M. Sternberg, U. S. A., to investigate the merits of inoculation for the prevention of yellow fever, as practised in Mexico and Brazil. The President is to be congratulated on having selected for his appointee a scientist who is in every way so admirably qualified to conduct the contemplated investigation.

THE Governor of Sonora last Tuesday telegraphed a denial of the existence of cholera in Mazatlan and Guayamas.

THE term of service of Surgeon-General Gunnell, as Chief of the Bureau of Medicine and Surgery of the Navy, expires in March, 1888.

THE Association of Genito-Urinary Surgeons has been recently formed, and will hold its first meeting at Lakewood, N. J., on May 17th and 18th, with Dr. E. L. Keyes, of New York, as temporary chairman, and Dr. R. W. Taylor, of New York, as Secretary. The Committee of Organization consists of the above officers with Drs. A. T. Cabot, of Boston; C. H. Mastin, of Mobile; J. N. Hyde, of Chicago; F. R. Sturgis, of New York; and J. W. White, of Philadelphia. The programme for the meeting includes a number of very attractive papers.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

[illegible]

DR. WYETH presented a patient from whom he had removed round-celled sarcomata of both parotids. [illegible] paper on "Ligation of the External Carotid Artery," published in THE MEDICAL NEWS of March 19, 1887, p. 313.] The main facts were as follows: Z. M., æt. forty-seven, began, about sixteen months ago, to notice enlargement of both parotids, which continued until her admission into Mount Sinai Hospital. She was strongly advised *not* to have an operation performed, and was told that, even if she survived, facial paralysis would result, but she insisted on being relieved. The right external carotid and superior thyroid were tied, and the neoplasm on the corresponding side was then dissected out. Three months later the more extensive growth on the opposite side was removed with great difficulty. The patient made a good recovery. A careful examination of both tumors was made by a competent microscopist, who pronounced them to be typical round-celled sarcoma. Attention was called to the fact that the patient had facial paralysis on both sides, more marked on the left. She could not close her eyes completely, but there was no keratitis. She was much troubled with dryness of the mouth, and had been advised to use olive oil, which had benefited her. There was no trouble about her nourishment, as she was restricted mainly to liquid diet. There was slight motion of some of the muscles on the left side of the face, but it was difficult to tell whether it was the group supplied by the motor branch of the fifth nerve, or those supplied by branches of the facial. The patient had no pain, and could talk very well.

In reply to a question from the President, Dr. Wyeth stated that the patient could chew without much difficulty, and was not obliged to push the food between her teeth with her fingers.

DR. ABBE asked if it was possible during the operation to distinguish the divided nerves at the edges of the tumors: could the opposite ends have been united by sutures, since the gaps left after the removal of the neoplasms could not have been very wide?

DR. WYETH replied that he saw the main branches of the facial nerves, but if he had stopped to suture the ends, the operation would have been prolonged, and there would have been no hope of the patient surviving.

CASE OF RUPTURE OF THE QUADRICEPS EXTENSOR TENDON [illegible] RECOVERY AFTER SUTURING OF THE DIVIDED ENDS.

DR. MCBURNEY presented a patient who, two years before, had slipped while lifting a heavy packing-box from a truck: the edge of the box struck him just above the patella, causing a rupture of the quadriceps tendon near its insertion, but without any external wound. A transverse incision was made across the joint above the patella, and the capsule was found to be extensively lacerated on either side of the bone, while there was a quantity of coagulated blood within the joint-cavity. The fibrous fringes and the torn ends of the muscles were turned inward. The latter were excised, the rent in the capsule was closed with catgut, and the ends of the tendon were united and kept in close apposition by "quill-sutures," which were secured by doubled silver wire, passed through the edge of the patella. A plaster dressing was applied, and the wound healed quickly, the recovery of motion being slow, but eventually complete. Now, there was apparently no difference between the two limbs. The patient refused to allow the application of passive motion, yet the result had been perfect.

In reply to questions, he explained that the quills

(which were pieces of rubber tubing) were placed transversely, one two inches above, and the other about two inches below, the incision; that the inverted fibrous strips lay upon the torn muscle; and that he had never heard of any record of a similar operation.

Dr. Markoe said that Dr. Weir had had two cases in which the lesion was the same as in the case described, and that he himself had observed one.

The President remarked that he had had a patient who had long before ruptured both quadriceps tendons. Although reunion failed, the patient, who was a laboring man, was able to attend to his work. He could ascend a ladder by aiding himself with his hands, and keeping his knees extended, and could stand without difficulty, as long as he kept his legs straight, but as soon as he bent his knees he would fall.

Dr. Sands thought that the operation performed by Dr. McBurney was undoubtedly the proper one; he believed that it had been done before, and that Maydl had reported a successful case in the *Zeitschrift für Chirurgie*.

Dr. Markoe asked if the separation occurred close to the patella.

Dr. McBurney replied that it took place as near as possible to the bone; there was a gap of one and one-half or two inches between the patella and the torn end of the tendon.

Dr. Briddon read the following paper on

EXTRAPERITONEAL RUPTURE OF THE URINARY BLADDER.

During my last service in the Presbyterian Hospital, in the city of New York, the two following complicated cases of rupture of the bladder came under observation:

Case I.—Reported by Dr. F. W. Shaw. The patient, a man thirty-three years of age, was admitted Sept. 3, 4 P. M. He was engaged, with several others, carrying a stone weighing 1600 pounds, when he fell accidentally, striking his right hip upon the ground. His companions losing control of the stone, it fell upon the right side of his pelvis. When seen by the ambulance surgeon, he was in a condition of very pronounced shock; there was a slight amount of blood oozing from the meatus urinarius. Examined one and a half hours after the accident, it was ascertained from the patient that he had emptied his bladder three hours before he was injured. There was a contusion of the right hip posteriorly, and an abrasion on the left; there were some dulness and fulness in the right inguinal region. He complained of pain and tenderness over the sacro-iliac junction and over the pubis. It was thought that when pressure was made over both ilia, that the right could be appreciably approximated to the median line. The introduction of a soft gum catheter gave exit to an ounce and a half of bloody fluid. A little later a silver catheter was introduced into the bladder. It was noted that its point did not rotate as freely as it should, and it gave exit to one ounce of the same kind of fluid.

Operation was performed by Dr. Briddon four and a half hours after the accident. Strict antiseptic precautions were used; the pubes and perineum were shaved, scrubbed, irrigated with solution of mercuric chloride, and then wiped over with an ethereal solution of iodoform. When under the influence of ether, an incision three inches long was made in the median line immediately above the pubes. When the subperitoneal fascia was exposed, its meshes were found infiltrated with blood; and on separating this with fingers and forceps, a large cavity was opened in the prevesical space. It was occupied by a considerable amount of bloody fluid that separated the anterior wall of the flaccid bladder from the posterior surface of the pubis. There was found an oblique fracture of the descending ramus of the left pubis, and a second fracture through the body of the right pubic bone; the bones were locked immovably, and their altered relations could not be restored; some small detached fragments were removed; the muscular and aponeurotic structures connected with the rami were torn, and there was no wound of the peritoneum. After careful and prolonged sponging, and the use of large retractors, it was possible to detect a long linear slit. Commencing in the upper and outer wall of the prostatic urethra, and passing up into the anterior wall of the bladder, it was estimated to be about one and a half inches in length. With some difficulty a silver catheter was introduced through the urethra and into the bladder, and was secured in position; a large rubber drainage tube was placed in the lower end of the abdominal incision; its point in contact with the laceration, and the remainder of the cavity was filled tightly with iodoform gauze. The patient was then placed in bed and surrounded with hot bottles. Temperature three hours after operation, 101° F.; reaction favorable.

4th. Temp. 100°. Considerable discharge through the gauze packing, which acts as an admirable drain. Several ounces of urine passed through the catheter, amber in color, acid, and slightly albuminous; contained granular and hyaline casts.

5th. Temp. 99°. General condition good; takes enough Magendie's solution to control what slight pain there is, and lithia water for a drink.

8th. Wounds dressed; the silver catheter was removed, and replaced by a rubber one; the prevesical wound was irrigated and filled with fresh gauze.

15th. No bad symptoms have presented; his general condition has steadily improved, but during the night the catheter failed to drain, and the urine overflowed through the wound above the pubes; on removing the catheter its lumen was found closed with calcareous deposits; it was determined to use the instrument only when a desire for urination existed.

23d. The bladder will now hold several ounces of urine, but unless the catheter is used frequently it will come through the wound; he complains of a good deal of pain in the penis, and especially in the corona.

Oct. 6. A small piece of semi-detached bone was removed from the right pubis.

19th. Two-thirds of the urine now passes through the urethra, the remainder through the abdominal wound; there is some irregularity or distortion in that portion of the urethra immediately anterior to the neck of the bladder, and it is deemed proper to introduce a conical sound every few days. The amount of urine passing through the wound gradually diminished, and finally ceased; he was discharged from the hospital in the last week in November. A small fistulous track leads from the lower end of the suprapubic incision downward and backward about three inches, and which will probably require a counter-opening in the perineum.

This patient was then presented for examination seven months since the accident occurred. There is a small sinus in the lower end of the abdominal sinus that has not discharged anything for the past week. He was advised to pass a large-sized sound occasionally, to counteract a disposition to lateral deviation of the infrapubic urethra, caused by displacement of the pubic arch, and No. 29 F. passes with ease. He has had no erection since the accident and I am not surprised, for the damage done to the soft structures was very great, and has, probably, implicated the nerve supply.

Case II.—Reported by Dr. A. S. Hooker. Patient aged forty-two years, a native of Ireland, married; engine wiper; a man of large frame and marked muscular development; good previous history, except an addiction to moderate indulgence in alcohol. He was cleaning a locomotive on the elevated railroad, when another engine was backed down, the buffer of the moving engine striking him on his right hip, and throwing him into violent contact with the buffer of his own engine, which struck him upon the abdomen; he had emptied his bowels and bladder half an hour before the accident.

When seen by the ambulance surgeon, December 2, 1886, almost immediately after the accident, and on one of the coldest nights of the season, the patient was suffering from shock, and complaining especially of pain in the right hip. As it was impossible to make a thorough examination where he was, he was at once transported to the hospital, where he arrived at 10.10 P.M.

On admission, his condition had improved under the influence of stimulants. There were found abrasions over both ilia; pain referred to right hip-joint, and increased by movements imparted to the limb of that side; there were no signs of fracture of the cervix; he experienced a desire to urinate, but was unable to do so. A soft-rubber catheter passed between nine and ten inches, when, after slight resistance, it entered a cavity, and gave exit to three ounces and a half of dark, bloody fluid; some hypogastric distress he had complained of was relieved by this. On percussing the abdomen, a somewhat triangular area of dulness was made out, situated to the right of the median line, its base corresponding to Poupart's ligaments. Shortly after this examination, the patient again complaining of pain, the catheter was passed, and less than an ounce of bloody fluid came away; withdrawing the catheter slowly, a point was reached when the dropping ceased, and on again withdrawing, until the eye of the instrument was nine inches and a half from the meatus, there was again a discharge, drop by drop.

Operation performed at 2.30 A.M., by Dr. Briddon; the night was bitterly cold, and it was found impossible to make the temperature of the amphitheatre comfortable to those who were warmly clad, the patient was, however, well covered with blankets, except in the parts to be operated upon; he had been prepared by scrubbing, washing, antiseptic irrigation, and the local application of ethereal solution of iodoform, and was under the influence of an anæsthetic. A staff was introduced without any difficulty into the bladder, but did not rotate as in the normal condition; perineal section was made, and when the knife entered the bladder a gush of bloody fluid escaped; the finger was then passed in, but the depth of the perineum prevented more than the distal phalanx entering, and it was found impossible to explore thoroughly the cavity of the bladder; a Thompson's rubber lithotomy tube was introduced and secured in position.

The patient's position was now changed to admit of suprapubic section, an incision was made from a point four inches above, down to the symphysis pubis. When the subperitoneal layer was exposed it bulged into the wound, its meshes infiltrated with blood; on tearing this apart, a large cavity was opened, bounded below by the posterior surface of the pubes; above, by the parietal peritoneum. The contour of the intestinal coils could be seen through the serous tunic, and a suspicious appearance was noticed in the color of the peritoneum—it was purplish-blue, significant of blood within. There was no time, however, for exploration, nor was it considered proper to make the attempt in so cold a room. Attention was then directed to the prevesical space; the cavity opened into was filled with blood coagula and fluid; there was a fracture, with some displacement, one inch distant from the symphysis. After diligent sponging, and the use of retractors, the point of the rubber tube introduced through the perineum was found lying at the bottom of the cavity, and in the neck of the bladder, which lay contracted about the instrument. With some difficulty it was found that there was a rent in the anterior wall, and by the use of tenacula it was made out to be vertical in direction, and quite extensive; there was no wound of the peritoneum. A second Thompson's rubber tube was introduced through the abdominal wound down and into the rent, and it was packed around with iodoform gauze. The patient was then removed from the operating table to his bed; small long rubber tubes were connected with the large suprapubic and perineal tubes, and conveyed the secretions to vessels beneath the bed.

3d. Reaction favorable, general condition good, but slight complaint of pain; there has been considerable flow of bloody fluid by the perineal tube.

4th. Patient has complained much of thirst; fluid slightly tinged with blood is discharged through the tube in about proper quantity, acid reaction, sp. gr. 1.028, contains 50 per cent. albumen, some pus, and epithelial cells; wound cavities are irrigated three times a day with warm boro-salicylic solution. In the evening his temperature rose to 101°; complained much of pain, referred to the penis; moderate tympanites, considerable annoyance from eructations of gas; small doses of morphia are given, only sufficient to allay pain.

6th. Temp. 102° at 8 P.M. The tampons were removed from the suprapubic incision, and continuous irrigation was instituted.

7th. Patient was delirious through the night. His temperature rose to 103°, then fell to 98°; it then began to rise steadily until it touched 106°, shortly before his death at 4 P.M. on December 8.

It was considered very desirable to have an autopsy, but circumstances which could not be controlled by the staff interfered to prevent. It is extremely doubtful if he died from the effects of the rupture of the bladder, as the drainage was perfect, and there was an entire absence of sepsis in the wounds communicating with the same. The symptoms preceding death indicated blood poisoning, but there were sufficient grounds to regard it as more than probable that there were undiscovered lesions within the cavity of the unbroken peri-

toneum to which it might be due. It will be remembered that it was noted during the operation that the color of the exposed peritoneum was bluish, such as would be caused by the presence of blood within the cavity; but as the operation was being done in an extremely cold room, and the indications were for its rapid execution, it was not deemed proper to prolong it by further exploration, but I have no doubt there were lesions in the abdominal cavity not recognized during life.

Simple extraperitoneal ruptures of the urinary bladder are generally caused by overdistention, due to obstruction in the urethra, either prostatic or from stricture. Factors aiding or predisposing to such accidents may be various pathological changes, ulcerations, tubercular or malignant herniæ, or, in fact, any other conditions that diminish the resistance of the walls. When under circumstances such as above referred to, the organ is in a state of repletion, it requires only a very small amount of violence, in the shape of concussion, as in lighting on the feet when falling; in injuries applied directly, as from impact with moving bodies; or in the not uncommon instances where rupture has been determined by contraction of accessory muscles in efforts to empty the distended organ.

In the cases which more directly concern us at present, those complicated with lesion of the bones entering into the composition of the pelvis, distention predisposes to rupture, but it may occur when the bladder is nearly empty, as in our second case, in which the patient distinctly asserted that he had emptied his bowels and his bladder half an hour before the accident occurred; and yet in his case, when the operation was done in less than four hours after the accident, and before he had recovered from the effects of shock, a condition in which very little urine is secreted, there was an escape of quite a quantity of bloody fluid when the perineal section was completed. In the first case it was presumed that the bladder was moderately distended, as the rupture occurred between three and four hours after urination.

The symptoms of rupture in the uncomplicated cases will vary extremely; generally something is felt to give way, either after the application of violence, or in the attempts to empty the bladder. This is generally followed by hypogastric pain and pronounced symptoms of shock, though in a number of recorded cases it is stated that the patients walked considerable distances to their homes, or to the institutions in which they were treated. It not infrequently happens that the cases are obscured by the accident occurring when the patient is under the toxic influence of alcohol. In such, on recovering from his debauch, complaint will be made of pelvic pain, and of the tormenting desire and inability to urinate. The condition will be determined by physical exploration, by percussion of the abdomen, digital examination through the rectum, bimanual palpation, the introduction of soft and metallic catheters, the former to determine whether the organ is empty or not. The latter may find nothing in the bladder, but it will probably be found that its movements are restricted. It may be possible in some cases to insinuate the point of the instrument into and through the rent, thus giving exit to urine that had escaped into the cavity of the peritoneum, or into the prevesical space of Retzius. If the rent is in the posterior wall, this manœuvre will be best made by using a short beaked instrument, such as the searcher of Sir Henry Thompson, which may be reversed when in the bladder. When the rent is in the anterior wall, it will be best accomplished by using a silver catheter with a large curve, and directing its point to the anterior wall of the bladder, by depressing the handle of the instrument between the patient's thighs.

A distinguished member of this Society brought a method of early diagnosticating intraperitoneal ruptures of the bladder before the profession,[1] in which he advocated injecting the bladder with an antiseptic fluid. It struck me that there are two objections to this procedure: First, that in the event of there being a rupture, it would diffuse the already extravasated fluid over a still larger surface; secondly, that it does not give reliable evidence of an intact bladder, inasmuch as there are several cases on record of intraperitoneal ruptures in which there was a fluctuant tumor in the hypogastric region resembling the distended bladder; and in some of these cases the size of the tumor was diminished by successful catheterism. The escape of a quantity of fluid equal to that injected would be more positive evidence.

In the cases of rupture complicated with fracture of the bones entering into the composition of the pelvis, there is generally an assemblage of symptoms which make the diagnosis comparatively easy. The accidents are the result of extreme violence; patient is in a condition of more or less profound shock; and when he begins to come out of this, his principal complaint will be a desire and inability to pass water. The introduction of a catheter will give exit to a small quantity of bloody urine. Further evidence can only be obtained either by waiting, to the great detriment of the patient, or by the prompt institution of explorative incisions, which can be utilized for drainage if rupture be found to exist. The treatment resolves itself into that for the treatment of extravasation, and the anatomical fact that there is no barrier to the extension of infiltration, external or internal, to the peritoneum, is a strong additional reason why the interference should be prompt and efficient.

My impression is, that it is best, first, to make a perineal section sufficiently free to permit of digital exploration of the bladder; that this should be supplemented by a suprapubic incision, carefully made, to open into the prevesical space, avoiding the peritoneum, unless it should be found involved. In these incisions I would arrange drainage-tubes of large calibre, so that their ends should meet in the cavity of the bladder, the upper tube being surrounded by a light tamponnade of iodoform gauze, which is itself an excellent capillary drain.

In connection with the paper he presented the patient upon whom an operation had been successfully performed. There still remained a small fistulous opening in the suprapubic wound.

He added, in conclusion, that the patient he had presented was troubled with a distressing symptom, viz., he had been unable to have an erection since the injury. He asked if any member of the Society could

[1] On a Satisfactory Method of Early Diagnosis in Cases of Intraperitoneal Rupture of the Bladder, by Robert F. Weir, M.D. Medical Record, Jan. 22, 1887.

suggest a remedy. He had himself advised the use of faradization, but the case appeared to be a hopeless one.

In reply to an inquiry, he said that the patient had sexual desires.

DR. WEIR suggested that the galvanism was preferable to the faradic current.

DR. BRIDDON thought the interrupted galvanic might meet the indications. There was some doubt as to whether the condition was due to a cutting off of the nerve supply, or to muscular paralysis.

DR. WEIR said that, although his experience had been limited, he would venture to criticise the practice of making the perineal opening first. He would first make the suprapubic incision, then carry the end of a pair of forceps through the infiltrated tissue, and cut upward upon it from the perineal side. He called attention to the fact that the method of detecting a rupture of the bladder, which he had suggested, was based on two points, the presence of increasing dulness in the hypogastric region from the gradual distention of the bladder, if uninjured, by the injected fluid, and the fact that the same quantity of fluid flowed out as was originally thrown in. Even if, in this test, some of the fluid did escape from the torn bladder, it would only give rise to an increased area of dulness over the hypogastrium, and would do no harm, as the surgeon would at once make his incisions for the proper drainage of the already extravasated urine.

DR. BRIDDON thought that the method suggested by Dr. Weir was not reliable, because there were so many cases in which the rupture was intraperitoneal. Heath and Rivington had been unsuccessful with it. The reader added that he did not claim much for the perineal section.

It was not performed in the case of the patient who recovered, because his condition was so bad that it did not seem to be justifiable. In the other case it was done as an explorative measure, and the opening could afterward be used for drainage.

The suprapubic operation was quite easy; as soon as the retroperitoneal fascia was reached, it bulged into the wound and was readily torn apart. There was no danger of opening the peritoneum. The reader reiterated his preference for the peritoneal section as an explorative measure, because in cases of extensive fracture, with great injury to the soft parts, it might not be advisable to make firm pressure over the hypogastrium, to aid in digital exploration.

THE PRESIDENT thought Dr. Briddon's experience showed that little was to be gained in the way of diagnosis by the perineal incision; he believed that, if it was made at all, it should be limited to a small opening for purposes of drainage. He had recently seen Dr. Keyes drain a bladder in this way after suprapubic lithotomy. A soft catheter was prepared by passing a needle, carrying a long piece of silk, into the eye, and out through the adjacent blunt end of the catheter. In the middle of the silk was a large knot, and the silk was drawn through until the knot stopped it. A long, narrow-bladed knife was passed into the membranous urethra, and along it, and then along the groove of the staff was carried an eyed probe threaded with the silk before mentioned. The end of the probe was passed into the bladder and drawn out through the hypogastric incision, and then, by pulling upon the silk, the end of the catheter was brought into the bladder. The other end of the silk hung out of the perineal wound and was used to withdraw the whole piece, the catheter being left in place.

DR. SANDS said that it was generally conceded that in cases of lithotomy the bladder could not be drained satisfactorily through the perineal wound.

DR. WEIR remarked that the bladder could not be drained through the perineal wound without a drainage tube being introduced through it, unless the lateral section had been made.

THE PRESIDENT said that in two of Dr. Keyes's cases the suprapubic wounds had closed and the bladder was perfectly drained from below.

DR. BRIDDON thought that if a perineal opening had been made in the case of the patient presented, the sinus would not have continued to discharge so long; in fact, it might still be necessary to perform that operation in order to cause its closure.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, April 7, 1887.

THE PRESIDENT, THOMAS M. DRYSDALE, M.D., IN THE CHAIR.

DR. B. C. HIRST read a paper on the etiology and treatment of cases of so-called

LATE INFECTION IN THE PUERPERAL STATE.

He related four cases of so-called late infection in the puerperal state, all due to the same cause, and yielding to the same treatment. The first case was a young primipara delivered without difficulty after a moderately long labor. She left her bed on the eleventh day, having had no fever, and having manifested no unusual symptom. Two days afterward her cervix was exposed to view by means of a bivalve speculum, and a slight laceration was discovered, healing by granulation. The following morning, the fourteenth day after delivery, the patient was unwell, her temperature was 102°; large doses of quinine were given, but the temperature rose to 103°, where it remained with slight morning remission for two days. A more careful examination being made, it was discovered that the uterus was unusually large, that the os was patulous, that there was a foul-smelling discharge, and considerable abdominal tenderness. The history of the case with these symptoms pointed to the retention of membranes, possibly a portion of placenta, and their subsequent decomposition, originated by the admission of air to the vagina and uterus by the use of the speculum. Acting upon this diagnosis, the uterine cavity was lightly scraped out with a dull curette, and a large quantity of decomposing decidua removed. This was followed by an intrauterine injection of bichloride of mercury through a Bozeman's double catheter. The woman's temperature at the time was 103°. The following morning it had sunk to 99°, and within twenty-four hours was normal, and so remained.

The second case was also a primipara. The labor was terminated by the forceps. Upon the eleventh day the woman, although perfectly well until that time, had a morning temperature of 101°, rising in the even-

ing to 102°. The uterus was found larger than it should have been. The os was patulous, and there was a fetid discharge. Profiting by the experience gained in the first case, the uterus was curetted, and a considerable amount of decidua removed, and an intrauterine douche given. In this case the womb almost at once contracted, and the discharge ceased; but the patient had, unfortunately, an exacerbation of a tubercular trouble in one lung, which kept the temperature high for some days.

In the third case, also a primipara, after an instrumental labor, and an apparently normal lying-in period, the temperature rose, on the twelfth day to 99.8°, and on the following day to 100°. At the same time a fetid muco-purulent discharge made its appearance. In this case a very large quantity of decidual membrane was removed, and the scraping was repeated on the following day, whereupon the temperature fell to normal, and the discharge ceased.

The fourth case was a primipara, who, on the sixth day, after an easy labor, had a temperature of 100°, although previously there had been no fever; the uterus here was very large, the os quite patulous, but in this case there was not much discharge. The same treatment was employed that had proved successful in the other cases, with the result of reducing the temperature within twenty-four hours to normal, where it remained.

This experience is entirely too limited to enable one to come to a definite conclusion as to the cause of late infection in the puerperal state, but these cases suggest the possibility, at least, that the retention and subsequent decomposition of shreds of membrane or fragments of placenta will be found to be the most frequent cause of fever late in the puerperal state, and that if not interfered with this condition may lead to septicæmia and pyæmia. Other causes of fever late in the puerperal state are, of course, well known. Partially healed wounds of the cervix, vagina, and perineum may be torn apart, and the fresh wounds thus produced may give entrance to the germs of septicæmia. Exposure to an atmosphere impregnated with emanations from sewers or water-closets from bad sanitation, may give rise to febrile diseases at any time during the puerperium, as proved in the cases related by Dr. Playfair in a recent English journal. There is a possibility that the pyogenic microörganisms which may carry on their work in the uterine cavity without very serious consequences to the patient, may in the tubes manufacture their product, pus, in such quantities that it cannot be drained off, thus producing an abscess that may possibly open into the peritoneal cavity. There is a still more remote possibility that a pyosalpinx may be developed late in the puerperium by other pathogenic microörganisms, by those of gonorrhœa, of tuberculosis, or even those of actinomycosis. Finally, any of the febrile diseases that may attack a woman at any time may fasten themselves upon her during the lying-in period; but it seemed to the author that the most common cause of late infection in the puerperal state is the decomposition of retained membrane or fragments of placenta, and that, therefore, the curette and the intrauterine douche might be employed as a routine treatment in all cases where there occurs late in the puerperium, fever associated with a large uterus, a patulous os, and a foul-smelling discharge. This treatment can do no harm but may effect much good.

Dr. Hirst then exhibited

THE ANTISEPTIC PAD

used by Richardson, of Boston, and Garrigues, of New York, to prevent the entrance of pathogenic germs to the vagina after labor.

Dr. Parvin was not impressed with the necessity for the antiseptic pad, believing that as good results could be had from antiseptic napkins. The oiled silk or muslin used in making it, it seemed to him, might hinder the ready escape of the lochia. After labor the vagina is practically a closed canal, open only for the egress of uterine discharge, and disease germs cannot enter unless that canal be opened by some manipulation of the nurse or the physician, as in giving a vaginal injection or in making an examination. It seems needless to close the vulva completely, and it also seems possible that such closure hinders the escape of the lochia. But be this as it may, if the vulva is carefully washed twice a day, with an antiseptic solution, and if napkins that have been wrung out of a 1 to 2000 corrosive sublimate solution are applied over it, changing them more or less frequently according to the amount of the flow, he thinks as good results can be had as by using the antiseptic pad. Moreover, it seemed to him doubtful whether antiseptic pads, though they have proved very useful in maternities, will be readily accepted in private practice, especially in the country.

The liability of glass to break is to him a conclusive argument against the use of tubes of this material. The best instrument, he believes, is Bozeman's catheter. Formerly it was his custom to wait in cases of septic infection until the flow was offensive, and then at first to endeavor to correct the condition by vaginal, before resorting to uterine, injections. He now knows that is wrong, for the patient may perish or have a protracted illness, and then make but partial recovery without the lochia at any time having an offensive odor. Within a year he has seen in hospital practice, and in consultation, eight cases of septic infection where the happiest results were promptly had from antiseptic solutions injected into the uterus. Most, if not all, of these patients probably would have recovered without these injections, but their recovery, judging from similar cases previously observed by him, would have been slow, possibly imperfect, and after a more or less prolonged period of suffering upon their part, and of anxiety on the part of the practitioner. We have in antiseptic uterine injections the essential, and the almost invariably successful treatment of puerperal septicæmia, if this treatment be begun soon enough, and properly carried out.

Dr. T. M. Drysdale, while conceding the importance of antiseptic precautions in hospital, thought the advantage of these measures in private practice more difficult to prove. Until he relinquished obstetric practice in 1874, he had met with but five cases of puerperal fever in over two thousand deliveries, and in none of these women were any antiseptic precautions used, other than cleanliness, as they were not then known.

Dr. Longaker believes with Dr. Hirst in the great utility of intrauterine post-partum medication. He has the greatest confidence in iodoform as used by Ehrenderfer, of Vienna, in the form of 100 grain pencils. One

of these is introduced into the cavity of the womb after irrigation, it dissolves very slowly, and continues to medicate the entire utero-vaginal canal for forty-eight or seventy-two hours.

In removing shreds of membrane, after labor at term, or after an incomplete abortion, he uses the finger, and prefers it to any form of curette he has used. Theoretically he would prefer a glass tube for intrauterine irrigation, chiefly for the reason that it is more easily cleansed and kept clean. Hitherto he has always used the Bozeman canula, the only objection to which is the difficulty of cleansing, and hence a possible danger of carrying sepsis from one case to another.

Dr. Baer emphatically endorsed what had been said in favor of Bozeman's tube for intrauterine irrigation, and against the glass tube. The return current is sure, and the small size of the instrument as compared with the glass tube renders the iniroduction easy and safe.

Regarding the pad exhibited by Dr. Hinst, if he believed the theory that the atmosphere is constantly impregnated with germs which poison whenever they come in contact with open vessels, he would certainly advocate the use of an impervious covering for the vaginal orifice. For the theory teaches that where there is no contact with the air there can be no sepsis. But he does not believe this fully; therefore he thinks it safer to place the napkin under and not over the vulva, so as to permit as perfect drainage as possible, thereby giving free exit to the lochia by making of the vagina a drainage tube, its natural function after parturition.

Dr. Hirst remarked that the pads were used dry by Dr. Richardson, and moist by Garrigues.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 21, 1887.

The President, A. Jacobi, M.D., in the Chair.

THE PRACTICAL VALUE OF OUR PRESENT METHODS OF TREATING THE UPPER AIR-PASSAGES.

Dr. Francke H. Bosworth said that notwithstanding the most ingenious mechanical devices, it is a fact that no case of chronic laryngitis has ever been cured by topical applications. The views of laryngologists have greatly changed within the last few years, and they have long since outgrown the notion that chronic laryngitis is either of tubercular or syphilitic character. The truth is, that non-specific chronic laryngitis is merely secondary to affections of the parts above.

As to applications to the lower pharynx, they are of no service whatever, and this part of the anatomy does not even belong to the air-passages at all, but to the food-tract. The vault of the pharynx is the seat of certain morbid changes which have been supposed to constitute naso-pharyngeal catarrh. The excessive secretion which is fancied to be characteristic of the condition, however, is an absolute myth. There is, in fact, diminished secretion (the secretion, however, being perverted, so that it becomes thick and inspissated to a degree that it is not removed by the ordinary efforts at expectoration), and the indication is not for astringent applications to the pharynx, but for some means of treatment which reaches the nasal passages. Topical treatment here, therefore, is of no use, and in such conditions as hypertrophy of the pharyngeal tonsil no local measure is of any service, except to act as a palliative. As to nasal catarrh, it is not a hypersecretion to be cured by astringents. These have all been tried to the fullest extent, and found to be of no avail. The essential symptoms are due to conditions which interfere with the great function of exosmosis of serum, and douches and sprays have never yet cured inflammatory conditions of the upper air-passages, although such applications are undoubtedly of more or less use. The nasal douche has attracted a great deal of attention of late years, and its dangers, as well as its benefits, have been vastly over-estimated. Inhalations have fallen into disuse, and the spray is now deservedly considered the most prominent means of local treatment. It is undoubtedly of great assistance as a cleansing and palliative measure, but is nothing more than this.

As to any special value to be attached to any particular form of apparatus, there is none. Compressed air is supposed to possess superior advantages for the spray, and the moral effect of the various devices resorted to for employing this agency is undoubtedly good; but with an instrument which can be purchased for a dollar and a half as perfect a spray can be made as with the most elaborate machinery costing hundreds of dollars. Millard's atomizer, he thought, is the one which is most convenient and serviceable. The curative treatment of affections of the upper air-passages, however, consists in treatment of the nasal tract by the removal of obstructive lesions, whether bony or of other nature, giving rise to nasal stenosis; and this is to be accomplished by the snare, the saw, the knife, or the cautery.

The object sought to be secured by the use of the cautery is not destruction of tissue. In hypertrophic disease the process involves principally the connective tissue, and the essential feature of chronic rhinitis is a chronic hyperæmia of the bloodvessels, with increased nutrition of the part. The local effect of cocaine is to produce anæmia, and, having reduced the existing turgescence with this agent, a mild caustic which will have very much the action of a film of collodion, should be applied. There is nothing so good for this purpose, in his opinion, as chromic acid; a few crystals of which laid upon the parts destroy the superficial layer of the membrane, converting it into a slough which adheres closely to the surface for three or four days, holding it down, as it were, and preventing a return of the turgescence. This simple method by chromic acid is greatly to be preferred to the galvano-cautery, enabling us to accomplish, as it does, all that can be effected with this complicated apparatus in a manner much more satisfactory in every way. The subject of neoplasms, he said, did not properly come under the present topic of discussion. Acute catarrhal inflammation of the nasal passages is merely a symptom of chronic rhinitis, and, as it can be readily eliminated by means of cocaine, did not require further consideration.

In speaking of our methods of examination, he said that the value of the laryngoscope, as generally employed, is greatly overestimated, and that neither in Tobold's nor Sars's instruments is there any optical principle involved. A small head-mirror, with a good

light, answers every purpose perfectly well. Laryngologists had ceased to treat by means of machinery when they learned how to treat their cases successfully; and he quite agreed with the sentiment expressed by Dr. Daly at the meeting of the International Congress at Copenhagen, that the sooner they ceased to be throat doctors and became throat surgeons, the sooner would they achieve success in their specialty.

Dr. Andrew H. Smith, while expressing his belief in the efficacy of topical applications in many more or less acute conditions, said that in long-established cases of what is known as chronic catarrh, there were serious doubts in his mind as to the advantage of any local treatment which had as yet been devised.

Dr. Wm. H. Thomson said that in his opinion the treatment of chronic disease of the upper air-passages should be directed by two principles. The first of these is the taking cognizance of the cutaneous nerves liable to be concerned in the trouble, and the second, local disinfection.

There are very few vaso-motor tonics, and there are none which compares with cold as a remedial agent. It is very useful to apply cold water to the nape of the neck on rising in the morning, especial care being taken that the hair should not become even dampened. Sponging of the throat is also excellent, and these cold applications should be kept up for a long period of time. The back of the neck and shoulders should also be well rubbed with olive oil. The second indication is to protect the cutaneous surface against exposure.

The second principle of treatment is local disinfection. For this purpose our methods are at present both crude and defective.

It is undoubtedly true that a considerable number of cases are to be attributed to malformations, either natural or acquired; but in those which are not, it is important to know what agents ought to be used. In his opinion, the carbolic acid class, including all coal tar derivatives, are best for the suppurative diseases. In necrotic cases, on the other hand, remedies of the chlorine group, including bromine, iodine, and sulphur, are indicated, and insufflations into the pharynx of bismuth and calomel have long been used.

Dr. H. Holbrook Curtis spoke of the great value of chromic acid, which for some time past he had used to the exclusion of all other escharotics. When this is applied to the turgescent or hypertrophied turbinated bodies, it not only has a most marked beneficial effect upon the parts immediately concerned, but also the vocal apparatus of the patient. Hence, such applications are of special service to singers, actors, and others obliged to use the voice in public. This is a reflex effect, and there can be no doubt that there is a distinct correlation between the turbinated bodies and the larynx. In illustration of this point, Dr. Curtis related the case of a prominent operatic prima donna who had presented herself at his office with a slightly congested condition of the vocal bands. He applied chromic acid to the turbinated bodies, and there was at once a marked improvement in the voice. So much pleased was the patient with the effect thus produced, that, on two occasions afterward, she came on from Philadelphia between her performances, expressly to have the application made; and whenever he repeated it, it was always successful in restoring the lost brilliancy of tone. His practice is to apply the agent in crystallized form by means of a flat copper applicator, and afterward wash off the parts with Dobell's spray. No bad results from the use of chromic acid have ever been published. In conclusion, he remarked that the sooner the farce of applying strong astringents and other baneful agents to the larynx is abandoned the better it will be for all concerned.

Dr. Wm. Chapman Jarvis thought it most judicious to pursue a middle course. The spray he had always found a very useful means of treatment when it was properly employed. Cocaine could be applied more efficiently by means of the spray than in any other way. When thus used it produced anæmia of the mucous membrane at once, and it was always noticeable that in painful conditions there was a return of the pain just as soon as the anæmia thus caused disappeared. If the cocaine spray is kept up for a considerable length of time with a small tube, we get beneficial results which can be obtained in no other way.

There is, however, a certain proportion of cases in which cocainization cannot be produced, and in these the application of rhigolene is to be preferred when highly congested growths of the turbinated bodies are to be operated upon. A few seconds are all that is necessary to produce profound rhigolene anæsthesia, and if a thick covering of any suitable unguent is made use of to protect the parts during the operation, the application of this agent is not attended with any unpleasant results.

The spray is also very useful for cleansing purposes. With a coarse spray all the advantages of the douche can be obtained, while the hearing is not endangered, as is sometimes the case when the latter is employed. He is in the habit of using ten pounds pressure with a tube one-eighth of an inch in diameter for a coarse spray, and with a tube of extremely small diameter for a fine spray. There is no method yet devised by which powders can be so satisfactorily applied to the upper air-passages as by means of compressed air. When suitable agents are applied in the infinitesimally divided condition which is possible by this method, they are soothing in effect; but when powders are used in any other way they are always irritating. As regards powders, however, there is only one that is tolerated by the upper air-passages, and that is iodoform. Even boracic acid or bismuth is not well borne, as can be readily tested even by any one whose nasal mucous membrane is in a normal condition.

As to caustics, he believes that both chromic acid and nitrate of silver serve a useful purpose in certain conditions. Chromic acid, however, he thinks, should never be applied for turbinated turgescence and hypertrophy. It is very slow in its action when thus employed, and though it probably eventually removes the hypertrophy, provided the patient and the physician both have patience enough, he considers it a very treacherous kind of drug. But for papilloma, especially of the larynx, it is to be regarded as a real specific. As regards the mucous membrane of the rest of the upper air-passages, he strongly doubts its efficacy. Nitrate of silver has its uses. Although its action in the larynx, as lauded by Horace Green, is no doubt exaggerated, it is still of considerable service in subacute laryngitis.

It is an especially useful caustic for mucous patches, which disappears under its protecting agency. Dr. Jarvis said he used the term protecting advisedly, as its characteristic action is to cling to the tissue until they heal, and no other agent will accomplish this purpose so well. That ulcers of the mucous membrane need some such protection as this he had demonstrated by covering one within easy reach with a little rubber cap. It at once showed a tendency to heal; but when the rubber cap was left off, it returned to the same condition as at first.

As to surgical procedure, compared with other methods of treatment, he thought it a well-established fact that it is not really worth while to keep on making topical applications for an indefinite period of time, when at a single sitting we can remove the whole trouble. What then is the use of worrying with chromic acid, nitrate of silver, or the galvano-cautery? The problem to be solved is merely a question of nasal drainage; and he claimed that there is not a hypersecretion, but that the trouble present is due to distortion of the nasal planes and gutters. The so-called hypersecretion results simply from accumulation, and when the nostrils are permitted to be flushed by the natural secretions, this entirely disappears. The indication is, therefore, to remove all existing obstruction.

In conclusion, Dr. Jarvis made some remarks upon atrophic rhinitis, stating that when a cure cannot be effected, great relief can be given by means of thorough cleansing and the use of unguents, especially vaseline, applied in the form of spray. In this manner patients whose life has been a burden often for ten or fifteen years, on account of the intolerable stench attending the condition of the nasal passages, have, by the simple use of the detergent douche and vaseline, been enabled to go once more into society without rendering themselves offensive to all around them. This practically constitutes a cure in this incurable dry atrophy of the nasal passages.

CORRESPONDENCE.

PREVENTION OF ARTERIAL HEMORRHAGE.

To the Editor of THE MEDICAL NEWS.

SIR: In the issue of THE MEDICAL NEWS for April 23, 1887, there appears an abstract of a paper copied from the *Lancet-Clinic* of April 2, 1887, entitled "A Simple Method of Preventing Arterial Hemorrhage," by Dr. Muscroft, of Cincinnati, which was successfully used in an amputation at the hip-joint, and a high amputation of the arm for elephantiasis.

"He proposed to pass a strong pin or needle under the femoral vessels *en masse*, high up in Scarpa's triangle, and then by winding a cord around the exposed ends of the needle, protected by corks, in a figure-of-eight turn to secure sufficient pressure to occlude the artery completely."

In the *Archiv für klin. Chirurg.*, Bd. 26, Heft 4, Prof. Trendelenburg, of Rostock, reports the following method for the avoidance of hemorrhage in hip-joint amputations: "A steel rod thirty-eight centimetres long, six millimetres broad, biconvex on section, and two millimetres thick at the centre, with blunt edges, but provided with a removable lance-shaped point three centimetres long, is passed obliquely through the soft parts in front of the joint, in the same way as the two-edged knife in the well-known method of Lisfranc, only about two centimetres higher. The rod enters, therefore, about four centimetres below the anterior superior spinous process of the ilium, passes between the femur and the femoral artery, and emerges at the fold of the scrotum. The point is now removed, and an elastic tube or band firmly wound in a figure-of-eight fashion round the ends of the rod and passing in front of the thigh" (*Amer. Journ. Med. Sciences*, April, 1882, pp. 582, 583).

It will thus be seen that the procedure of Dr. Muscroft is identical in principle with that of Trendelenburg. On the 13th of June, 1882, I amputated at the hip-joint successfully, according to the method of Trendelenburg, and reported the same in *The American Journal of the Medical Sciences* for October, 1882, p. 394. I also exhibited the instrument above described to the surgical section of the American Medical Association at its meeting in Washington in 1884.

THEODORE R. VARICK, M.D.,
Surgeon to Jersey City Hospital,
Medical Director and Surgeon to St. Francis Hospital,
Jersey City, N. J.

NEWS ITEMS.

MONTREAL.

From our Special Correspondent.

ROYAL VICTORIA (JUBILEE) HOSPITAL.—Two of our millionaires, Sir George Stephen, Bart., and Sir Donald A. Smith, have announced that it is their attention to build and endow a hospital in honor of the Queen's Jubilee. This hospital is to be for purposes of medical education and the training of nurses as well as for the treatment of the sick poor. Each gives the magnificent sum of $500,000—of this, $250,000 is to build the hospital and $750,000 to endow it. They have requested the city to donate to them unconditionally a lot of land situated at the base of the mountain on which to build the hospital, as this is the only favorable site they have been able to find. The City Council have favorably received the request. The details of the scheme have not yet been disclosed, but it is believed that the appointment of the medical and surgical staff will be made specially in the interests of medical education.

CONTINGENT FUND FOR THE WISCONSIN BOARD OF HEALTH.—The Assembly of Wisconsin has passed a bill appropriating $15,000 as a contingent fund to be used, if necessary, in the next two years, by the State Board of Health, in preventing the introduction of cholera into that State.—*Sanitary News*, April 16, 1887.

MASSACHUSETTS GENERAL HOSPITAL.—Professor R. H. Fitz has been appointed visiting physician to this hospital, *vice* Professor Francis Minot, resigned.

THE ASSOCIATION OF GENITO-URINARY SURGEONS will hold its first annual meeting, at the Laurel House, Lakewood, N. J., on May 17 and 18, 1887.

The following papers are announced in the programme:

Address of Welcome, by the temporary Chairman, Dr. E. L. Keyes.

Connection between Masturbation and Stricture of the Urethra, by Dr. S. W. Gross, of Philadelphia.

On Chancroids, by Dr. F. B. Greenough, of Boston.

On Horny Growth of the Penis, with Exhibition of a Remarkable Case, by Dr. J. H. Brinton, of Philadelphia.

Suprapubic Cystotomy for Vesical Tumor and Large Calculus, with Comments upon Suture and a Suggestion for Drainage, by Dr. E. L. Keyes, of New York.

Case of Hysterectomy for the Relief of Pyelitis from Obstruction, by Dr. A. T. Cabot, of Boston.

On the Choice of Operation for the Removal of Vesical Calculus in Cases Complicated by Prostatic Obstruction, by Dr. J. P. Bryson, of St. Louis.

Idiosyncrasy as Affecting the Specific Treatment of Syphilis, by Dr. P. A. Morrow, of New York.

Observations on the Use of Oil of Wintergreen in the Treatment of Gonorrhœal Rheumatism, by Dr. R. W. Taylor, of New York.

Some Cases of Pyelitis in which Frequent and Painful Micturition was the Chief Symptom, by Dr. George Chismore, of San Francisco.

On Temporary Overstrain of the Bladder Producing Chronic Retention of Urine, by Dr. F. N. Otis, of New York.

Early Syphilitic Epididymitis, by Dr. J. N. Hyde, of Chicago.

Prostatotomy for Obstruction: Two Cases, by Dr. A. T. Cabot, of Boston.

A Plea for the More General Use of Nitrate of Silver in the Deep Urethra, with an Improved Instrument for its Application, by Dr. E. L. Keyes, of New York.

A Rare Form of Septicæmia, following Operation for Urethral Stricture: Septicémie Foudroyente Gazeuse, by Dr. R. W. Taylor, of New York.

Exhibition of Sections of Tubercular Testes with Bacilli, and of the Coexistent Bacilli in the Sputum, by Dr. R. W. Taylor, of New York.

The American Climatological Association will hold its fourth annual meeting in Baltimore, on Tuesday and Wednesday, May 31st and June 1st.

The State Medical Society of Arkansas will hold its twelfth annual meeting in Little Rock, on Wednesday, Thursday, and Friday, June 1st, 2d, and 3d.

The Ontario Medical Association will hold its seventh annual meeting in Toronto, on Wednesday and Thursday, June 8th and 9th.

The Best Type and Colors for School Books.—The following is the advice of Dr. Turner, Director of the Museum of Hygiene of the United States Navy, in his annual report:

Without entering upon an extended notice of this section of sanitary science, leaving out for the present the consideration of the school-house, a note here appears necessary concerning the hygiene of the eyes of school children. Some German sanitary observers in this direction have condemned the dark slates now in use on physiological grounds, and on the same grounds have suggested the use of white slates with dark pencils. Taking these premises, with the results of some personal experience and observation in determining ranges of vision, as well as of the color-sense, the writer is led to suggest that a uniform "face" of type, as *antique*, be adopted for school books, and that the traditional black printing ink be abandoned for inks of neutral tints in printing such books.

This accepts a proviso that the paper remains as now—white and unglazed. How far sharpness of definition of letters can be secured by such color use, the printer can determine. Further observations may support the correctness of these suggestions; that there is a strain upon the nervous apparatus of vision in the reading of books as printed at present (black on white) is an accepted fact; that this strain is a cause of asthenopia, is also well made out, and that the apparatus of accommodation in the eye is affected, follows as a consequence. This strain, expressed in ordinary language as "tired eyes," is relieved by letters printed on tinted paper, and by colored printing inks on white or colored paper; and thus a circus poster, from these facts, oftimes contains more refreshing reading, in a hygienic as well as a mental sense, than some newspaper or books. It needs but the simple statement, in this consideration, that glaring colors are always to be avoided. —*Chicago Journal and Examiner*, March, 1887.

Dr. Lewis Sayre's Clinical Lectures on Orthopædic Surgery have been translated into French by Dr. Henri Thorens.

The Celebrated Greek Scholar, Dr. Ernst Curtius, who is seventy-three years of age, recently left Professor Schweigger's Hospital, after a successful operation for cataract.

Analysis of "Temperance Drinks."—The chemist of the Massachusetts State Board of Health has recently analyzed a large number of so-called temperance drinks, and has found that all of them contain alcohol, one of them containing as much as 44.3 per cent. Several of them contain more than 40 per cent., and a very large proportion more than 20 per cent. One of these is said by its manufacturer to be "a purely vegetable extract, stimulus to the body without intoxicating." "Inebriates struggling to reform will find its tonic and sustaining influence on the nervous system a great help to their efforts." This preparation was found to contain 41.6 per cent. of alcohol.

Tonics.

Carter's Physical Extract, Georgetown, Mass., 22 per cent.

Hooker's Wigwam Tonic, Haverill, Mass., 20.7 per cent.

Hoofland's German Tonic, Philadelphia, 29.3 per cent.

Hop Tonic, Grand Rapids, 7 per cent.

Howe's Arabian Tonic, New York, 13.2 per cent.

Jackson's Golden Seal Tonic, Boston, 19.6 per cent.

Liebig Company's Coca Beef Tonic, New York, 23.2 per cent.

Parker's Tonic, New York (advertised as without stimulants), 42.6 per cent.

Schenck's Sea Weed Tonic, Philadelphia, 19.5 per cent.

Bitters.

Atwood's Quinine Tonic Bitters, Boston, 29.2 per cent.

Atwood's Jaundice Bitters, Portland, 22.3 per cent.

Baxter's Mandrake Bitters, Burlington, 16.5 per cent.
Baker's Stomach Bitters, New York, 42.6 per cent.
Brown's Iron Bitters, Baltimore, 19.7 per cent.
Burdock Blood Bitters, Buffalo, 25.2 per cent.
Carter's Scotch Bitters, Georgetown, 17.6 per cent.
Colton's Bitters, Westfield, 27.1 per cent.
Drake's Plantation Bitters, New York, 33.2 per cent.
Flink's Quaker Bitters, Boston, 21.4 per cent.
Goodhue's Bitters, Boston, 16.1 per cent.
Hartshorn's Bitters, Boston, 22.2 per cent.
Hoofland's German Bitters, Philadelphia (claimed to be free from all alcohol), 25.6 per cent.
Hop Bitters, Rochester, 12 per cent.
Hostetter's Stomach Bitters, Pittsburg, 44.3 per cent.
Sulphur Bitters, Boston (contains no sulphur), 20.5 per cent.
Langley's Bitters, Boston, 18.1 per cent.
Mexican Tonic Bitters, Boston, 22.4 per cent.
Porter's Stomach Bitters, New York, 27.9 per cent.
Bush's Bitters, New York, 35 per cent.
Sherry Wine Bitters, Wakefield, 47.5 per cent.
Cinchonia Bitters, Providence, 13.1 per cent.
German Bitters, Concord, 21.5 per cent.
Strengthening Bitters, New Bedford, 29 per cent.
Old Continental Bitters, Lynn, 11.4 per cent.
Walker's Vinegar Bitters, New York, 6.1 per cent.
Warner's Safe Tonic Bitters, Rochester, 35.7 per cent.
Warner's Bilious Bitters, Boston, 21.5 per cent.
Wheeler's Tonic Sherry Wine Bitters, Boston, 18.8 per cent.
Wheat Bitters, New York, 13.6 per cent.
Faith Whitcom's Nerve Bitters, Boston, 20.3 per cent,
Williams's Vegetable Jaundice Bitters, Lowell, 18.5 per cent.—*Boston Med. and Surg. Journal*, March 10, 1887.

DR. CHRISTOPHER JOHNSTON, of Baltimore, has recently, in an address delivered before the Alumni Association of the University of Maryland (*Maryland Med. Journal*, April 9, 1887), given the following new illustration of the old adage that there is nothing new under the sun. Dr. Chassaignac, in 1850, revived the drainage tube, and claimed its discovery. But this valuable instrument had a much higher antiquity, since its employment was regarded as an "easy remedy" one hundred years before. Thus it is related in the *Country Housewife's Family Companion*, by W. Ellis, farmer, London, 1750: "How a person's wounded thigh was cured by a most easy remedy." "Now it happened, that in this interim of time, Mr. Edward Thome, a butcher, of great dealing, living at Little Gaddesden, in Hertfordshire, and who killed all or most of the Duke of Bridgewater's beasts for his numerous family, had a violent scorbutick humour broken out in his thigh, that so lamed him, as to necessitate his having recourse to a professed surgeon, but notwithstanding his application Mr. Thome was still in a very painful sad condition; in so much that the late good Scroop, Duke of Bridgewater . . . seeing this man (his butcher) in a very decrepit condition, asked him what was the matter? He told his Grace how lame he was by a wound in his thigh, and that he was hardly anything the better for what his surgeon had done for him. Upon this the Duke offered to give him his letter for carrying it to London, and to wait on that celebrated surgeon the late Mr. Bouchier, for his advice; for you must know that this person was so skilful as to be encouraged (as I am informed) by a large yearly salary from government, for giving his advice gratis to his Majesty King George the Second's subjects; and abundance of service he did to great numbers of people, amongst whom was this Mr. Thome, who, when he had presented him the Duke's letter, and seen his wound, asked him who was his surgeon? He told him. Says Mr. Bouchier, go tell him he is a blockhead, for proceeding thus in a wrong manner, and bid him get a black-lead pipe thrust into the wound, there to remain for the pus to evacuate through it, and as the wound heals it will push out the pipe by degrees, which must from time to time have its end clipped off with a pair of scissors, lest the shirt catch it and tear it out, for no salve will affect this sort of wound.

. . . . . .

"N.B.—The black-lead pipe was at first four inches in length, with a hole in the middle of it, a little bigger than that of a common tobacco-pipe, and of its shape, which, by the help of a bandage, kept in the wound, till it descended by leisure degrees, and was diminished by frequently clipping of, till the cure was perfected."

LEPROSY AMONG NORWEGIAN IMMIGRANTS.—The Norwegian Government has taken another step toward discovering the origin and nature of leprosy, which is so common on the west coast of Norway, by dispatching Dr. G. A. Hansen, Director of the Leprosy Hospital at Bergen, to North America, for the purpose of inquiring into the heredity of the disease among Scandinavian emigrants to the United States.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING APRIL 23, 1887.

RUSSELL, A. C. H., *Passed Assistant Surgeon, U. S. N.*—Ordered to duty at Naval Laboratory, New York, May 2, 1887.

HEITZINGER, A. C., *Passed Assistant Surgeon, U. S. N.*—Ordered to Widows' Island, Me., to superintend building a naval hospital, wharf, and other improvements under instructions of the Surgeon-General of the Navy.

WOODRUFF, CHARLES E., *Assistant Surgeon, U. S. N.*—Resignation accepted, to take effect April 8, 1887.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 19 TO APRIL 25, 1887.

SMITH, J. R., *Lieutenant Colonel and Surgeon.*—By Par. 8, S. O. 92, A. G. O., April 21, 1887, detailed as member of board to meet in Washington, D. C., April 28, to prepare rules and regulations for the government of the Hospital Corps of the Army.

HUTCHINS, CHARLES L., *Major and Surgeon.*—By Par. 8, S. O. 92, A. G. O., April 21, 1887, detailed as member of board to meet in Washington, D. C., April 28, to prepare rules and regulations for the government of the Hospital Corps of the Army.

TAYLOR, MORSE K., *Major and Surgeon.*—Relieved from duty at Fort Sill, I. T., May 10, 1887, to proceed home, San Antonio, Texas, preparatory to retirement.—*Par. 20, S. O. 92, A. G. O.*, April 21, 1887.

AINSWORTH, FRED. C., *Captain and Assistant Surgeon.*—By Par. 8, S. O. 92, A. G. O., April 21, 1887, detailed as member of board to meet in Washington, D. C., April 28, to prepare rules and regulations for the government of the Hospital Corps of the Army.

MOSELEY, EDWARD B., *Captain and Assistant Surgeon*—Ordered for duty at Whipple Barracks, Arizona.—*S. O. 89, A. G. O.*, April 18, 1887.

CABELL, JULIAN M., *First Lieutenant and Assistant Surgeon* (recently appointed).—To proceed to Fort Omaha, Nebraska, and report in person to the commanding officer of that post for temporary duty.—*Par. 19, S. O. 92, A. G. O.*, April 21, 1887.

ORIGINAL ARTICLES.

A REPORT OF FIVE CASES OF PLEUROTOMY BY RESECTION OF THE RIBS FOR EMPYEMA.

BY W. M. STRICKLER, M.D.,

OF COLORADO SPRINGS.

To avoid repetition, I will in the beginning briefly state my method of operating. The sixth rib in the axillary region is my principal guide. Across this, nearly at right angles, I make an incision down to the ribs, about three inches long, commencing just in front of the posterior axillary fold, so that its centre shall correspond with that of the sixth rib. Across the centre of this incision I make a cross cut about an inch in length. The object of this last is not so much to facilitate the operation as the after-treatment. The sixth rib being bared, with a Hey's saw I cut it well nigh through at two points, completing the severance with bone forceps. By cutting the intercostal arteries with the saw they do not bleed. In fact, ligatures are seldom required at all in the operation. The pleura is now opened and the pus allowed to commence running out. With the forefinger in the cavity I feel to make sure of my distance from the diaphragm. I now remove a section of the seventh and then of the fifth ribs. I usually remove an inch and a half of the sixth, and about an inch of the seventh and fifth. The object of the longer section of the sixth is to facilitate the washings and use of the drainage tube after the resected ends of the others come together, which sometimes occurs immediately.

The cavity is thoroughly examined with the fingers or the whole hand inserted to the thumb, if need be. All large masses of fibrinous material and false membranes are removed with the fingers. Search is made for adhesions, and if any are found that would probably hinder reëxpansion of the lung, they are separated. A large quantity of hot water is injected from a Thudicum bottle or fountain syringe.

The patient is now turned on the affected side, to allow any water that remains to run out. A couple of stitches are inserted, the centre of the wound being left quite patulous. Gauze is placed over the wound, and over this a mass of oakum, which is held in place by a broad binder encircling the chest.

The main point in the after-treatment is to keep the cavity clean. To this end it is flushed out once a day with hot water injected as mentioned. At first two or three quarts are required to give a clear return current. These washings are kept up for a month, or longer, if need be.

About the end of the first week a tube is required to keep the wound patulous. I use a rubber tube at first, about the size of the little finger, diminishing as the case progresses. It is inserted just through the chest wall. As a case progresses, I guard against interfering with commencing adhesions by inserting only a small flexible tube in washing out the cavity, also by allowing only moderate force to the ingoing current. But little, if any, medicine is used. If the effusion be large, and especially if it be on the left side, congestion of the liver, from pressure of the ascending vena cava, is apt to remain for a time, requiring a cholagogue to set the patient on the road toward rapid improvement.

In the cases I shall now report it is hoped there will be found peculiar to each sufficient of interest to merit a perusal of all.

CASE I.—My first operation was done July 17, 1886, on a man of twenty-four years, of bilious temperament, and of good natural constitution. He afforded the following brief history. The month of April was spent in bed from typhoid fever, from which he convalesced slowly. On July 1st a troublesome cough led to an examination of the chest, which showed the left pleural cavity to be distended with pus. There was markedly present a symptom which I have found in all my cases of purulent pleuritis—a thickening of the subcutaneous cellular tissue over the site of the effusion. It was not detected by direct pressure, but by pinching up a fold of skin of the affected side it was found to be two or three times as thick as a corresponding fold of the opposite side.

July 8. His condition from loss of appetite and sleep, and from a distressing cough, was most pitiable. With the aspirator one pint of pus was drawn off, and five days later one and a half pints, with but little benefit.

17th. With the assistance of Drs. Jacob Reid, J. T. Eskridge, Hazlehurst, and E. C. Kimball, the operation was done as described. No disturbance was caused by the admission of air into the chest cavity; on the contrary, the pulse—which at the beginning of the operation was 130—fell during it to 100, the breathing improving in corresponding ratio.

On opening the pleura about two quarts of pus escaped. The lung was seen and felt to be greatly compressed against the mediastinum. No adhesions were found. The subsequent progress of the case was so smooth as to afford but little worthy of note. There was no bad odor in the discharge at any time, or elevation of temperature after the first few days. The pulse fell to 80, became full and strong, the appetite good, and the patient took on flesh rapidly. He did not keep his bed after the first week, although subsequent experience has convinced me that an early leaving of the bed should not be encouraged.

At the end of the fourth week, all discharge having ceased, the tube was removed and the wound allowed to close. The falling in of the chest wall was quite apparent, but as there was no abrupt sinking in at any one point, there was no deformity worth mentioning. There was some dulness on percussion from the thickened pleura, but the respiratory murmur was good everywhere. The man became quite fleshy and robust, and to all appearances perfectly well.

Case II.—This case is even more interesting than the first, owing to the existence of phthisis.

Dec 30. I was invited by Dr. Jacob Reid, of this city, to see a young man of twenty-two years, whose left pleural cavity was greatly distended, evidently with pus. Four years previously marked dulness with broncho-vesicular respiration was found at the left apex. The patient had suffered more or less with cough for years. Although delicate, he was not entirely unfitted for light occupation, and was seldom seen by his physician. His family history is bad—his father and mother being both very frail. The patient himself is tall, lean, and of a nervo-sanguine temperament—altogether a bad subject for an operation.

His illness dated back eight weeks, and was diagnosticated as sero-fibrinous pleuritis in the beginning. After a few weeks the fluid was thought to have diminished, but changed to a purulent character with subsequent increase a week or ten days prior to this visit. His temperature was 105°, with breathing and pulse to correspond. He was very much emaciated, and almost as pale as a corpse. He was greatly harassed by a distressing cough, the intervals of rest being of but a few minutes, many times only seconds. The expectoration—which was abundant—was quite pinkish from admixture of blood. With the aspirator one and a half pints of slightly pinkish pus were drawn off. The improvement in his condition was marked, but of only short duration.

January 1, 1887, with the assistance of my associates in Case I., and that of Drs. Tucker, Solly, and Pennington, the operation of pleurotomy by resection of ribs was performed. The quantity of pus was estimated by gentlemen present at a gallon, and yet, notwithstanding the opening admitted the hand, only about one-third of it flowed out with the patient on his back. The lung was compressed against the mediastinum until it seemed not thicker than a man's hand. There were some long bands of adhesion, but as they were situated laterally I did not think they would hinder expansion, and did not interfere. In this case there were not only large masses of debris, but the gutter at the junction of the diaphragm and ribs in the posterior part of the chest was filled with a semi-gelatinous mass which was removed with the fingers. Although I supposed I had removed all the larger masses, either by the fingers, or by means of the bucket of water which was injected into the cavity, yet at the next washing several brain-like pieces as large as a lima bean came away. The progress of the pleural trouble toward recovery, although slow, was uninterrupted. The tube was not removed until the end of the eighth week.

As the lung began fairly to reëxpand, the expectoration became large, amounting to more than half a pint of sero-purulent matter daily, while abundant moist râles filled the lung. Under less salubrious surroundings, but one issue would have been expected. In the aseptic air of this dry and elevated region the result was watched with interest, but without apprehension, as the appetite was good, the temperature normal—the patient meanwhile taking on flesh continuously.

It is now three months since the operation. Reexpansion of the lung is complete—the moist râles have disappeared, and the expectoration amounts to almost nothing. His weight is up to his average, and he is enjoying life immensely.

Case III.—Feb. 12, I was invited by Dr. Fuller, of Manitou, to operate on a young man of twenty, who had been ill three weeks with pleural trouble. Within a few days past he had been tapped twice, a quart of pus being withdrawn on each occasion. With the assistance of Drs. Fuller, B. F. D. Adams, Kimball, and Hazlehurst the operation of resection of ribs was performed. On making a small opening into the pleura a stream of pus spurted to a distance of five feet, and persisted for some time. On enlarging the orifice a large quantity came away. The quantity in this case was enormous—more than it would seem possible for a pleural cavity to hold. The position and shape of the lung were interesting. It had been prevented from rising in the cavity by adhesions to the diaphragm and was compressed from above as well as laterally, so that the apex was on a level with the axilla—the fingers introduced in the wound passing readily above it, The lung, compressed against the mediastinum in every direction save from below, resembled in shape one-half of an ear of corn, split lengthwise, excepting that it was somewhat flanged at the base. The adhesions at the base were not interfered with, as it did not seem that they could hinder expansion.

The after-treatment was conducted by Dr. Fuller, who informs me that good expansion occurred, with reëstablishment of vesicular murmur everywhere, with perfect obliteration of the cavity by agglutination of the pleural surfaces—in short, that the patient did finely—far beyond all expectations.

Case IV. *Empyema of eight years standing.*—March 11, 1887, with Dr. Adams I was called by Dr. S. E. Solly in consultation to see Mr. D., aged forty-four years, weighing 190 pounds, of strong build and powerful constitution, with the following history:

Eight years ago he had pleuritis of the left side. Was aspirated forty times at intervals of from four to eight days—pus being drawn. This was in the first year of illness. Subsequent to the last aspiration, on various occasions a large amount of pus had been discharged through the mouth, indicating the existence of a pleuro-bronchial fistula. He came to Colorado six years ago, and remained here three and half years, with great improvement. He then returned to Boston and remained there two and a half years. His health again failed. He expectorated largely, had copious night-sweats, and became greatly emaciated. He returned to Colorado in

November last. His expectoration soon ceased and general improvement occurred, and continued to within a week of this time. Since then he has been having a rise of temperature of from two to five degrees, with loss of appetite, oppression about the chest, and general malaise. Inspection of the chest disclosed a cicatrix between the third and fourth ribs, extending from the sternum a distance of six inches to the left. About the centre of this there was a small sinus, which extended down between the ribs, and which discharged a few drops of serous fluid almost daily with occasional small quantities of pus. By the physical signs a small collection of fluid in the subaxillary region was diagnosticated, which, from the history of the case and present symptoms, was believed to be pus. The following condition was also thought to exist: a condensation of the subpleural and interlobular cellular tissue, of long duration, with incomplete reëxpansion of the lung, and a consequent pocket with walls that slowly secreted pus which did not thoroughly drain off through the sinus in front.

To secure obliteration of this space the operation of resection of the ribs was advised and the following day was set for the operation. In the meantime quite a discharge of pus took place from the sinus, with relief from discomfort. But as the sinus was badly located for complete drainage, and as accumulations had occurred from time to time for years, and as there was constant danger of a reopening of the bronchial fistula and the patient was hostile to any further half-way measures and anxious for a radical cure, we decided to perform the operation.

On reaching the ribs a grooved director was pushed into the cavity between the sixth and seventh ribs which passed two and a half inches before encountering the lung. Upon its withdrawal no pus escaped although some was contained in the groove. An inch and a quarter of the sixth and seventh ribs was removed. On passing the finger into the cavity a depression four inches in diameter was found in the upper part of the lower lobe, in the margins of which were straggling bands of adhesions. In its centre a cicatrix marked the site of the bronchial fistula. The lung was greatly puckered about this point, and the visceral pleura thick and unyielding for a couple of inches in every direction. Beyond the margins of this cup-shaped depression the pleural surfaces were closely united in every direction excepting in front. The lower anterior margin of the upper lobe had evidently united to the chest while pushed upward from a former effusion, for when the adhesions were separated, it immediately expanded, dropped downward and backward, and jutted out into the wound. To relieve the lower lobe of constriction from adhesions they were separated for four or five inches in every direction from the site of the cicatrix. Beyond this they were so firm as to resist reasonable force. No expansion of the lung occurred in the vicinity of the cicatrix. To the eye this scar tissue was bluish and looked altogether different from the surrounding lung tissue.

At the time my opinion was that sufficient collapse of the ribs would occur, to approximate the chest wall to the bottom of the depression, but should such not be the case, from previous experience I felt satisfied that by keeping the wound open, any space left would fill up by granulation. In this case I had fears of resulting acute pleuritis, but it did not occur to any extent worth mentioning. In fact the patient scarcely lost a meal. In a few days the discharge became quite free, of an odorless purulent character.

It is now nearly three weeks since the operation and the case is progressing with every prospect of a perfect result.

CASE V.—March 24, 1887, Dr. Adams and I were called by Dr. Kimball to see with him a man of twenty-three years, who had recently been brought in from the mountains suffering from pleuritis of less than four weeks' duration. His temperature was from two to four degrees above the normal. The right side was bulged out, immobile, with obliteration of intercostal depressions. Heart apex in left nipple line. Skodaic resonance at right apex in front, resonance good between sternum and right nipple line to diaphragm, indicating adhesions of the lung in front. Flatness on lateral region and back from diaphragm to axilla and spine of scapula. Fremitus weakened but not suppressed. Vesicular murmur weakened and distant, yet heard all over the region of flatness so distinctly as to be quite perplexing. Subcutaneous cellular tissue of affected side thickened.

With the aspirator only a few drops of pus could be drawn despite repeated efforts, after several introductions of a probe to clean the canula, and yet when the aspirator was detached about half a pint was discharged through the open canula. Two days later pleurotomy by resection of ribs was performed. The most notable feature was the presence of a large amount of solid matter in the pleural cavity. After all pus had been emptied, the posterior and lateral parts of the cavity were found filled by a mass of fibrinous material. It was so solid that it had to be broken up and removed piecemeal. There was a pint measure full of it. It extended from the diaphragm to the spine of the scapula and from the spinal column to the axillary line. There was no difficulty in effecting its complete removal, although it was somewhat adherent to the opposing pleural surfaces. The cavity was left thoroughly clean. The lung was adherent in front and at the base and was greatly compressed from behind and laterally. It is, at the date of writing, five days since the operation and everything points toward an uninterrupted recovery.

ABDOMINAL SECTION FOR PELVIC ADHESIONS.

BY JOHN B. SHOBER, M.D.,

HOUSE SURGEON IN THE PENNSYLVANIA HOSPITAL

ANNE D., æt. thirty-four, came under observation during the first week of last December. The following notes were taken at the time: As a child she was never particularly strong, though she enjoyed fairly good health. Occasionally she had attacks of diarrhœa, and when fourteen years old she had

pleurisy. She married at the early age of sixteen, and seven months later had a miscarriage which was followed by nine others during the ensuing seven years. She then had a child at full term, who is now living and enjoys good health. She has had one miscarriage since, this was about seven or eight years ago, after which she was treated for chronic inflammation of the womb. It was at this time that she first experienced pain on the left side, extending from the back to the groin and down the thigh. Exertion of any kind would cause her abdomen to swell upon this side. She frequently had cramps with alternating diarrhœa and constipation. She has worked hard during the past three years, and all her unpleasant symptoms have become exaggerated. She now complains of intense pain upon any exertion, especially severe in the region of the left ovary, cramps, flatulence, sometimes severe headaches, obstinate diarrhœa, great weakness, and general wretchedness. Rigors sometimes followed by fever and sweating have been among her many other symptoms during the past month.

She is a small, much emaciated woman, very anæmic, and of a highly nervous temperament; weight about ninety-eight pounds; lungs, heart, and urine normal; liver apparently normal; abdomen tympanitic, decided pain on pressure in left iliac region. Vaginal examination shows well-marked retroversion of the uterus, the left ovary bound down and adherent in the floor of the pelvis, the Fallopian tube thickened and of a doughy consistency. There is a decided pain throughout this mass. The right ovary is not so large or tender as the left and is more movable.

There is a profuse leucorrhœal discharge, a slight bilateral tear of the os uteri, and a lacerated perineum. She has been rapidly losing strength and weight, and has been a great sufferer for the past three months.

For two weeks preceding the operation she was placed upon the most active tonic and supporting treatment, notwithstanding which she seemed to lose rather than gain; her worst symptoms being left ovarian pain, cramps, flatulence, diarrhœa, daily rigors, followed by slight fever and sweating; steady and progressive loss of weight and strength. Her condition was most critical.

On the 21st of December, at the patient's home, with the assistance of Dr. Joseph Price, I removed the left ovary and Fallopian tube. The patient being etherized, a two-inch incision was made in the median line. The ovary was found firmly adherent to the floor of the pelvis and to folds of intestine. The uterus was slightly retroverted owing to traction by the adhesions, but otherwise normal. The right ovary was quite free. Enucleation was accomplished with difficulty. A silk ligature was applied close to the cornu of the uterus; the ovary and tube were then removed and the pedicle washed with 1: 1000 $HgCl_2$ and returned. There was no hemorrhage from either broken adhesions or pedicle. The abdominal wound was closed tightly with catgut sutures, no provision being made for drainage. The dressing was protective, iodoform and bichloride gauze, a large mass of bichloride cotton, and a flannel binder.

During the first forty-eight hours she was allowed nothing but champagne, of which she took four ounces every second hour. She then began taking milk, beef-tea, soups, etc., and in a few days her diet was increased to semi-solids. Her highest rise of temperature was on the evening of the second day, when it reached 100⅘° F., from which point it steadily fell to normal on the fifth day and remained there. Metrostaxis came on thirty-six hours after the operation and lasted three days, accompanied with some pain and tympany. On the third day she had two large, offensive bowel movements, and from that time, throughout her convalescence, she had two or three large and usually offensive movements every day. On the eighteenth day the dressing was removed for the first time and complete union was found to have occurred. In a few days she was allowed to sit up and was soon able to be out of bed. During her convalescence she occasionally had twinges of pain in the left side, but not of the same character as those she had previously suffered. This soon passed off, so that now she experiences no pain whatever. She no longer has rigors or fever. Her strength is daily increasing and she has gained eleven pounds since the operation. Her bowels, which were troublesome for some time after the operation, are now regular. She has returned to her work as seamstress, and says that she has not felt so well and strong for years.

Upon examination the walls of the tube were found to be decidedly thickened, and though evidently the seat of inflammatory changes, it contained no pus and only a small amount of epithelium. Its calibre, however, was decidedly enlarged. The ovary contained four cysts with thin walls, each holding an amber-colored fluid, the largest being about one-half of an inch in diameter, and the smallest about the size of a pea.

I had expected to find in this case what has been termed pyosalpinx, or at least a desquamative salpingitis. I found neither of these conditions. It is true the ovary was the seat of cystic changes and appeared cirrhotic, but it has been claimed that this condition of the ovary is not necessarily pathological,[1] and I cannot persuade myself that the great suffering this patient experienced previous to the operation was due entirely to pathological changes in the ovary or tube. It seems more likely that the cause of all her trouble was a recurring pelvic cellulitis or peritonitis resulting in adhesions on the left side, which, by dragging on the appendages and binding down the ovary, caused pain by traction and, perhaps, interfered with function and gave rise to her other reflex ovarian symptoms.

It has been suggested that in these cases it would be sufficient simply to break up the adhesions, thus freeing the bound-down appendages, and a question might be raised as to the propriety of removing the ovary and tube in this case.

The following considerations will, perhaps, justify the procedure:

1. The patient had for many years been the subject of recurring attacks of severe pain in the left

[1] H. C. [illegible] Journal of Obstetrics and Diseases of Women [illegible]

ovarian region, accompanied by the symptoms above described. These attacks had become gradually more and more frequent, so that during the two or three months immediately preceding the operation she was a constant sufferer, was rapidly losing strength and had become alarmingly emaciated.

2. Upon sight, the ovary and tube appeared to be diseased, and it has not yet been decided that they are not. Sections have not been made.

3. By dropping the appendages after breaking up the adhesions, the patient is subjected not only to the risk of peritonitis caused by rupture of cysts after necessarily rough handling, but also to the certainty of new adhesions forming, which might give more trouble than before, and might even lead to another operation.

ELECTRICAL AIDS IN THE TREATMENT OF INSOMNIA.

BY G. BETTON MASSEY, M.D.,

PHYSICIAN TO THE DEPARTMENT OF NERVOUS DISEASES IN THE HOWARD HOSPITAL; ELECTRO-THERAPEUTIST TO THE PHILADELPHIA ORTHOPÆDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES, ETC.

WANT of sound, refreshing sleep is a symptom of many chronic diseases that taxes most severely the mental health of the patient, and, reacting upon the body, effectually opposes our best directed efforts toward a relief of the primary conditions. In relentless persistence it envelops its victims within the grasp of a hopeless hunger that causes them to look back upon moments of sleep with a longing far more intense than those of the desert traveller for the "shadow of a great rock in a weary land." The imperious nature of these longings needs to be felt to be understood, and the absence of familiar reference to them in the highly poetic language of the Orientals is strong presumptive evidence of the freedom of the ancients from this characteristic consequence of modern overwork and worry.

But whatever may have been the experience of the past on this point, there is no doubt of the present prevalence of this bad habit of the nervous system, and of the great value of any means to break it up that will not in its turn give rise to a habit equally pernicious. Such a means we undoubtedly possess in electricity, either alone or combined with massage, and its value in the treatment of the obstinately insomnious is too little appreciated by the majority of those called to combat the effects of narcotic habits or the insomnia of incipient nervous and mental diseases. While total failures occasionally occur, the results of its use are at times exceedingly noteworthy; and it, of course, has the advantage of being incapable of giving rise to a habit of its own, to the future detriment of the patient. The somnolent power of certain applications is so great that I have frequently had patients who were not troubled with insomnia go to sleep under them while sitting upright in a chair engaged in conversation. The principal disadvantage connected with this plan of treatment is the necessity for each dose being given by the physician himself or by a trained assistant; and too much stress cannot be laid upon the statement that neither the patient nor the ordinary attendants are capable of administering electrical currents for this purpose with any chance of success. I have been particularly impressed with the delicacy of technique required in some cases; a slight deviation from the proved method, an accidental shock, or the use of a too strong current destroying the good effect for the subsequent night at least.

The particular methods to be adopted and the question of conjoining other means of treatment must be decided in accordance with the nature of the case and the nervous balance of the individual, the rejection, or selection and combination, of drugs, electricity, massage, and other aids demanding the most intelligent judgment on the part of the physician.

Four different methods have been of service in the cases under my observation. Two of these methods are by no means hypnotic, but seem to make sleep at a subsequent hour more possible, and are best applied at any time that is convenient during the day up to within an hour or so of bedtime. One of them consists in a general stimulation of all the accessible muscles of the body, except those of the face and neck, by local applications of the faradic current after the manner prescribed so largely by Dr. S. Weir Mitchell in cases of rest cure. Beginning with one of the limbs, each muscle or group of small muscles related in action is stimulated in turn to contract some six or eight times until the whole body, except the face and neck, has been traversed. Medium or large electrodes will be found most convenient in stimulating the several groups, and I have also found the slowly isolated currents (about 80 per minute) most efficient in producing the greatest amount of motion with a minimum of pain.

During the application the temperature rises as a result of the work forced upon the muscles; the central organs are relieved of any surplus of blood; the whole of the peripheral motor system is exercised without calling upon the jaded nerve centres; and the latter are probably affected by salutary influences due to the direct centripetal conveyance of sensory stimulations. This procedure is especially valuable when the general nutrition is below par, or when the patient suffers from cold extremities and other inequalities of the circulation.

Another method that may be applied during the day is general franklinization. The patient is insulated and connected with one pole of a Toepler-Holtz machine; the other pole, in the shape of a ball electrode, is carried over the whole person above the clothing in such a manner that short sparks are drawn from all parts of the surface except the face and hands. All-wool clothing will be found to be the best medium for the trans-penetration of the sparks between the electrode and skin, as linen, and to some extent cotton fabrics also, intercept the current by virtue of being passable conductors themselves. The result is a strong stimulation of the sensory apparatus through excitations that fall entirely upon the peripheral terminations of the nerves. The element of motor stimulation being wanting,

this procedure is less conspicuously tonic and recuperative than the method of general faradization just mentioned, but it produces a decided feeling of exhilaration that is often followed by a reposeful reaction in which sleep occurs. From a physical point of view, this method of franklinization is closely analogous to Beard and Rockwell's mode of administering general faradization, and in practice I have found it to possess an equal therapeutic value without the disadvantage of requiring the clothing to be removed. In a case of chloral habit recently seen not only was the night's sleep notably improved, but a nap in the daytime occasionally followed the applications.

For the immediate production of sleep, however, these stimulating methods of treatment are frequently inferior to more sedative applications administered after the patient has been prepared for the night and surrounded with appropriate quiet and repose. Of these latter the most serviceable is the continuous galvanic current applied with anode to occiput and cathode to the back; although a gentle, rapid-succession faradic current similarly applied will act better in some cases. With both currents the electrodes must be large and well wetted, and should be placed in position while the current is at its lowest, the strength being then increased to the desired point. With the galvanic current a rheostat is absolutely necessary for the gradual increase of the current to about three to five milliamperes and its equally gradual diminution at the end of the application. A milliamperemeter will also be found of great service in accurately indicating the current strength at a given moment; in its absence the sensations of the patient may be taken as a guide, the limit being a pleasurable warmth or slight burning sensation. Ten to fifteen minutes duration will suffice, at the end of which the current is to be imperceptibly lessened to nil and the appliances removed as quietly as possible. All shocks from sudden interruptions or variations of the current should be carefully avoided.

Instead of applying the anode of the galvanic current to the occiput, it may be applied to the subaural region as in the so-called galvanization of the sympathetic. The hypnotic effects are here at times greater, but the manipulation required is more delicate, and there is a strong chance of increasing the patient's wakefulness by blunders. As a rule two milliamperes are sufficient in subaural galvanizations for this purpose.

Simple anodic faradization of the occiput is frequently attended with most gratifying results. In making this application the cathode should be placed in the position least likely to give rise to sensation (on the heel is preferable, but *not* on the thin skin of the instep), both poles being well moistened. The current is increased at once from the initial weakness to a strength that is distinctly felt at the anode and is not increased further, notwithstanding the rapid fading of the sensation as the nerve ends become tolerant of the stimulus, for a gradually increasing faradic current is anything but sedative. The full effect of this application requires that the note emitted by the hammer of the interrupter shall be clear and free from quavers due to irregular vibrations.

17 W. Ashley Street.

REPORT OF AN OBSTETRICAL CASE, WITH SERIOUS COMPLICATIONS, CAUSED BY INDIGESTION.[1]

BY WILLIAM R. WHITE, M.D.,

[illegible]

THE nature and probable cause of complication in the following case will, it is hoped, justify the writer in reporting it.

Early in the morning of November 26, 1886, Mrs. J. sent for me to attend her in her first confinement. On arriving at the house, more than a mile distant from my own, I found her to be an American, short in stature, well formed, and eighteen years of age. She had not expected her confinement so soon by a month, but had no reliable data for determining just how many months gestation had been progressing. Her general appearance indicated perfect health, and her own statement that she "had never been sick" was undoubtedly true. Her condition during gestation had been excellent in every particular. She had attended to her usual household duties without inconvenience, had been out of doors more or less daily, had had a good appetite, had not been constipated, and had noticed no constitutional or local disturbance, except such as was incident to her increased size. Her feet and ankles had been slightly œdematous for a few weeks past.

Between two and three o'clock on the afternoon previous, she had been a guest at a bountifully laden Thanksgiving-day dinner-table, and, feeling perfectly well, had done ample justice to the feast of things so good to the taste, but oftentimes so bad for the digestion. She ate freely of the turkey and the numerous etceteras, including dressing and rich gravy. For dessert she had an abundance of suet pudding with sweet sauce. She suffered nothing from her repast, however, and retired that evening all right, so far as she knew. But she could not sleep, and about two o'clock the next morning, much to her surprise, began to have labor pains which continued. About the time they began, she had two or three loose, painless stools, of which no more exact description could be obtained.

Upon my first examination, at about 7 A.M., I found every sign and symptom of the case to be favorable. The woman was dressed, and about the house, being disinclined to lie down. She was cheerful, betraying little or no nervousness or dread. Her tongue was somewhat coated. The pulse was 72, and of excellent character. No œdema of the extremities existed. She had taken no nourishment since her Thanksgiving dinner, and desired none. Examination showed the vagina to be moist, the rectum empty, the os uteri partially dilated, with its margins thin and yielding, the membranes intact, and a vertex, easily reached,

[1] Read [illegible] Rhode Island Medical Society, March 17, 1887.

presenting in the right occipito-anterior position. The fœtal heart was readily heard, its rate being about 150 per minute. The pains were then quite brief, and not very severe. They were frequent; but during the intervals the patient was as comfortable as need be, not complaining at all of nausea, intestinal pain, headache, or anything else. The urine was passed often. I advised her to take a little light nourishment, which was declined. Not caring to return home, I spent most of the forenoon within sight of my patient, and can assert that in every particular, so far as was manifest, the progress of the case for the next few hours was normal. Late in the forenoon the pains grew sharper, but the patient bore them well and insisted on keeping about, although advised to save her strength by lying down a part of the time at least. The pulse, noted frequently, ranged between 72 and 80, its good quality being constantly maintained. In short, up to twelve o'clock noon I anticipated only a normal condition of things for mother and child to the end of the labor. I will state just here that no opiate or medicine of any kind had thus far been given.

But now a decided change in the aspect of the case occurred. The pains became longer and more severe as the first stage of labor merged into the second stage, and the woman became very uneasy. She was now as anxious to get to bed as she had been persistent in keeping about the room. She was hurriedly assisted to undress and lie down. On examination I now found the os fully dilated, the head low down in the pelvic canal, with the membranes intact and greatly distended. On counting the pulse, I found, greatly to my surprise, that it was exactly 48 per minute. It was weak and soft, but regular, perfectly distinct, and easy to count. Auscultation revealed no abnormal heart-sounds. The slowness of the pulse, however, was almost startling in view of the existing circumstances and the suddenness with which the very marked change had taken place. If its rate had been 98, or 108, or 118, I should not have been surprised; but a pulse of 48 in a healthy, young primipara, just entering on the second stage of labor after a perfectly normal first stage, was a phenomenon never before encountered by the writer.

I am sure that the drop in the pulse-rate occurred within a period of ten or fifteen minutes, and during the excitement and hurry of being put to bed, as it had been counted not long before and found to be between 70 and 80. This great change in the pulse, however, was not accompanied by any immediate unfavorable change in the general condition of the patient. She was not pale, had no dyspnœa, showed no signs of syncope, or even weakness, and complained of nothing but the labor pains, which were strong and very frequent. On listening now for the fœtal heart I could not hear it at all; partially for the reason, I think, that the woman was so uneasy on account of the pains, though possibly its sounds may then have been so weak as to be inaudible, even under favorable conditions for listening. It will be remembered that earlier in the forenoon they had been heard and counted with ease.

The maternal pulse-rate of 48 continued, and I realized the need of completing delivery at once, for the safety of both mother and child. Natural forces very kindly accomplished the desired result and so promptly that even if the forceps had been applied with all skill and expedition, little time could possibly have been saved, as it was only twenty minutes after the woman lay down that the membranes were ruptured, the head appeared distending the vulva and was immediately born, the shoulders and trunk following without delay. The whole expulsion was accomplished, practically, by one prolonged uterine contraction, something in itself not often observed in cases of primiparæ at term. The mother's condition did not perceptibly change during the prolonged and severe expulsive effort, and I was able to devote my attention wholly to the infant for the next few minutes.

It was a male child, between five and six pounds in weight, fully developed and, apparently, dead, as it did not move, or cry, or breathe, or even gasp. Its entire skin was blanched to the degree of complete exsanguination.

But the heart was beating feebly, and leaving the funis untouched, I tried various methods of resuscitation—with no success for several minutes. It was only by repeatedly forcing my own breath into its mouth and trachea that I finally obtained the first attempt at inspiration. The child came round all right and soon the cutaneous circulation was re-established, making the skin as red as it had just been pallid. The cord was then tied and the placenta delivered immediately. The uterus contracted well and remained firm. The mother's pulse was still exactly 48, but she showed no signs of failing strength. Very soon, however, she began to complain of intense frontal headache, which had come on suddenly.

I ordered the application of cold water compresses to the head, gave her five grains of Dover's powder, to be repeated once if the pain continued. The room was darkened, and my directions were to keep everything about the patient as quiet as possible. I remained in the house an hour, when the pulse had risen to 54 and had improved in degree of strength and fulness. The headache was still severe. Hoping the patient would soon fall asleep, if left to herself, I went home.

Visited the case at 6 o'clock the same afternoon. Found the baby all right but the mother in an unsatisfactory condition. She had slept none, the headache had been incessant and very severe. She had been restless, tossing about and sitting up in bed. There had been considerable flowing, but not to an alarming extent. The uterus was well contracted. The urine had been voided. The pulse was 54, temperature, by the mouth, 102° F. The face was flushed, the eyes suffused. There was photophobia. Water had been taken freely to allay thirst. The patient's appearance was wholly unnatural, manifesting discomfort and restless excitement. She did not complain of nausea or abdominal pain. I readjusted the binder which had become displaced, and gave her twenty grains of bromide of sodium with directions for ten

grains to be given from time to time if the headache, wakefulness, and restlessness continued.

About 9 o'clock the same evening, a messenger came to tell me that my patient had been acting strangely, that she had been vomiting, had not been able to see, had for a time been unconscious, had been convulsed, and had not seemed to be in her right mind since. Of course, I went to the case as soon as possible, with thoughts of uræmia and post-partum convulsions or coma vivid in my mind. Found the woman quiet, but feeling strange and bad in her head. She knew me, but was much confused as to what had occurred to her since my 6 o'clock visit. She spoke without difficulty and said she had had some sort of a fit, during which she had bitten her tongue. Her pupils were alike but dilated. There was no other paralysis. Her pulse was 54, temperature 102° F. She had vomited profusely, but the matter ejected had been thrown away. She had passed water just before I arrived, but there was so much uterine blood mingled with it that it was useless to test it for albumen. I did not pass a catheter.

Anticipating a return of the brain symptoms, I decided not to leave the case that night, and went into an adjoining room to prepare a ten grain dose of calomel which I proposed to give her immediately and to follow it later by a full dose of castor-oil. Just then I heard the woman attempting to vomit. I went to her and supported her head while her stomach unloaded itself of a basinful of nasty, offensive, sour-smelling matters, evidently the products of indigestion, diluted by the water she had drank.

The effect of thus relieving the overburdened stomach was immediate and most favorable, as the woman said directly that she felt very much better, which was perfectly evident. The headache was less severe and the mind was now clear. The pulse remained 54.

The patient became quiet and bade fair to go to sleep soon. I directed that she should not be disturbed for any medicine that night, but be allowed to sleep as much as possible. I left her, feeling pretty confident that the worst trouble in her case was over. Saw her the next forenoon. She had rested well and was now quite comfortable, though the head still ached. She had not vomited again and there had been no return of the alarming symptoms of the previous evening. Her pulse was 54, temperature and pupils normal, tongue covered with a thick, white coating. The urine passed during the night contained too much blood to admit of a reliable test for albumen. I directed that she be given an ounce of castor-oil.

Upon my next visit, the following forenoon, my patient's unpleasant symptoms had all disappeared. The oil had caused free catharsis, the headache was all gone, she had slept well, the tongue was clearing up, appetite returning, breasts distended, temperature normal and pulse 65. I saw her a few times subsequently; she did not have a single unfavorable symptom, and at the end of two weeks I left mother and child doing as well as possible.

I have given the clinical history of this case thus explicitly in order that others may form their own opinions as to the cause of the unlooked-for alarming symptoms which complicated it, and which certainly form no part of the history of a natural confinement. Whatever may have been the cause of the abnormally slow pulse, headache, elevated temperature, and subsequent brain symptoms, on the part of the mother, it certainly came near resulting in the death of the infant from failure of the circulation, and, for a few hours at least, the woman's condition was not encouraging. I cannot assert that there was no albumen in her urine; indeed, very likely there was a trace or even more of it present at the time, but I do not think albuminuria or uræmia had anything whatever to do in causing the trouble. There certainly was no sign of septic influence, and hysteria may also be eliminated.

My own impression is that it was the excessive overloading of the stomach, on a day and hour most unfortunate for the patient, that must be regarded as the real and primary cause of the severe complications. Progress has been made recently in the study of the fermentative and putrefactive changes which the contents of an overloaded stomach may undergo, resulting in the development of certain toxic elements whose effects on the nerve centres and the circulation may be serious in the extreme. Possibly in this direction we may look for an explanation of some of the conditions present in the case just described.

Undoubtedly, also, the disturbance that would, under other circumstances, naturally have resulted from the excesses referred to, was greatly aggravated by the inevitable reflex irritation incident to the first and second stages of labor, and hence this reflex irritation may be regarded as the exciting cause of some of the symptoms.

SULPHURETTED HYDROGEN INHALATIONS AS A METHOD OF TREATMENT FOR PULMONARY TUBERCULOSIS.

By ARTHUR C. HUGENSCHMIDT, M.D.,

The subject of the treatment of pulmonary tuberculosis by means of sulphuretted hydrogen has attracted so much attention for past weeks, that it may not be without interest to describe the employment of this gas by another method which, during the many years it has been used, has given very satisfactory results. This method has added to its interest this factor, that while the treatment of phthisis by enemata shows, strange to say, no diminution in the number of tubercle bacilli contained in the sputa, and even, in some cases, an increase in quantity is said to have been observed, in this method, after a few days' treatment, the microörganisms are found to have greatly decreased in number, and, in some cases, totally disappeared.

The observations we shall describe have been made by Dr. B. Niepce, physician in chief at the mineral springs of Allevard, France, who, for a period of thirty-two years, has been enabled to observe the beneficial influence of the inhalation of the gases contained in the sulphurous water in the treatment of affections of the respiratory passages, having

obtained, in many cases, cures of phthisis of the first stage, and even second stage, with a notable amelioration of the distressing symptoms of the last stage.

The inhalations as administered at Allevard are given as follows: The patients are placed in a spacious room, which is about twenty-one feet long, eighteen feet wide, and eighteen feet high, with very large windows, to allow a rapid ventilation after the inhalations are over. In the centre of the room there is a jet of the mineral water, which, striking a concave plate placed six feet above the lower reservoir, causes the jet to separate and divide itself into many drops, which liberates the gases contained in the water. The gases and their quantity contained in a litre of the mineral water are:

Sulphuretted hydrogen gas .	24.75 c. cm.
Carbonic acid	97.00 c. cm.
Nitrogen	4.00 c. cm.

The cures of phthisis which had been obtained by Dr. Niepce during his long practice he could only attribute to the beneficial influence of the mineral water producing a salutary modification of the organism, but further explanations could not be given.

In 1883, however, he began his observations as to the influence of the inhalations upon the presence of the tubercle bacilli; and, to his surprise, found that, after a few days' treatment, in patients of the first and second stages of the disease, there was a great diminution in number, even sometimes complete disappearance.

He then undertook a long series of experiments, of which the following are the principal.

1st. Having ascertained the presence of bacilli in a sputum, he inoculated two rabbits and guinea-pigs with it. One month later they were all tuberculous.

2d. He left, for twenty minutes, in the atmosphere of the inhalation-room, a portion of the same sputum, which he then directly inoculated in rabbits and guinea-pigs; three months later, at the autopsy, no signs of tuberculosis could be discovered; these observations, repeated several times, gave negative results.

In a third experiment he took four mice, which were inoculated with portions of sputum containing bacilli; two of them were placed in the inhaling-rooms, the others left outside. Six weeks later, at the autopsy, the ones exposed to the inhalations of the gases were found free from tubercle; the other two, on the contrary, being absolutely filled with tubercular nodules.

Such satisfactory results led Dr. Niepce to experiment with inhalations of sulphuretted hydrogen alone, with equally good results.

1st. Two rabbits and two guinea-pigs were inoculated. On the twentieth day the two guinea-pigs were sick, and on the forty-fifth day the autopsy revealed extensive tuberculosis. The two rabbits, however, which had been inoculated with the same material, but which had been submitted for three weeks, three times a day for half an hour, to the inhalations of sulphuretted hydrogen alone, were absolutely normal at the autopsy.

2d. Sputum which had been exposed for ten minutes to an atmosphere containing three per cent. of sulphuretted hydrogen, was inoculated in rabbits, the organs of which were found normal three months later. This same sputum, which had not been exposed to the vapors, produced the disease in every animal inoculated with it.

3d. A patient in the second stage of the disease was submitted four times a day, for a period of fifteen minutes, to inhalations of an atmosphere containing three per cent. of sulphuretted hydrogen. On the twelfth day the number of bacilli had greatly diminished, and on the twenty-seventh day, when the cutaneous surface and sweat had an odor of sulphur, and the sputum contained sulphide of sodium, this sputum was inoculated in guinea-pigs, with negative results, no tuberculosis being produced; showing evidently that the bacillus or septic poison had lost its virulence.

To approximate the method of administration of this gas as nearly as possible to the one established by him at Allevard, he employed a reservoir made of zinc (that metal not being acted upon by the gas), the capacity of which was fifty litres; he dissolved twenty-seven cubic centimetres of sulphuretted hydrogen in each litre of water. The vessel being then filled with this water containing the gas in solution, was placed at a height of about ten feet, and an opening half an inch in diameter at the bottom of this reservoir allowed the water to come out as a small stream into a zinc vessel placed beneath it, the gas being so set free. The patients are directed to inhale four times a day, fifteen minutes at a time, and continue such treatment for several weeks, when the inhalations are suspended for some time, and then again resumed.

Dr. Niepce had already expressed the results of his experiments in a paper presented before the Academie de Médecine, in January, 1884, in which he concluded that the "inhalations of pure sulphuretted hydrogen, employed as a therapeutical agent, modify, and sometimes cure, pulmonary tuberculosis." His experiments were confirmed by Professors Cavalier and Mairet, of the Faculty of Montpellier; also by a recent graduate, Dr. Pilatte, who undertook researches on the relative power of the different antiseptics known, as regards their action on the tubercle bacillus, and reached the conclusion that, "of all the antiseptics employed, sulphuretted hydrogen was the most reliable, preventing the development of the bacillus, at the same time destroying this microörganism."

Such satisfactory results have been obtained from the employment of sulphuretted hydrogen brought into direct contact with the lung tissue, as to warrant further and extensive experiments in that respect, which will certainly prove most interesting.

The combined use of these two methods, namely, enemata and inhalations, may prove to be of the greatest benefit, for one might replace the deficiency of the other, when acting at the same time. For instance, the gas, when given by enemata, seems to have lost, when exhaled by the lungs, that special power of destruction of the tubercle bacillus which it possesses when brought in direct contact

with it; for we know the number of bacilli remains the same, or even increases under such treatment. It would be interesting to know if the sputum, after the patient has been subjected to the enemata treatment for several weeks, is capable, when inoculated in animals, of producing the disease. If so, sulphuretted hydrogen inhalations, by destroying the bacillus, and preventing its development by direct action upon it, will certainly be a most valuable adjunct to the new treatment.

THE ADMINISTRATION OF GASEOUS ENEMATA SIMPLIFIED.

BY H. M. BRACKEN, M.D.,

WISHING to try the treatment of pulmonary diseases by means of gaseous enemata the following appliance was used, on the suggestion of Dr. J. Clark Stewart.

An ordinary siphon bottle charged with carbonic acid gas and water in the usual way: a pound bottle containing a sulphide in solution, closely corked, and having a long inlet and a short outlet tube, both of glass; a rubber tube attached to the siphon connecting it with the bottle containing the sulphide solution, and the tubing with the metal tip of an ordinary fountain syringe conveying the sulphuretted hydrogen from this bottle, where it is generated, to the rectum. When ready for use the siphon is inverted (for in this position only the carbonic acid gas escapes) and the cock is opened slowly. It is very easy to regulate the supply of gas in this way. The advantages of this appliance are:

1. *Cheapness*, a thing always worthy of consideration in trying new methods. All the material required will not cost over one dollar, and any physician can put it in working order.

2. *Convenience for manipulation*, there being no delay in generating carbonic acid gas and preparing the ordinary gas bag. It also does away with the double valved syringe bulb and its continuous manipulation.

Siphons, charged, can be obtained from druggists or bottling companies at a nominal cost. Those charged with ordinary pressure will supply gas for two or more enemata.

One attendant can easily hold the inverted siphon, regulate the supply of gas, and observe the effect on the patient, while the patient is able to control the rectal tube.

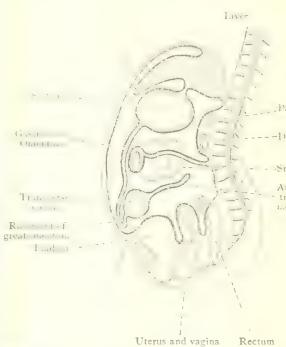
AN ANATOMICAL ANOMALY OF THE PERITONEUM.

REPORTED BY ALLEN J. SMITH, M.D.,

IN the abdominal cavity of a case recently upon the post-mortem table in the Insane Department of the Philadelphia Hospital a peculiar anatomical anomaly was discovered. On opening the abdomen, it was found that the course of the colon was entirely different from the usual arrangement. The cæcum lay in the normal position. The colon ascended on the right side to the lower surface of the liver, where, doubling on itself anteriorly, it passed downward; and when again in the right iliac region passed transversely across the hypogastric zone to the left iliac region. Here it turned upward, passed up to the left hypochondriac zone along the anterior wall of the abdominal cavity, where it doubled on itself posteriorly, and passed down to the sigmoid flexure. The gastro-colic omentum, usually insignificant in measurement, extended here six or more inches along the longitudinal axis of the body. The great omental apron was represented by a mere rudiment seen along the lower surface of the transverse colon.

Lifting up the transverse colon, another singular condition presented itself, explaining the unusual course of the colon. The transverse meso-colon was present, but entirely unattached to the posterior wall of the cavity, and limited posteriorly by a curvilinear free margin. At its widest point this meso-colon measured three inches. In the folds of the meso-colon along the margin passed the left colic vessels to and from the descending colon. This unattached meso-colon formed the posterior wall of a large pocket, the anterior wall of which was represented by the broad gastro-colic omentum; and in this pocket lay all the small intestine except a few inches of the lower portion of the ileum. The weight of the transverse colon, the weight of the small intestine, and the unattached transverse meso-colon had caused, by the continued downward pressure and lack of support, the anomalous course of the colon.

As seen from the outline of a median longitudinal section, the arrangement of the peritoneum in



The heavy black line represents the course the peritoneum takes [illegible]

this case prevented entirely the presence of the small peritoneal cavity which usually communicates with the great cavity by the foramen of Winslow. The peritoneal reflections in this case were as

follows: From the surface of the stomach the peritoneum passed downward a considerable distance; it then passed in front of the transverse colon, formed the rudimentary great omentum, and then passed posteriorly and inferiorly over the transverse colon. It then passed backward to form the lower fold of the transverse meso-colon, but instead of attaching to the posterior wall of the abdominal cavity, it doubled on itself and returned to cover the superior portion of the transverse colon, and passing off the colon formed the inner layer of the rudimentary great omental apron. Thence it was reflected upward to the lower curvature of the stomach, passed over its posterior surface, and gained the lower posterior surface of the liver. Thence it passed to the posterior wall of the abdominal cavity, over the pancreas and duodenum, covered in the small intestine, regained the posterior wall, and passed downward to be reflected over the pelvic organs. This accomplished, it covered the anterior wall of the abdominal cavity, and was reflected along the lower surface of the diaphragm back as far as the position where it became the suspensory ligament of the liver. It passed over the upper surface, margin, and lower surface of that organ, and then passed over to the upper and anterior wall of the stomach.

Laterally the folds of the anomalous transverse meso-colon were reflected as usual over the ascending and descending colons.

Unfortunately, the friends of the subject would not permit a permanent preparation of the anomaly to be made; and because of the rarity of the peculiarity, it was deemed proper to make a careful study and give an extended description of it.

JOHNSON'S QUANTITATIVE GLUCOSE TEST.

BY CHARLES F. ADAMS, M.D.
OF BORDENTOWN, N. J.

DR. JOHNSON has shown that an alkaline solution of glucose, when heated with a solution of picric acid, will reduce the bright yellow of the acid to a dark mahogany-red color, the depth of color being dependent on the amount of sugar present.

℞.—Glucose solution (gr. j to ℥j) . . f℥j.
Liquor potassæ . . . . . f℥ss.
Saturated sol. picric ac. (gr. 5.3 to f℥j) ♏xl.
Water . . . . . ad f℥iv.—M.

Put in a test-tube, mark the height of the mixture on the side of the tube with a file or other instrument, boil sixty seconds, cool by immersing the tube in cold water, and, if any loss by evaporation, add sufficient water to bring up to the line marked on the tube. The color obtained by this reaction is due to the reduction of as much picric acid to picramic acid as one-eighth grain of glucose, the amount present, will reduce.

Thus, having made a standard solution, we take a drachm of the suspected urine and add the liquor potassæ, acid, and water, and proceed as above. A comparison is then made between the resulting fluid and the standard solution, by means of the picro-saccharometer, which consists of a graduated tube of ten and one hundred equal divisions, with a shorter tube containing the standard solution clamped to one side of it. (See figure.)

Into the graduated tube a portion of the liquid to be tested is introduced to the ten-division mark. Should the two agree precisely in color, the suspected urine will have contained one grain of sugar to the ounce. If the mixture is darker than the standard solution, then add distilled or soft water cautiously, shaking until the color reaches the standard: then read off the degree of dilution. Each ten degrees of diluted fluid equals one grain of sugar to the ounce of urine. Thus, if ten degrees were enough, then one grain per ounce; if thirty degrees were required, then three grains per ounce.

The amount of acid used in the test will not reduce more than six grains of sugar per ounce; hence, in using the test when the scale indicates the maximum amount the urine should be diluted with an equal amount of water, and the operation repeated, care being taken to note the number of times the urine was diluted, in making the final estimate.

In making a series of fifty trial tests of urinous solutions of glucose of varying strength, unknown to myself, I calculated exactly the amount thirteen times; within a quarter of a grain of the amount, seventeen times; within half a grain, ten times; within three-quarters of a grain, six times; within one grain, four times. Calculated too low, eighteen times. Calculated too high, nineteen times. Average amount missed per ounce, one-third of a grain.

As will be seen, the estimation varied almost equally in the number of times it was too high and too low, showing the fault to be with the operator, and not the test.

As the color of the glucose solution is not permanent, Dr. Johnson imitates it with a solution of ferric acetate, made by the following formula:

℞.—Liq. ferri perchloridi . . . f℥j.
Liq. ammonii acetas,
Ac. acetic glacial (sp. gr. 1.065) . aa f℥iv.
Liq. ammoniæ . . . . . f℥j.
Aq. destil. . . . . ad f℥iv.—M.

The ingredients are all of the strength of the British Pharmacopœia. I therefore have substituted the following:

℞.—Liq. ferri chloridi . . . f℥j.
Ammon. carb. . . . . ℥j.
Ac. acetic . . . . . f℥v.
Aq. destil. . . . . ad f℥iijss.—M.

These are of the strength prescribed by the United

States Pharmacopœia, and make a solution of the same shade.

A picro-saccharometer can be constructed very neatly by clamping to a 100 c. c. glass-stoppered "mixing bottle" a "German weighing bottle," both being standard bottles and sold by dealers in chemists' supplies. It is well to have them of the same diameter, although it is not necessary, as the ferric solution must be standardized by first comparing with the standard color solution made as before described. If the containing bottle be of greater diameter than the measuring, then the solution may be rendered lighter by adding water; and if of less diameter, it will be necessary to add a few drops of the liquor ferri chloridi.

As the solution of acetate of iron is bleached when long exposed to the light, I place the bottle containing the standard solution in a test-tube rendered impervious to the light by painting the inside with asphaltum varnish, the tube being of such diameter as will catch the lip of the standard bottle. Then, having the top of the stopper also coated with varnish, the solution is readily protected from light when not in use.

I found it much more convenient to measure five cubic centimetres of each liquid with a pipette of the proper size, than to measure the number of minims in a graduated measure. It is also easier to remember the five cubic centimetres than a different number of minims for each article.

With the following alterations in the strength of the solutions, we get the same result by taking five cubic centimetres of each:

R.—Urine	5 c. c.
Liq. potassæ (sp. gr. 1.036) . .	5 c. c.
Sol. picric acid (gr. 3.5 to ℥j) .	5 c. c.
Water	5 c. c.

Mix and proceed as before.

In standardizing the iron mixture, greater accuracy can be obtained by holding the solutions against a translucent substance, such as a pane of ground glass, or a sheet of white paper held between them and the direct light. The same precaution should be taken ever after, as the light transmitted through clear glass makes the standard iron solution look as much lighter as would be equivalent to three-quarters of a grain of glucose to the ounce in the test through translucent glass; the color of the *urine* solution is the same in either form of light.

An impromptu instrument that answers very well can be made by taking two test-tubes of equal size, and making eight or ten equal division marks on one tube, and using the other tube to hold the standard solution. In testing, place enough of the boiled urine in the tube to fill it up to the first mark, then dilute as before described in using the picro-saccharometer. Each mark will represent a grain of glucose to the ounce.

As Dr. Johnson has shown, we may reduce the amount of sugar per ounce to the proportion per cent. by a simple proportion, in which the first term is 455.7 grains—the weight of an ounce of water at 0° Cent., 100 the second term, and the quantity of sugar per ounce the third. Thus, if there be twenty grains of sugar to the ounce, then as 455.7 : 100 :: 20 : 4.3; or we may multiply the number of grains by the decimal 0.219; grains 20×0.219=4.3 per cent.

HOSPITAL NOTES.

PHILADELPHIA HOSPITAL.

A KYPHOTIC PELVIS.

Reported by BARTON COOKE HIRST, M.D., [illegible]

WHILE this deformity is not infrequently met with, a typical case is perhaps sufficiently rare to merit a short description. Frau Z., born in Posen, æt. thirty, has had five children, three of whom were stillborn. Her labors have all been tedious. A successful operation was performed seven years ago, in Schröder's Clinic in Berlin, for a vesico-vaginal fistula that followed her fourth confinement. She is but four feet seven inches high, although in other respects strongly built, and upon the lower part of her back is a projection formed by the last three lumbar vertebræ, which, she says, is the result of a fall in early infancy. The measurements of the pelvis are as follows:

Distance between iliac spines (ant.) .	26 cm.
" " " crests . .	28 "
Right [illegible]	20 "
Left "	21 "
External conjugate (Baudelocque's) .	18 "
[illegible]	11¼ "

Distance between the tuberosities of the ischia, 12 cm.; the width of the sacrum at the sacro-iliac junctions, 6 cm. Internally, per vaginam, it is possible to feel the bifurcation of the aorta and the powerful pulsations of the common iliac arteries. There is no spondylolisthesis, although the last lumbar vertebra is slightly displaced backward. The uterus, owing to the diminished length of the abdominal cavity, is longer in its transverse than in its vertical diameter, and the child lies transversely, with its head to the left. The woman is in the eighth month of pregnancy.

MEDICAL PROGRESS.

LAWSON TAIT'S METHOD OF CLEANSING THE PERITONEUM.—At a recent meeting of the British Gynecological Society, MR. LAWSON TAIT gave an address, with demonstration, of his method of washing the peritoneum with copious streams of warm water. The trocar which he employs for tapping the cyst resembles a large double-eyed catheter terminating in a rounded but flattened and sufficiently sharp point. To this is attached a long India-rubber tube. This instrument he also employs as a siphon for washing out the peritoneal cavity. Having first immersed it in a ewer of water of the requisite temperature, an attendant raises it when required, and the water flows through the trocar in a steady stream, which can be directed upon any part desired. Mr. Tait prefers this method to the excessive use of sponges, especially in cases where the peritoneum and intestines are smeared with the adhesive colloid material from a friable cyst. This substance is readily soluble and easily

washed away by the warm water. The water is clean water taken from the tap, and no special antiseptic precautions are employed.—*British Medical Journal*, April 9, 1887.

Fatal Result of Intrauterine Medication.—Dr. Otto Engström, of Helsingfors, relates the following case in a Swedish medical journal. A woman, aged thirty-seven, had suffered from persistent metrorrhagia. The uterus was retroflexed, but no signs of past or present inflammation could be discovered. It was replaced and scraped out with a Simon's sharp spoon, two small spoonfuls of hyperplastic tissue being removed. A solution of iodine in iodide of potassium at 45° C. was then injected, the relative proportions of iodine, iodide of potassium, and water, being 1, 2, 30. No fever, and scarcely any pain followed. In five days' time a second injection was used, the temperature being 40° C., and the relative proportions of iodine, iodide of potassium, and water, 1, 2, 10. No pain was experienced, and the patient walked up and down stairs. On the evening of the second day, however, a rigor came on, followed by pyrexia, abdominal tenderness, diarrhœa, and convulsions, death occurring two days later. At the necropsy there were found broncho-pneumonia, chronic œdema of the lungs, endocarditis, and purulent peritonitis. The substance of the uterus was soft, friable, and gray-colored, containing specks of blood and lymph. The peritoneum over the uterus was of a yellowish-red color, and covered with puriform matter. The Fallopian tubes and their fimbriated extremities were not dilated or particularly reddened, and the mucous membrane presented no abnormality. The os uteri was too small to admit a fine probe. A large quantity of pus occupied the peritoneal cavity. Dr. Engström does not think any of the injection can have passed into the tubes, still less into the peritoneal cavity, and believes that the fatal peritonitis was due to an extension of the inflammation directly from the uterine wall to the peritoneum.—*Lancet*, April 16, 1887.

Arsenic and Lithia in Diabetes.—At a meeting of the Paris Société de Thérapeutique (February 23d) Dr. Martineau recommended the following treatment, with which, he said, he had cured sixty-seven out of seventy patients suffering from arthritic diabetes:

Carbonate of lithium . . .	3 grains.
Arseniate of sodium . . .	$\frac{1}{10}$ grain.
Carbonic acid water . . .	2 pints.

Effect the solution under pressure. The effervescing liquid is to be drunk at meals, mixed with claret, and the foregoing dose is to last for at least three meals, being taken at the two principal meals of the day, customary in Paris. No change of diet is necessary. Dr. Martineau's fellow members—Dr. Dujardin-Beaumetz among them—were somewhat sceptical about the value of the treatment, but it is so simple and easy that it can be given a trial when the patient is not dangerously ill.—*Therapeutic Gazette*, April 15, 1887.

Iodized Starch as an Antiseptic.—England describes his preparation and use of this substance as follows in the *American Journal of Pharmacy*, for April, 1887:

Apropos of the subject of antiseptics, the author was led some months ago to advocate the use of *iodized starch* as an addition to our rapidly growing list of these compounds. Reasoning that the antiseptic activity of iodoform and bismuth subiodide must depend, in part or in whole, upon the iodine freed in their decomposition, in contact with decomposing putrescent organic matter, it was thought that if an iodized compound, readily decomposable, was subjected to the same conditions, that it would induce the same healthful process in the latter case as well as in the first. Full experience has demonstrated the value of the theory in this instance, and iodized starch is now used daily in our hospital practice, and recognized as a valuable adjunct in certain forms of antiseptic treatment. It is applied in the same manner as other antiseptics, namely: first washing out the wound with pure water, and drying out as far as practicable, then thoroughly dusting in with iodized starch and covering the wound, even beyond its outer edges. The applications are generally made in the morning and evening.

In the removal of the dressings the absorption of the iodine is most strikingly shown. Whereas, in the central parts of the wound, where the exuding pus or matter has come in contact with the bluish-black powder, the same has become wholly decolorized, and shows the white color of the starch, yet, around the outer limits of the dressing, where no excretive matter has exuded, the bluish-black color remains unaffected.

Then comparative trials with iodoform, subiodide of bismuth, and iodized starch have demonstrated that it possesses valuable antiseptic qualities as a dressing, and though it may not be superior to the first two named, yet, at the same time, it has occasionally succeeded where they have given unsatisfactory results.

In its preparation the pharmacopœial method, given under "Amylum Iodatum," has been followed, namely, the trituration of 5 parts of iodine with a small quantity of distilled water, and the gradual addition of 95 parts of powdered starch, until the compound has assumed a uniform, bluish-black color. Then dry at a temperature not exceeding 40° C. (104° F.), powder and bottle or box.

Hygiene of the Eyes among School Children.—*The Sanitarian* for March, 1887, quotes Dr. Lincoln, author of the Lomb Prize Essay, as follows:

In school work we should require (1) a comfortable temperature, and especially let the feet be kept warm and dry; (2) good ventilation; (3) loose clothing; (4) erect posture; (5) little study before breakfast, or directly after a hearty meal; none at all in twilight or late at night; (6) great caution about study after recovery from fevers; (7) light abundant, but not dazzling; (8) sun not shining on the desk, or on objects in front of the pupil; (9) light coming from the left hand or left and rear; under some circumstances from in front (no light from the right of the pupil permitted); (10) the book held at right angles to the line of light, or nearly so; (11) frequent rest by looking up; (12) distance of book from eye about fifteen inches.

The Treatment of Endometritis.—Doléris, of Paris, concludes his articles in the *Archives de Tocologie*, March 15, 1887, as follows:

In the majority of cases of chronic endometritis, the

process of sponging or swabbing out the uterus with cotton saturated in glycerine-creasote, one-half or one-third, was employed. To apply this properly, the uterus should be pulled down; if possible, the cervical canal should be dilated, this may be done advantageously with tents soaked in creasote and glycerine. If sponging or swabbing prove inefficient, curetting the interior of the uterus should be employed, and afterward injections of suitable antiseptics.

Doléris has treated, upon these principles, 339 cases. The treatment has been unattended by accidents, and the large proportion of the cases resulted favorably.

An Ointment for Eczema.—We quote from the *Journal of Laryngology* for April, 1887, the following formula for Van Harlingen's eczema ointment:

R.—Glycerol. plumbi subacetat. (Squibb) ℥ss.
Glycerin. . . . . ℥jss.
Ung. aq. rosin. . . . . ℥j.
Ceræ albæ . . . . . q.s.
Ft. ung.

Herniotomy under Cocaine Anæsthesia.—Southam, at the Manchester Infirmary, performed the operation mentioned, as follows: "Twelve drops of a ten per cent. solution of cocaine were injected into the subcutaneous tissue over the hernia, and five minutes afterward the operation was commenced and carried out in the usual way; the sac was opened, and its contents, which consisted of a knuckle of congested intestine, readily returned into the abdomen after the stricture had been divided. The sac was separated from the surrounding tissues, and a catgut ligature having been secured round its neck, it was removed on the distal side of the ligature. The operation, which lasted about twelve minutes, was almost painless; the patient was just sensible of the skin incision, and complained of a little pain while pressure was being made upon the bowel during its reduction, but the other steps of the operation appeared to be hardly felt."—*Medical Chronicle*, April, 1887.

Microörganisms under the Antiseptic Dressings.—Stäheli has investigated this subject extensively, and his results are quoted by the *Medical Chronicle*, of April, 1887, as follows: "As the question of the occurrence of microörganisms under antiseptic dressings has been variously answered by many observers (Ranke, Busch, Hirschfeld, Fischer, and others), the author has investigated the subject afresh, and with newer methods. His researches are based on fifty-nine cases (amputations, herniæ, removal of tumors) observed in Professor Socin's Clinic. In that clinic the operation-room is disinfected with carbolic acid, so are the instruments; the sponges are kept in a five per cent. carbolic solution, and are disinfected with seven per cent. zinc milk (zinkmilch, of which the composition is not given). For irrigation, 1 : 1000 sublimate solution, or 1–2 per cent. zinc milk is employed. On the line of suture, zinc paste, over that gauze saturated with zinc milk, with pads of cotton-wool, or turf moss cushions. During the first change of dressing, with a platina needle that had been submitted to a red heat, some secretion was taken out of the deeper part of the drainage tube and inserted into peptone glue, gelatine, or blood serum, or they were used for the preparation of dry specimens. Besides this, a small piece of tissue was taken with a sterilized scissors from the wound (after Kümmel's method) before the application of sutures, and implanted into the nutritive substance. The microscopical examinations were made with a Zeiss' immersion $\frac{1}{12}$ and Abbe's illuminator. Of the fifty-nine cases, twelve healed by the second intention, and in all of these microörganisms were found. In the remaining forty-seven healing took place by first intention; in fifteen microörganisms were discovered, four times they were only found in the dry preparations—in the latter cases the organisms were dead, and did not develop in the cultures. The antiseptic method therefore is able to keep the microörganisms from the wound. The microörganisms found in the wounds which healed per primam and per secundam were cocci, bacteria, and bacilli, either alone or in combination. Pathogenity, therefore, does not depend on the form or quality of the microörganisms. The influence produced by their number can only be determined by experiments on animals, and only very imperfectly by microscopic examination of the secretions. The infection of the wound is brought about chiefly by contact. The behavior of the secretions is a chief factor in influencing the healing. When drainage is not perfectly free, microörganisms in large numbers, and of the most varied kind, are found. The relation of the fever is not quite constant. In twenty-two of forty cases, in which microörganisms were found, healing went on without any elevation of temperature; and in four of seventeen cases, in which no fungi were discovered, fever occurred. The gravity of the operation exercised a very distinct influence on this symptom. Of the wounds that healed per secundam only in those that resulted from small operations was there a normal temperature. The portions of tissue removed before the application of sutures showed almost always—nine of eleven cases—that fresh wounds already contained microörganisms. Only in one case on the third day new bacteria were found, in addition to those previously discovered in the tissues. These microorganisms increased in number as time advanced. The author thinks that the microörganisms found during the process of repair have generally gained access to the wound at time of operation, and the antiseptic means employed do not in all cases prevent this. A wound may contain non-pathogenic microörganisms without any detriment to the healing process. Of the pathogenic fungi, which may act injuriously, staphylococci (aureus and albus) occur most frequently, and wound secretions, when stagnant, are the best soil for the development of these microörganisms."

Anti-strumous Resolvent Lotion.—Descroizittes is quoted by the *Journal of Laryngology* for April, 1887, as prescribing the following:

R.—Chloride of sodium . . . ℥ij.
Sol. bichloride of mercury . . . ℥ij.
Tincture of iodine . . . ℥ij.
Distilled water . . . ℥xxxvj.

Compresses soaked in this solution are applied to strumous enlargements.

BINIODIDE OF MERCURY AS AN ANTISEPTIC.—DR. P. K. BOLSHESOLSKY, of St. Petersburg (*Vratch*, No. xi., 1887, p. 220), from numerous experiments made by himself in Professor A. P. Dobroslavin's laboratory, concludes that biniodide of mercury is a more powerful and less poisonous antiseptic than corrosive sublimate. Thus he fully confirms the observations of Bernhardy. A solution of 1 : 4000 destroys putrefaction microbes more completely than a sublimate solution of 1 : 2000. The biniodide dissolved in a solution of iodide of potassium was recently tried, with apparently good results, in three cases of laparotomy, under Professor A. I. Krassowski. For washing the floor, a solution of 1 : 4000 was employed; for disinfecting the hands, 1 : 2000; for instruments, 1 : 2000 and 3000.—*British Medical Journal*, April 9, 1887.

METHYLAL.—DR. B. W. RICHARDSON has written, in the *Asclepiad* No. 13, as follows:

In my report of 1869 I showed that methylal, which is very soluble in water, could be administered by the mouth when diluted with water, or by hypodermatic injection, and I have prescribed it occasionally, as a mixture several times. I usually begin with a fluid drachm dose, mixed with either glycerine or syrup of orange flowers and distilled water. Example:

Methylal, pure	℥xj.
Syrup of orange flowers	℥iv.
Distilled water	℥vj.

Mix. To make a solution of 6 ounces; of which let 1 to 2 fluid ounces be taken in a wineglassful of water as directed. The dose may gradually be increased to twice the above quantity or more.

In action, as a medicine, methylal lies between alcohol and anhydrous ether. It quickens the action of the heart with reduction of arterial pressure; it makes the respiration slow and deep; it induces a tendency to sleep; and it is a sedative to pain, but not to a very deep degree. On the whole, it would be best to keep it in the group of anodyne antispasmodics, in which I originally put it. It causes very little muscular excitement and no vomiting, but after long inhalation of its vapor it produces a free flow of saliva. As it mixes well with alcohol and with ether it might be administered with either of these agents; and it might also be given with amyl nitrite for the relief of colic, asthma, angina pectoris, or tetanus; but before it can come into general use it must be reduced in price.—*American Journal of Pharmacy*, April, 1887.

AUTO-CÆSAREAN SECTION.—AISENSTATT, of St. Petersburg, reports the following case in the *Vratch* for 1886, No. 42:

The official inquest found that a peasant woman, having been five times pregnant previously, had conceived the sixth time unlawfully, in the absence of her husband. Although upon his return she was kindly treated, she had made the incision while in the upright position, and extracted the child; it was of the male sex, twenty inches long, and weighed six pounds; it lived twenty-four days.

The mother was found by the daughter, and still possessed the strength to go to the stove (or oven), and there lay down. The oven answers the Russian peasant oftentimes as his bed. After some time she left her position, but fell exhausted; she died that night from hemorrhage.

The autopsy found the body of a young, very anæmic woman; in the *linea alba* an incision five inches long, with cleanly cut edges, between which no blood-clots remained.

The uterine wound was straight, made in the lower portion of the uterus, and four and a third inches long; the uterus was enlarged, the *os uteri* permeable for four fingers.

In addition to this case, one reported by Eon, occurring in a negress, in 1769, is cited; and also the "Viterbo" case, both of which recovered.

THE FERTILITY OF WOMEN.—SCHBANKOW concludes as follows in an article in the *Zeitschrift für Geburtshilfe und Frauen Krankheiten* (Russian, 1887, No. 1):

His investigations were upon the influence on the fertility of women exerted by absence, at different intervals, of their husbands. In the districts of Jaroslawl and Kostrowa, and in many other Russian provinces, the greater portion of the male population of the villages is obliged to seek work in other localities during the summer, twelve per cent. of the entire population thus temporarily emigrating.

Women whose husbands remained at home during the entire year averaged 9.2 children each, excepting the sterile women, who were 3.33 per cent. of the whole number; women whose husbands left their homes to procure work averaged 5.2 children each, excepting the sterile, who were 11 per cent. of the whole number.

The writer finds the cause for these facts, not in bad hygienic surroundings, but in the severe manual work which falls upon the women in the absence of the men, tending to produce uterine disease and facilitate abortion, and also to produce amenorrhœa; in the interruption of the sexual relations thus produced; and in the frequency of syphilis and other venereal diseases, as contracted by men in strange towns, and communicated to their wives.

TREATMENT OF SEVERE MALARIAL INFECTION.—DR. MANSON, of Richmond, Va., in a paper published in the *Transactions of the Medical Society of Virginia* for 1886, described the following plan of treatment which had been very successful in his hands:

Should the employment of morphia have failed to allay the pain, nausea, and vomiting, it should be repeated, but allowing at least four or five hours between the administration of the doses, whether introduced beneath the skin or into the rectum. At bedtime—say, at 9 or 10 o'clock—it is our invariable rule to administer a cathartic dose of calomel and rhubarb of 10 or 12 grains each. At some period before or after midnight the fever will generally be found more or less to decline. We prefer this period for the commencement of the abortive means, because our experience teaches us that quinine, the principal remedy, is better borne, and produces its salutary effects in a more decided and complete manner than at any other time. We now, therefore, usually administer from 15 to 20 grains of the sulphate of quinine at a single dose, in pills or capsules,

administer the *larger quantity;* if *very moderate,* the *lesser will answer.* Under the combined action of the mercurial and quinine, free evacuation of the bowels will usually occur, but rarely excessive. Three or four hours are now suffered to elapse. The condition of the patient will now be found generally much improved. The gastro-hepatic and cerebro-spinal pains are either removed or mitigated, the pulse becomes less frequent and more soft, the skin relaxed and moist, and the gastric irritation subdued. We therefore repeat the quinine in diminished doses of 5 or 6 grains every three or four hours, until the period of chill has passed, generally exhibiting altogether from 25 to 40 grains before that time. Under this simple plan of treatment, remittent fever is certainly and safely cured. We have in this manner arrested the disease in many hundred cases, in one night.

Alarming Hemorrhage after Tonsillar Excision Arrested by Torsion of the Artery.—Dr. Clinton Wagner reports the following case in the *New* [illegible] *Journal of Medicine:* Miss [illegible] F., aged about thirty, an opera-singer by profession, consulted me for sore throat. I found the left tonsil greatly enlarged, and she informed me that it frequently became acutely inflamed. I recommended excision. The gland was partly covered anteriorly by the column of the soft palate, and extended so far downward into the pharynx that I had great difficulty in encircling its inferior portion within the ring of the guillotine; finally I succeeded in removing almost the entire gland. A gush of blood followed, but apparently not greater in quantity than is usual after this operation. The bleeding increasing instead of lessening, I applied to the cut surface of the gland the persulphate of iron, which failing, I resorted to compression, but I discovered afterward that it had not been exerted in the proper direction. Nearly an hour had elapsed since the operation, a large amount of blood had been lost, vomiting of the blood, which had found its way into the stomach, ensued, and the patient was rapidly losing strength. I cleansed the parts thoroughly of clots of blood, but, not finding the source of bleeding, I forced the tongue, by means of the depressor, upon the floor of the mouth as far as possible. In the space between the pillars of the soft palate, apparently springing from the root of the tongue, I discovered an artery of considerable size, bleeding freely and with such force that the blood was projected over and beyond the depressed tongue to the opposite side of the mouth. The bleeding vessel, now located, was, without much difficulty, taken up with an artery-forceps and twisted, and all further hemorrhage was effectually controlled. I think the divided artery was either the tonsilar branch of the facial, or the largest of the pharyngeal branches of the ascending pharyngeal, both of which are given off from the external carotid.

Antisepsis by Corrosive Sublimate in Tracheotomy.—The method of Watson Cheyne, of London, is as follows: The trachea must be opened more freely than usual, with the primary object of inspecting the interior of the trachea. If the trachea is healthy, it will present a bright red appearance; if membrane be present, it will have a dull gray color. When no membrane has been formed, either a canula is inserted into the lower angle of the wound and the trachea filled up above with strips of thin rag soaked in a watery solution of bichloride of mercury (1 in 2000), the process being repeated every two hours; or, the trachea is kept open with Golding Bird's dilator, and the surface brushed from time to time with a weak solution of the perchloride. There are contending advantages in each method. If the membrane has spread to the trachea, it is pulled off with dissecting forceps, the resulting raw surface, and especially the spreading edge, being touched with the 1 in 500 bichloride solution.—*Journal of Laryngology,* April, 1887.

Pomade for Cutaneous Disorders during Pregnancy.—Monin, in *L'Union Médicale,* of March 29, 1887, gives the following formula:

Zinc. oxid. pulv.	gr. 3.
Hydrarg. ammoniat. (white precipitate)	gr. 1½.
Ol. theobromi,	
[illegible]	ʒ iij ss.
[illegible]	ad. 10.

This may be applied to the face morning and night.

When Shall Tracheotomy be Done?—Raneon de la Sota y Lastra, of Seville, in the *Journal of Laryngology* for April, 1887, after citing the statistics of the principal hospitals of the world, concludes as follows:

"Undoubtedly, too many patients are allowed to die from indecision on the part of the operator. It should be a golden rule to *operate early, slowly,* and *carefully,* and not to halt between two opinions until the child has passed from a comparatively comfortable stage 'in extremis.' There is probably no operation in which indecision is more fatal. This indecision is partly due to the failure of the operator to realize the right moment for action, and partly to fancied dangers as to the operation itself. Trousseau's maxim, that a badly performed operation, with skilful after-treatment, will lead to a satisfactory result in many a case in which an operation, skilfully performed as possible, left to careless after-treatment, would have been followed by fatality, should be always borne in mind. The country practitioner should always be able to perform tracheotomy, and should have the necessary instruments always in his possession. The prognosis of his case may become absolutely hopeless while he is occupied in sending miles for the skilled surgeon, and he should have sufficient knowledge of anatomy and surgery to be able to act promptly in an emergency."

An Ointment for Obstinate Acne.—The following is known as Wilkinson's ointment:

R.—Naphthol, ...	ʒ ij.
Sulphur præcipitat. . . .	ʒ ij ½.
Vaseline or lanoline,	
Potassium soap	ad ʒ vij.

M. ft. unguentum.

Sig.—Local use daily.

PHILADELPHIA.

SATURDAY, MAY 7, 1887.

ELECTRICITY IN THE TREATMENT OF CERVICAL CATARRH.

THE use of electricity in the treatment of diseases of women constitutes one of the most important advances in medicine. It is probable that we are only beginning to recognize the value of this agent, and that the future will show that it has a much greater utility than has yet been given to it.

From Lutaud's *L'Obstetrique et la Gynecologie en* 1886, we learn that JOURET treats catarrh of the neck of the womb by faradization of the uterus, and galvano-caustic applications to the cavity of the neck. The purpose of the former is to excite contractions of the uterus, and thus relieve its engorgement and the hindrance to circulation, a condition so liable to occur from the anatomical structure and functions of the organ. In all autopsies of chronic endometritis there are found not only lesions of the mucous membrane, but also of the parenchyma. It is claimed that electricity, by exciting contractions beginning at the internal orifices of the oviducts and at the fundus, relieves the stasis in the muscular parenchyma; and that the uterus is subjected to interstitial massage which restores its lost tonicity. It not only produces these results, but by its dispersion upon other pelvic organs, it also exercises a favorable influence upon their circulation and innervation.

For the application Jouret directs that the patient should lie upon her back, with the pelvis somewhat elevated, and that the bifurcated positive pole (covered with moistened chamois skin) should be applied to each side of the recti muscles just above the pubes. The negative pole, having the form of a uterine sound, and covered with caoutchouc to a little more than an inch from its extremity, is introduced into the cavity of the neck, or of the body, if the internal os permits. Tripier's instrument is preferred; by it the number of interruptions may be made to vary from fifty to three thousand per minute, and the current can be graduated in tension and intensity. In uterine faradization the intensity of the uterine contractions should be progressively increased according to the sensations of the patient; but when the pain becomes decided, the intensity should be lessened. The duration of a sitting will vary from five minutes as the minimum to ten as the maximum, according to the sensibility of the person, or the atony of the uterus, the degree of the engorgement, and the length of time it has continued. After an application, if it be properly conducted, the patients, nine times out of ten, express themselves as feeling lighter and able to walk better.

That which Tripier has called the chemical galvano-caustic of the cavity of the neck, has been defined by him as a potential cauterization of the cervical tract by the continuous current. Jouret does not regard this as in all cases indispensable, but it is necessary sometimes in consequence of the development of the glands of the cervix, forming the so-called ovula Nabothi; sometimes by the formation of hypertrophies of the mucous tissue which give origin to a thick, creamy, purulent discharge, or which, when ulcerated, cause hemorrhages. In the application of the constant current, a large plate of tin, covered with agaric or chamois which is thoroughly saturated with cold water, is placed upon the abdomen, or upon the thigh, and is the positive pole. The caustic electrode, the negative, is then introduced into the cervix, which is exposed by a speculum; if cauterization of the uterus is desired, the pole is passed into its cavity. Usually the intensity of the current is from fifteen to twenty milliampères, and the sitting is from five to ten minutes. The cauterization is, if necessary, repeated according to indications—that is, until the disappearance of the abnormal secretions arising from inflammation of the mucous membrane and from the hypertrophied glands.

Jouret states that he applies this electric treatment almost invariably in chronic endometritis, and that a long experience has led him to prefer it to any other method of treatment, because of the facility of execution and the constancy of the favorable results.

The favorable effects from faradization of the engorged uterus are so generally recognized by those treating diseases of women that it is not necessary to add a word to the commendation of this treatment given by Jouret. If a like satisfactory result can be had in chronic endometritis from galvanization by others as well as by Jouret, this hitherto obstinate disease will cease to be an opprobrium to the profession.

PROFESSIONAL REPUTATION.

THE desire of praise belongs to man in common with many of the inferior animals. The education of some of these animals is chiefly effected by appeals to this desire, rewarding, for example, the dog, when teaching him to retrieve by kind words, and possibly some food dainty; or the horse, when teaching him to stand without hitching, in a similar way. It also is of large application in educating the child. It furnishes one of the most powerful motives to industrious, philanthropic, or heroic action, on the part of the adult, no matter in what calling he is engaged. The physician is by no means exempt from the ambition for reputation; and although Milton did refer to fame as the last infirmity of noble minds, it is one of the most powerful means, not only in advancing his influence and capability for doing good, but of promoting the interests of the profession. Having in a previous number of THE NEWS made a few observations upon some of the financial aspects of a medical life, addressed more especially to those entering upon practice, we propose now, very briefly, to refer to a few points relating to professional reputation.

One thing must at this day be very obvious to the thoughtful physician, and that is, that a professional reputation cannot be so extensive as it has been in past years. The time has gone forever when a great ovariotomist, like Washington Atlee, could claim the continent as the abode of his *clientèle*, and still more remote is that when patients with stone would travel two thousand miles or more, to an interior town in Kentucky, to have lithotomy done by Dudley. The reason is, there are Atlees and Dudleys in almost every State in the Union, men who can do equally well the operations they did; and, so far as ovariotomy is concerned, with even a greater success. There is less concentration of reputation in a few individuals than there once was; there are so many competitors that the prize has been divided, and a larger number receive a share. This aspect of the question certainly is encouraging to the young physician, for the prizes now are many instead of few. How numerous the little worlds in the one great world! Some of these subdivisions are very small absolutely, but to those who dwell in them they are more than all other worlds. We read the *Smithville Weekly*, and the doings and happenings in that excellent village justly occupy a larger space than those of the greatest city upon the continent, or upon the globe; while, on the other hand, a newspaper of one of those cities may not have occasion to mention Smithville from the beginning to the end of the year, may, indeed, remain always ignorant of its existence. To be the chief surgeon, physician, or obstetrician in the latter, is something, but to occupy such position in the county is more, and in the State still more; there is a regular gradation in honor, and usually all the steps must be taken in order, none omitted, as the boy wins his first prize in the common school, then in the academy, finally in the college.

If one hopes for that larger fame which shall make his name honorably known throughout the country, and even in foreign lands, an object attained by so few, there is an aspect of the question which is not at all encouraging to the ambitious who seek laurels while they live. Many of the greatest medical reputations have been posthumous. Think of what honors are paid to the memories of Harvey, Jenner, and McDowell, and how little fame these men had during their lives. The truth conveyed in the familiar couplet as to the Greek poet has at least approximate illustrations in many medical histories:

"Seven wealthy towns contend for Homer dead,
Through which the living Homer begged his bread."

In the further consideration of the subject, we remark that the reputation sought by the young doctor is usually first among the people, and next with fellow practitioners. To secure the former, honest, wise and faithful work at sick beds is the only legitimate way. Sick people care but little about individuals or places of education, when they send for a physician, but they wish to be cured pleasantly, safely, and quickly, as the old Latin saw runs. Now he who cures thus is certain of numerous clients; he may have to wait for them, but they are coming as sure as fate. Let him beware of exciting any personal hostilities, or begetting any professional antagonisms, for success is a plant which thrives best, grows strongest and largest amid calm and sunshine, not in darkness and storms. Even if Z makes a correct diagnosis, after several or all of the preceding capitals of the alphabet have failed, and cures the patient, that is glory enough without depreciating the character of his professional associates; the time has been, when he himself made similar failure, and such time is coming again. Charity for the errors of others, and a consciousness of his own fallibility, furnish a condition of mind which every physician should have. The reputation built upon the ruins of that of another, has a very insecure foundation, and is liable at any time to fall.

So, too, the young physician should beware of criticising the practice and opinions of others. In the first place, has he all the facts and statements necessary to a just judgment? Then does he know the lessons of the personal experience of that individual out of which the opinions and practice have grown, or by which they have been modified? Finally, behind all these merely external things, there is the personality, the individual himself, and we can no more quarrel with that than we can with

the shape of his nose, his stature, or his weight. There is still another reason for abstinence from criticism by the young physician, and that is his own limited knowledge: possibly the opinions which he now holds as sacred truths next year may be divested of their sanctity and regarded as only probabilities, the next they will be possibilities, and a while after they are cast as rubbish to the wind. The *rôle* of critic is one of the highest in the profession, and belongs rather to the wisdom of old age, wisdom won by long years of careful study and patient observation, than to the hasty and imperfect generalizations and inexperience of youth; moreover, the older a physician is, the less disposed he is to criticise the work of others.

Participating in medical societies and contributing to medical publications is a legitimate means of acquiring reputation among doctors. Honest, truthful work of this sort is sure to be recognized, while falsehoods will sooner or later be known, and once a man is set down as a liar by his professional brethren, he can never acquire any desirable professional reputation. There are counterfeit notes and coins which so coarsely vary from the genuine, that their character is at once recognized, while others are so well executed that they must be subjected to an expert to ascertain whether they are true or false. It might astonish some who hasten to publish their marvellous successes in medicine, in surgery, or in obstetrics, asserting, it may be, an improbable, or even an impossible number of cases attended, or of operations performed, or results occurred, how quickly some hearers, or readers at once say, "That man is lying." In some instances, the liar for a time succeeds, but he is sure to come to grief finally; the medical shores are strewn with the wrecks of those who sailed under false colors, and while some may pity, none are so poor as to do reverence to these wrecks.

It is doubtful whether work done in societies or journals solely for the purpose of getting practice has received that condemnation it deserves. A man had better hold his tongue unless he can speak, or believes he can, for the instruction of others, and any bidding for practice is not reputable. A monograph upon a prevalent malady, proclaiming the author's experience with it, and his facility and success in treating it, mailed at his own expense to thousands of practitioners, is scarcely less an invitation for sending patients than that of the professor who throws his arms around the candidate for graduation, exclaiming, "My dear fellow, I am delighted with your examination. Send me all your consultations."

The young physician should beware of making the secular press his ally. The better class of the profession shrink from newspaper notices, and are naturally suspicious of the ability, or of the moral characters of those whose names are frequently found in connection with patients attended or operations performed by them; newspaper doctors are, as a rule, quack doctors. Our great cities are not without some who thus endeavor to herald their professional exploits, but they are not recognized as the gentlemen of the profession, nor do they deserve success; sometimes this yearning for publicity arises from an overweening vanity, whose possessor is never happy unless people are talking about him, or from a desire to impart new life to a dying fame, just as the woman whose charms of face the years have taken away endeavors by enamelling and coloring to hide the wrinkles of age and restore the beauty of youth.

But no matter where or by whom done the reputation thus gained is very liable to be shortlived. On the other hand, the reputation founded in the grateful hearts of those whom he has relieved by his skill, and comforted by his kindness, founded, too, upon honest and useful contributions to medicine, and upon just and courteous treatment of fellow practitioners, is that to which the young physician should aspire, for it is that alone which endures.

THE FUNCTIONS OF THE THYROID GLAND.

THE relations of the thyroid to myxœdema, and the induction of a cretinoid condition after the extirpation of goitres, have stimulated physiologists to study anew the functions of this gland. J. R. EWALD, of Strassburg, records some remarkable experiments in the *Berliner klin. Wochenschrift*, No. 11, 1887, which, without leading to any positive conclusions, indicate the direction which research may take. In the dog removal of one thyroid—the two halves are distinct—is not followed by any symptoms. After double extirpation remarkable phenomena occur in three or five days. As discovered by Schiff, there are curious periodic contractions of the muscles, sometimes general, over the body, but, according to Ewald, usually confined to two regions, the muscles of the shoulders and the temporals. The contractions induce a stony hardness of the muscles and follow each other with great rapidity.

Another curious symptom is the vermicular movement of the lingual muscles. The animals are apathetic, move slowly, and are with difficulty aroused. Schiff holds that the thyroid forms a material necessary for the nutrition of the central nervous system, and the following experiment of Ewald's indicates that the fresh gland contains an active principle capable of profoundly influencing the brain. If the expressed and filtered juice of the recently removed gland is injected subcutaneously in a dog, the animal, in about three hours, falls into

a curious hypnotic state, standing motionless, taking no notice of anything, and allows the limbs or head to remain in any position in which they are placed. After persisting for an hour and a half or two hours the condition passes away and the animal recovers. There is no fever. A number of control experiments were made with the juice of other parts of the body, but this remarkable pheromenon never occurred except when that of the thyroid was used.

Whether this material, whatever may be its nature, which influences so strongly the nerve centres, is elaborated in the gland or is only excreted by it from the blood cannot be definitely stated. On the latter view the changes in myxœdema and after thyroidectomy may be regarded as the result of a slow poisoning of the system by material which it is the function of the thyroid to remove or render inert.

DEATH IN LABOR FROM DYSPNŒIC URÆMIA.

THE so-called uræmic intoxication, as it occurs in a woman in pregnancy, during or after labor, may have different manifestations. CHARLES, in the *Journal d'Accouchements* of April 15th, narrates the case of a primigravida at the eighth month of twin pregnancy, who died from asphyxia. She had been anasarcous from about the middle of gestation, the anasarca being most marked in the lower limbs and the external genital organs, but there was no albumen in the urine. She was suddenly attacked with difficult respiration and great præcordial distress; meantime labor came on, though the pains were not severe, and the os dilated slowly. She gradually became cyanosed, but her intelligence was not impaired, and there were no convulsions; in a few hours she died undelivered.

Whether the explanation of death given in this case is correct or not, the history illustrates the dangerous consequences of what Stoltz and his pupils have described as the serous cachexia or hydremia of pregnancy, a condition which, though entirely neglected by some authors of works upon obstetrics, we believe demands a prompt recognition and as faithful treatment as does albuminuria in the pregnant woman.

THE ninth annual meeting of the American Climatological Society will be held at Baltimore, on Tuesday and Wednesday, May 31st and June 1st, and we understand that interesting papers have been promised by Drs. Loomis, Trudeau, Westbrook, Shattuck, Donaldson, Musser, Curtin, and Reed, all on phthisis in one or other of its phases. Drs. Rice and Peale will make reports on mineral springs, and Dr. Linn on some health resorts.

THE State Medical Society of Wisconsin will hold its forty-first annual session at Oshkosh, commencing on Tuesday, May 3d, at 8 P.M., under the presidency of Dr. S. C. Johnson, of Hudson.

AMERICAN NEUROLOGICAL ASSOCIATION. — The American Neurological Association holds its thirteenth annual meeting at Long Branch, N. J., on July 20th, 21st, and 22d.

THE annual commencement of the University of Pennsylvania was held last Monday, and the degree of M.D. conferred on ninety-nine graduates. THE MEDICAL NEWS prize of $100 for the best graduation thesis was by the award of the Medical Faculty divided between Arthur C. Hugenschmidt, of Paris, France, and Peter J. J. Martin, of Pennsylvania.

At the annual meeting of the Alumni, held in the afternoon, Dr. Alfred Stillé was re-elected President.

REVIEWS.

A MANUAL OF OBSTETRICS. By A. F. A. KING, A.M., M.D., Professor of Obstetrics and Diseases of Women and Children in the Medical Department of the Columbian University, Washington, D. C., etc. Third edition. 12mo. pp. 379. Philadelphia: Lea Brothers & Co., 1886.

Since this little book first appeared, it has been gradually growing in size, and increasing in the number of its illustrations; presenting now forty more pages and forty-three more woodcuts than in the second edition of 1884. The volume is more attractive in appearance, and embraces a larger range of subjects, which are, of course, treated in very few words. Its popularity is evinced by the fact that a third edition has so soon been called for. Manuals should never take the place of more comprehensive treatises, but may serve a good purpose as ready remembrancers to busy country practitioners, and are often much better for their use than many of their antiquated works, which are apt to be behind the age.

The author has fallen into some of the errors of Playfair, viz., "hydatiform pregnancy," instead of hydatidiform, or like a hydatid. "Spondylolithetic pelvis," for spondylolisthetic, or a slipping of the vertebra. Both of these were corrected in the last American edition, and the Greek derivation of the latter given in a footnote. By a recent English review, we notice that Dr. Playfair has renewed the latter error in his last edition, and been taken to task for it.

Under the "Cæsarean section," nothing is said of the new method of Sänger, in its present simplified form, for closing the uterine wound; or of the largely diminished fatality under it. No spray is used in this operation, and no drainage tube is required, as there should be no leakage. The average time required is one and a quarter hours, and from twenty to thirty-seven sutures have been used by different operators. Dr. Lusk, in his recent successful case, inserted thirty-four. We must differ with Dr. King, when he says that the relative merit and danger of the Porro operation, when compared with the Cæsarean section, is "so unsettled as not to admit of either statement or discussion in his work."

With fifty-two operations and thirty-seven recoveries under the improved Cæsarean method, a fair comparison may be made.

What is called Simpson's method of treating placenta prævia, was used by Dr. Ruschenberger, of Philadelphia, fourteen years before the Edinburgh professor recommended it; the lady saved being the wife of a Peruvian army officer. We are glad to see the advanced views of the author in reference to the employment of laparotomy after uterine rupture; in our judgment the abdomen should be opened and cleansed, and the uterine rent sutured in all cases of laceration where the state of the woman will admit of it, even if she has been delivered *per vias naturales:* and we believe that the present advances in abdominal surgery will bear us out in this opinion. To deliver the fœtus is to leave the work only half done, if we expect to save the woman.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, April 27, 1887.

H. Augustus Wilson, M.D., in the Chair.

Dr. Charles H. Burnett read a paper on

EAR-TRUMPETS.

There are three reasons, he said, why the deaf should use ear-trumpets:

1. In order to aid the hearing. 2. To improve the hearing. 3. For the convenience and comfort of those conversing with the very deaf.

1. When a person becomes very deaf in both ears, some resort to an artificial aid of hearing must be made. So long as one ear remains fairly good, patients will not use an ear-trumpet for the deaf ear. But when ordinary tones near the ears are heard either very imperfectly, or not at all, the sufferer gladly resorts to some form of ear-trumpet. Most of these are unpleasant and imperfect aids, from their disagreeable resonance, and poor conducting powers. They also bruise the meatus, in most cases being made with an ear-piece which fits into the mouth of the auditory canal. These discomforts and imperfections, in the average ear-trumpet of all forms heretofore invented, added to the natural indisposition to employ an ear-trumpet because of its conspicuousness, have in most cases led to an early abandonment, or a partial use at least, of such an instrument.

The cause of ordinary deafness is, in most cases, a catarrhal thickening of the mucous membrane over the ossicles and the inner surface of the membrana tympani, leading to more or less ankylosis in these parts. Passive motion overcomes in them, to a greater or less extent, the immobility induced by this sclerotic process, as it does elsewhere in the osseous and muscular system. The form of passive motion which acts most naturally on the ossicula auditus and their joints, is sound. If, therefore, sound-waves are concentrated in more than usual quantity or vigor upon the stiffened membrana and the ossicles, as by means of an ear-trumpet, hearing is induced, if the auditory nerve is unimpaired. If the latter is impaired, no form of ear-trumpet will be of use.

2. Not only does such a form of passive motion give immediate relief to the deafness in most cases, but such a form of passive motion, acting frequently and systematically upon the ear, prevents further ankylosis in the conductors, and fatty degeneration of the auditory nerve from desuetude. This, of course, tends to a permanent improvement of the hearing, and, in some instances, patients come to hear at last without a trumpet. If such a force were brought to bear early in cases of deafness from ankylosis in the ossicula, the defects in hearing could, in most cases, be arrested, and, to some extent, removed. This form of aid to hearing has its happiest results in very deaf children, in whom the loss of hearing often entails loss of speech, if they have already learned it. If they have not learned to talk, and their deafness depends on catarrhal disease in the middle ear, and not on a lesion of the acoustic nerve, the use of a good ear-trumpet will rescue them from entire deaf-dumbness.

3. The convenience and comfort of those who communicate with the deaf by means of a trumpet are not the prime, though important considerations. For, if this mode of conversation is rendered difficult by reason of the imperfect ear-trumpet at command, it will not be readily or willingly employed, and, in the case of children, therefore, not enough will be said to them to improve their hearing or to teach them speech.

The most useful ear-trumpets yet presented to his notice are those of Mr. Maloney, who exhibits them here to-night. They are not only useful as conductors of sound, succeeding where other forms fail, but they do not fit into the meatus. They are held to the ear, the aural end of the instrument being supplied with a disk, and not a tip for the meatus. This does away with bruising the canal, or exciting furuncles in it, so common in the employment of the forms heretofore in use. They have been devised in a scientific manner, and introduced to the profession on their own merit. The best results, or the most signal ones, have been obtained by the so-called silent instrument. This is simply because it is the most powerful, and hence renders most aid to the very deaf, the only people who are really willing to use any instrument. The smaller instruments are just as good for those not very deaf, and, if used by such patients, would aid in the retention of hearing, and tend to cure their hardness of hearing, as he has shown. But the less afflicted class seem unwilling to use any form of ear-trumpet. All ear-trumpets of any value must possess some size in order to contain a column of air sufficient to impress the drum. They must be larger than the auricle with which the patient is already supplied. Hence, all invisible appliances, so-called, are self-evidently good for nothing.

Mr. J. A. Maloney, of Washington, said that he commenced his labors in "Aural Mechanics," with a mode of procedure as follows:

1st. To develop instruments as far as he could to meet the various phases of defective audition.

2d. To construct the instruments to give satisfactory results without entering the auditory canal.

3d. To use artificial drums or membranes to guard against impact of air upon the "membrana tympani," and prevent reverberation, so common in all the old forms of instruments. He decided that a scientific instrument should possess these three essential qualities: it should be large enough to be of practical value; it

should augment sounds: but with such augmentation the "timbre" or quality of sound should be preserved.

We are all aware that the membrana tympani, unlike other stretched membranes, responds to all vibratory motions within a certain limit, whether they are in the form of noise or of composite tones, transmitting through the intermediate agencies of the middle and inner ear, to the nerve of hearing auditory sensations. Could a stretched membrane be arranged, so closely imitating in function the one given to man, as to show how beautiful are the harmonies of nature?

After experimenting twelve months, he adopted the form of membrane which he presented. The reason for its adoption came about in this way: In the early stage of his experiments he invariably found a lack of clearness of tone, until one day the thought occurred to him that he could secure uniformity of tension by clamping the membrane between two rings. When this was done, he found it a great improvement over all other methods, and consequently adopted it after thorough tests. Even after obtaining good results, he could not but feel that there must be some other result produced by the rings than that of maintaining a uniform tension of the membrane. He found that while the membrane was upon the stretcher-frame, with the rings glued upon each side of it, like any other membrane, it would be thrown into sympathetic vibrations by tones corresponding to its fundamental; *but that when cut from the frame*, and dependent for its tension upon the two rings alone, it would not respond to a tone corresponding to its fundamental. Now it has been thought that the last named feature exhibited by the membrana tympani was produced by its union with the auditory ossicles. But may it not be due to two facts? 1st. That the margin is thickened. 2d. That the middle layer, or "substantia propria," is fixed to a ring of bone.

His membrane describes a central vertical line between the two rings acting as clamps, and the rings themselves represent the ring of bone to which the middle layer, or "substantia propria," of the membrana tympani is attached. In the construction of the instrument, the fact must be borne in mind that it must be arranged to suit and compensate for the defect of hearing. 1st. Arrange for high tones, if the defect is in that direction; or for low tones, if the defect is in that direction. 2d. The augmentation and clearness must be to the extent that the person will hear every word spoken, instead of a word here and there, as heretofore, which involves a severe mental strain to construct the incomplete sentences.

DR. S. S. COHEN said he had the pleasure of seeing, some time ago, a demonstration of these instruments in the case of some patients of Dr. J. Solis Cohen, and they acted very satisfactorily. A letter was received some time ago from Dr. Lacharrière, of Paris, the eminent physician in charge of the National Institution for Deaf-Mutes, inquiring as to the truth of reports that in certain institutions in this country, especially in New York, ear-trumpets were being used in the instruction of so-called deaf-mutes and that it had been found that a gratifying proportion of children thought to be totally deaf, reacquired in this way a certain degree of hearing power. After some correspondence he learned that Mr. Currier, Professor of Articulation in the Deaf-Mute Institution at Washington Heights, New York, had used an instrument different in construction from that of Mr. Maloney, with good results. He published accounts of them in the *Annals of the Deaf and Dumb* for January and for October, 1885. He reports a number of cases that have acquired the power to carry on conversation. Mr. Currier uses what is termed the "conical conversation tube," attaching two mouthpieces and tubes to a single earpiece, in order that the patient may hear his own voice as well as that of the instructor. His system of instruction to reawaken so-called "latent hearing" is ingenious, and, from his reported cases, apparently quite successful. If Mr. Maloney's earpiece was attached to Mr. Currier's double tube, it might be found still better.

DR. C. WIRGMANN asked if there were any liability for the rubber disk to get out of order?

MR. MALONEY said, with reference to the durability of the rubber, that it has a protective coating. During the past nine months he has exposed them to varying changes of temperature without any apparent effect. If the membrane should get out of order it can easily be replaced. He had never had his attention called to the instrument of Mr. Currier until the matter was mentioned by Dr. Cohen this evening. He finds that his instrument is open at both ends. In speaking of what he terms No. 3, or "silent," instrument he neglected to state that it is closed at the end nearest the ear. The object of this is to prevent the impact of the air on the drum of the ear. Such impact has a tendency to destroy the clearness of the tone. With his instrument the only impact on the "membrana tympani" is that of the column of air in the auditory canal between the membrane of the instrument and the drum of the ear, thereby developing *true auditory sensations*, which cannot be produced by instruments open at both ends.

While he has done something in the way of testing those supposed to be entirely deaf, he was not prepared, without his notes, to speak on this subject, because he has not yet finished the line of tests marked out. He could say, however, that he has made tests in two cases supposed to be totally deaf and dumb. One was a man, forty-two years of age, and deaf from childhood. He made him hear on both sides, *noise only*, for the percipient functions had never (as in such cases) been trained or educated. The other was a boy, eleven years of age, supposed to hear very slightly on one side only. Upon making tests he found he could hear on both sides, *noise only*, for the same reason as mentioned in the foregoing case. When he completes the line of tests marked out he shall be glad to present the results to the Society.

DR. C. H. BURNETT said that the question of so-called latent hearing in deaf-mutes is, of course, very important. In one sense, there is no such thing as latent hearing. Without doubt, many deaf children lose the power of talking if they have previously acquired it, or fail to learn to speak on account of their inability to hear. In the case of a graduate of two deaf-mute colleges, the man's wife discovered that he could hear to a certain extent, and by systematically talking to him, he acquired the power of hearing an ordinary tone of voice while in an adjoining room. This case was reported to him by Mr. A. Graham Bell, of Washington. In most cases, deafness is due to ankylosis, and the use of an ear-trumpet is simply another application of the movement cure.

He has himself seen a child a little over two years of age, just learning to talk, lose its hearing to a marked degree. By persistent teaching on the part of the mother the hearing was much improved, and the child was rescued from a condition of deaf-dumbness. The child is now twelve or thirteen years old, and while the hearing is not perfect, she is far from being a deaf-mute. Many deaf-mutes can hear something. It is very onerous for even a parent to exercise the hearing by the unaided voice, but with an instrument, like those of Mr. Maloney's, the parent may be induced to undertake the task.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, April 18, 1887.

THE PRESIDENT, JOHN SHRADY, M.D., IN THE CHAIR.

CARCINOMA OF THE PANCREAS.

DR. THOMAS C. TAYLOR reported a case of carcinoma of the pancreas, with infiltration of the omentum and walls of the stomach, along the greater curvature, occurring in a female thirty years of age. The case, he said, he presented for the reason of the infrequency of the affection, and the obscurity as regards its diagnosis. Perhaps, however, such cases were not as infrequent as was generally supposed, since many patients died with symptoms similar to those met with in the present instance, which were attributed to some other disease; whereas, had autopsies been made, the primary cause of death might have been found in the pancreas.

In the case in question, he said, there were absent three important and common symptoms, generally regarded as diagnostic of cancer of the pancreas, viz., jaundice, œdema, and fat in the alvine discharges. According to Dr. Norman Moore, in the *St. Bartholomew's Hospital Reports*, jaundice was always found where the pancreas was the primary seat of a new growth. In ten cases coming under his observation, in which post-mortem examinations were made, jaundice was found in all. Sir Charles Murchison also referred to persistent jaundice as a common symptom of the disease; but Dr. Louis Starr had shown that it was of clinical importance to note that the ductus choledochus does not always pass through the head of the pancreas, but sometimes merely passes over it. When this was the case any enlargement of the pancreas would simply push it aside without giving rise to any jaundice. According to Nyss, this happened fifteen in twenty-two times.

Œdema occurred, according to the majority of authorities, in more than half the cases of cancer of the pancreas recorded; while fat in the alvine discharges was said to be found in nearly all the cases. The same condition, however, might occur, according to Reynolds, when the duodenum, and not the pancreas, was diseased. Dr. Taylor said that he had been unable to find any authority who gave even one pathognomonic sign, and, therefore, he thought that Da Costa's manner of diagnosticating these cases was the most feasible, that by exclusion. As to the invasion of the stomach in the present instance, according to Pepper, this disease rarely extended to the stomach, but rather affected the neighboring lymphatic glands, the duodenum, and the liver. In regard to the possibility of prolonging, by operative procedure, the life of a patient suffering from cancer of the pancreas, provided the diagnosis could be made out sufficiently early, he thought that the two cases reported by Billroth were of much interest, where he had made a partial resection of the organ, removing the tail in one and a portion of the head in the other, but, of course, not injuring the duct. Both patients recovered from the immediate effects of the operation, but how long they lived or whether the disease returned, he did not state. Dr. Taylor thought that when he first saw his case, but a very small portion of the head was involved, and that if the diagnosis could then have been established, it would have been an excellent opportunity to perform an operation similar to that of Billroth.

DR. WM. T. LUSK read from notes the report of a

SUCCESSFUL CASE OF CÆSAREAN SECTION.

Bridget C., aged twenty-four, Irish, domestic. She was sent, March 21, 1887, to Bellevue Hospital, on account of deformity of the pelvis resulting from hip disease. The latter dated from the time when she was eleven years old, and on account of it she was sent to the hospital at Dublin, at that time, for treatment. She was discharged cured; but during her pregnancy she noticed some suppurative discharge from the old sinuses which had formed at that period.

On March 22d, on examination, much to his surprise, he discovered that she was already in the early stage of labor. The pelvis was of the Naegele oblique type, and its measurements were as follows:

Distance between the anterior spines, 21½ centimetres. Distance between the cristæ ilei, 24 cent. External conjugate, 16 cent. Distance between anterior and posterior spines, right side, 14½ cent. Distance between anterior and posterior spines, left side, 16 cent. Diagonal conjugate, 9 cent. Internal conjugate (estimated), 7.5 cent. Distance between ischia, 6.5 cent.

The shortening of the right leg (measured from the trochanter to the malleolus) amounted to 4 centimetres. On the right side the iliac bone ran in a nearly straight line, and on the left the curve was greatly diminished.

With the sanction of Drs. Isaac E. Taylor and H. J. Garrigues, who saw the case in consultation, he determined to perform Sänger's operation. Craniotomy is generally considered comparatively simple; but with the dimensions that were found in this case he had no doubt that the dangers from it would be greater than that of Cæsarean section, provided the latter was performed sufficiently early. Dr. Taylor was of the opinion that the case was nearly identical with one in which Dr. Lee performed craniotomy and where the patient died. Dr. Lusk also referred to a similar case in the practice of Dr. Studley, where the pelvis was fractured in the effort to deliver the child.

As the patient was already in labor, he determined to operate at once. Both the private pavilions of the hospital were occupied, and he was accordingly obliged to perform the operation in one of the wards. The examination was made about noon, and at 3.30 P.M. the operation was commenced. The abdominal incision was made through the linea alba, and extended from three inches above the umbilicus to a point two or three fingers' breadth above the symphysis pubis. The peritoneum having been slit up, the left cornu of the uterus came up into the wound, and the organ was everted by press-

ure with the hands over the abdominal walls. When the uterus had thus been turned out, the intestines were placed beneath the abdominal walls and retained by a flat sponge, and the uterus was wrapped in warm towels; a solution of bichloride of mercury, 1 : 10,000, being used. A rubber tube was then placed around the lower segment of the uterus in order to prevent hemorrhage. In opening the uterus an incision two inches long was made near the lower segment, and with the scissors the opening was afterward increased to five inches. Owing to the pressure upon the vessels secured by the elastic ligature, the incision was nearly bloodless. It was followed by a hernial protrusion of the membranes through the opening.

The child was found with the head presenting in the left occipito-anterior position, and on being extracted was in a cyanosed condition. Through the well-directed efforts of Dr. A. B. Ball, however, it was resuscitated. With the finger the membranes and placenta were readily separated; the delicate cobweb-like processes connecting the decidua with the residual portion of the mucous membrane remaining adherent to the uterus, described by Leopold, were at this time beautifully exhibited. The uterus remained of a pale, waxy color, on account of the constriction of the elastic ligature.

In closing the uterine wound thirty-four carbolized silk sutures were employed, of which sixteen were deep and the rest superficial. In the deep sutures, he said, special pains should always be taken to avoid the mucous membrane of the uterus. The Lembert suture was used in making the superficial sutures. When the rubber tube was removed from the uterus the blood slowly returned to the pallid organ. At first it assumed a delicate rosy hue, and finally a deep purple color. A very slight oozing was observed at one point. The uterus was then returned to the abdominal cavity, and a drainage tube inserted behind the organ. It was impossible, however, to pass the tube into Douglas's cul-de-sac, owing to the pelvic contraction. Silver wire sutures were employed to close the abdominal wound. At the end of the operation the patient was in excellent condition. The operation lasted altogether one hour and fifteen minutes, and twenty minutes of this time were taken up in the effort to stop the oozing referred to.

For two days after the operation the temperature did not go as high as 100°. Then there was a little tympanites, and it went up to 101½°; but a Seidlitz powder had the effect of promptly reducing it again. The highest temperature was reached on the fifth day (102¾°), but fell, however, to 100½° after a spontaneous evacuation of the bowels. On the sixth day the drainage tube was removed. Immediately after the operation the discharge from it was stained with blood, but it soon became colorless. Dr. Lusk said that the tube was not probably needed in this case; but at the same time there was a certain feeling of security in knowing that it was in position. On the day following the removal of the drainage tube there was some oozing from the opening left by it. At the end of a week the abdominal sutures were removed. At this time the temperature would usually go up to about 100½° in the evening, and then fall again by morning.

On the ninth day some fluctuation was detected in the line of the abdominal wound, and a little pus was evacuated; after which the temperature became nearly normal. At the end of two weeks, however, the temperature went up to 101.6°. Still, no trouble whatever could be discovered about the abdomen, and as the patient complained of pain in the right hip, an examination was made which showed an accumulation of pus in the site of the old sinuses which had given the trouble during the patient's pregnancy. Accordingly a knife was inserted, and about a pint of pus evacuated. Since that time the woman had been in most excellent condition. Ever since the second day, by which time she had recovered from the effects of the ether given for the operation, she had been able to take abundant nourishment. She passed her water freely, was comfortable in every way, and on the whole seemed to think it rather an easy way of having a baby. The baby now weighed nine pounds, and was also doing finely.

Dr. Silva, lately house-surgeon in Bellevue Hospital, who had had charge of the case, stated that the patient did better than any other case of laparotomy that he had the opportunity of observing during his service at the hospital.

Dr. Thomas Kearney inquired whether it would not have been better in such a case as this to perform Porro's or Tait's operation, in order to prevent the woman's becoming pregnant again.

Dr. Lusk replied that Harris's statistics showed that with the Sänger operation (modified more or less from the original procedure proposed by Sänger) there were over 70 per cent. of recoveries, while in Porro's operation the recoveries were only 40 per cent. It was, therefore, unquestionably a more dangerous operation. In regard to Tait's operation, it seemed to him that the additional risk to which the removal of the ovaries subjected the patient rendered it inadvisable, the extremely vascular condition of the parts constituting a serious objection. At all events he should not like to attempt this, in addition to the Cæsarean section, unless he had time to consider the matter very carefully beforehand, and in the present instance the operation was undertaken in a very hurried manner, as he had no idea that he would find labor actively commencing at the time he made his first examination of the patient.

Dr. J. R. MacGregor said that he had been with Dr. Studley at the time that the fracture of the pelvis referred to by Dr. Lusk occurred. The patient had ankylosis of the right hip, with a projection inward of the ramus of the pubes on that side; but it was thought that she could be delivered *per vias naturales*, with the aid of artificial assistance, until the accident occurred. The patient died, though not immediately.

Dr. Silva said that in *The American Journal of the Medical Sciences* for 1879, N.S., lxxvii. 43–65, Dr. Robert P. Harris, of Philadelphia, had published statistics of one hundred cases of Cæsarean section, and out of nineteen of the cases, occurring in dwarfs, only one mother and five children were saved. In all of these cases the operation was only undertaken as a last resort, when the patient was utterly exhausted, and the results certainly afforded ample proof of the importance and desirability of early surgical interference.

Dr. C. S. Wood said that in the course of his experience he had performed three craniotomies, and this class of cases was without doubt as disagreeable and

repulsive as one could possibly meet with. If, therefore, by this operation it was possible to save more mothers than by craniotomy, it would be a great boon. Thus far, however, the statistics unfortunately showed that it saved a far smaller proportion of mothers. In two of the cases of craniotomy that he had met with the mothers recovered, while in the third the mother was lost. Yet in one of the successful cases he labored under great disadvantages, as, not expecting to be called on to perform craniotomy, he had no instruments for the operation, and was so situated that none could be obtained at such short notice. Under these circumstances he resorted to the device of manufacturing such rough instruments as he was able from some shoemaker's tools, and he thought the case was interesting as showing what might be accomplished by very simple means sometimes in an emergency.

There seems, he said, at present to be gaining ground a sentimental notion that it is of the greatest importance to save the child, but he was one of those who believed that the mother should always be saved at all hazards, whether the child was sacrificed or not; and as long as it could be shown that more mothers' lives were lost by the Cæsarean section than by craniotomy, he thought the latter should be preferred.

DR. KEARNEY said that he could not agree with the views expressed by the last speaker. Dr. Bedford, he thought, had given the most rational statistics, and if, as was undoubtedly the case, it could be shown that in the aggregate more lives (of mothers and children taken together) could be saved by Cæsarean section, it should without doubt have the preference over craniotomy. The matter was not merely one of sentiment, it was more than that, and involved a question of deep ethics. By simple logic alone the justice of the Cæsarean operation could be established, and he had never yet seen the objections against craniotomy adequately answered by any author with which he was conversant.

DR. LUSK said that if in speaking of Cæsarean section reference was made to the old operation, as it had usually been performed, unskilfully or carelessly, and when the patient was already in a dying condition, the mortality was without doubt very heavy. It was a fact that in most of the cases it was resorted to only when the woman was moribund, when all other methods of delivery, craniotomy included, had been exhausted. When it was remembered also that a rude and careless way of operating had also been the rule, it was no wonder that the patients died, and that statistics based on such cases bore heavily against the value of the procedure. But even under all these disadvantageous circumstances, a few cases had recovered.

At the present time it is getting to be understood that the operation should be performed, whenever this is possible, under more favorable conditions and in the same careful way as other surgical procedures involving the abdominal cavity. The operator should take sufficient time to make out the pelvic diameters and consider fully the risks that would be encountered in performing craniotomy. If, having done this, he decides that the Cæsarean section offers the best chance of success, he should make his preparations as deliberately as the circumstances of the case will allow, and perform the operation by methods in accordance in every particular with the precepts of modern antiseptic surgery. When this course was pursued, the results were infinitely more satisfactory than those met with in the old operation, as was shown very clearly by the cases of Leopold, for instance, who, if he remembered rightly, had operated ten times with only one death. Even the case that he had lost Leopold thought that he would now have been able to save, in the light of his later experience. Very few obstetric surgeons, Dr. Lusk thought, could show a result of 90 per cent. of recoveries in their cases of craniotomy. Within the last eighteen months Harris had collected 52 cases of Cæsarean section, with 71 per cent. of recoveries; while the best results of craniotomy in these difficult cases showed only 60 per cent. of recoveries. Still, he was quite aware that too implicit reliance was not to be placed in statistics.

Other operators besides Leopold had reported a number of successive cases without a death. One great reason for the gratifying success of the modern operation, Dr. Lusk believed to be the use of the rubber ligature, which so effectually prevents hemorrhage from the severed uterine structures. When this is employed the surgeon can go to work very deliberately, and bring the edges of the wound together with the greatest acccuracy. In his own case there was absolutely no symptom during the lying-in period which was referable to the uterine wound. In conclusion, he would only say that if we were to wait until the woman was dying, instead of interfering early, as in this instance, we should only have the old statistics repeated.

In reply to an inquiry as to what he thought of the operation of laparo-elytrotomy in these cases, he said that this procedure is particularly adapted to a special class of cases, viz., when the head is arrested at the brim of the pelvis and the cervix is already dilated, or in a dilatable condition. If, however, after laparo-elytrotomy we were obliged to extract the child through an undilated cervix, it became a very serious operation. In case, therefore, we desired to operate early, we had to do it at a time when the conditions favorable for laparo-elytrotomy did not exist. Of the twelve cases of this operation which had been reported, six had resulted in recovery and six had proved fatal; the latter being cases in which success was impossible from the conditions existing at the time.

AMPUTATION OF THE PENIS FOR EPITHELIOMA OF THE GLANS AND PREPUCE.

DR. J. R. MAC GREGOR presented a portion of a penis which he had amputated about six weeks before for epithelioma of the glans and prepuce. This variety of cancer, he said, is very interesting, not only as regards the result to the patient, but also from its special pathological features. In this case there was a great deal of thickening, and there was marked increase of the connective tissue of the part. At the time of the operation much care had been taken to prevent any subsequent constriction of the urethra at the end of the stump, and thus far the result had been altogether satisfactory. The chances were also fair, he thought, that there would not be a reproduction of the growth.

DR. GOULEY said that it was an interesting fact that in epitheliomatous growths of the glans or prepuce there was always antecedent balanitis or balano-prostatitis,

and the greater proportion of cases occurred in individuals who were the subjects of chronic balanitis. This condition was, for the most part, due to the lack of cleanliness on the part of the patient, allowing of the accumulation of smegma behind the glans, and at first there was simply an alteration in the normal epithelium. Later this went on to be developed into this peculiar form of carcinoma, and the proliferation was rapid enough not only to involve the mucous membrane, but to extend to the cavernous bodies of the penis.

So far as his experience goes to show, the amputation operation usually resorted to in this class of cases is insufficient, and is apt to be followed by a recurrence of the disease more or less rapid; this new development always occurring at the end of the stump. It also is sometimes met with in the lymphatic glands. Atresia of the extremity of the urethra is apt to be a very unpleasant consequence of the amputation of the penis, and Dr. Gouley related a case which first came under his notice when he was a hospital interne, in which, although there was no return of the epithelioma whatever, the patient died of pyelo-nephritis resulting from this atresia following the ordinary amputation operation; the fatal issue occurring within two years after amputation. About 1860, having occasion to amputate a penis for epithelioma, he first used the écraseur to break up the cavernous bodies. Then, leaving the urethra fully three-quarters of an inch longer than the stump, he fastened the urethra to the free extremities of the cavernous bodies. By this and other devices, therefore, it is not difficult to avoid the atresia referred to.

In consequence of the frequency with which the epitheliomatous growth recurred, however, he finally made up his mind that in the next case that he had he would excise the whole penis, and, accordingly, in April, 1878, resorted to this procedure in a patient fifty years of age. He dissected out the entire penis, without opening the cavernous bodies; removing the crura and all. In this instance about one-half of the cavernous bodies had been involved in the disease. The patient was discharged cured on the 11th of June following; but he was unable to say what was the subsequent history of the case. Having exhibited this penis preserved in alcohol, Dr. Gouley went on to say that it seemed to him that a radical operation of this kind gave the patient the best chance of avoiding a recurrence of the disease; for if the slightest cancerous deposit were allowed to remain, the growth was sure to go on developing again. He believed, therefore, that in the majority of cases it is not only justifiable, but the most proper measure to adopt. It seems like a formidable operation, but in reality it is not, and in the case in which he performed it the patient made a rapid recovery after it.

DR. JOSEPH D. BRYANT said that he had had some experience with amputation of the penis, and he recalled three cases of it in particular very distinctly. In two of them the operation was performed for cancerous disease involving the glans and anterior portion of the penis, and in the third for general carcinoma, involving not only the penis, but the whole system. The latter, as a case of remarkable interest, he related in detail. At the autopsy it was found that there was scarcely an organ in the body which had not been invaded by the cancerous disease. The kidneys were probably the starting-point of its development, and even the spinal cord was among the structures involved. One of the other cases referred to was a young man of twenty-five, who attributed the origin of his trouble to a woman with whom he had had intercourse, whom he believed to be affected with the same disease.

In these cases he had performed the amputation just in front of the scrotum; cutting the spongy body three-quarters of an inch longer than the corpora cavernosa, and attaching the integument to its extremity. He said that he was fully of the belief that the entire removal of the organ was the only ultimately safe procedure. He could understand, however, that if the growth was very slight, it might be allowable to consult the patient's wishes on the subject, and if he objected, make the amputation pre-scrotal.

CORRESPONDENCE.

IS THE TREATMENT OF CONSUMPTION BY MEANS OF SULPHURETTED HYDROGEN AND CARBONIC ACID GAS A NEW IDEA?

To the Editor of THE MEDICAL NEWS,

SIR: Prior to the beginning of the nineteenth century a Dr. Saiffert, of Paris, introduced a treatment in that city, or at least used it, which attracted a great deal of attention, and for the time being gave him considerable notoriety. It consisted in placing the consumptive patient in a cow-stable in close proximity to several cows, and in such a position as to expose him thoroughly to the vapors arising from the manure. In fact, the bed was so arranged that the liquid manure might stagnate underneath it. In this way he cured cases of consumption that had progressed to the last stages. He was much criticised by the profession and scoffed at by the people, but nevertheless continued his plan of treatment with some success.

In 1799 Dr. Thomas Beddoes, an English physician of some fame and a somewhat noted author in his day, introduced the plan of treatment into England and Ireland. He recorded some successes, and in 1803 published a book in which he gave details and set forth his idea of the *modus operandi*.

On page 40, in a foot-note, he says: "Alkaline vapors, sulphuretted hydrogen gas, and carbonic acid gas were very conspicuous in their effects. The nature and proportion of these gases require further examination."

On page 51 he says: "The principle on which I conceive the cow-house vapors to have acted is well understood in the treatment of ulcers; certain applications disposing them to heal. And what way is there, upon which we can depend, of making applications to pulmonary ulcers, but that which gases and vapors offer us?"

The plan of treatment apparently became somewhat popular in France, England, and Ireland, and even crossed over to America. Even at this day an idea exists among the people that sleeping in a cow-house will cure consumption. A few years ago, when I was myself suffering from a lung trouble, I was several times advised by laity to avail myself of this plan of treatment.

NEWS ITEMS.

A Physician as Speaker of the Ontario Legislature.—We are pleased to learn that Dr. Baxter has been elected to the office of Speaker of the Ontario Legislature. This mark of distinction will be gratifying to the profession at large, for while it has always a good representation in Parliament, the places of honor have mostly fallen to the law.—*Canada Lancet*, April, 1887.

Changes in the Faculty of Vienna and the Rules for the Admission of Foreign Students.—Professor Max Gruber, of Graz, has been appointed Extraordinary Professor of Hygiene. It has been decided that the vacation courses are only to be open to foreign medical men in cases where the full number of the classes is not made up by Austrians. This may prove rather a serious matter for some of the English and Americans who frequent the Vienna Hospital for the short courses, for which it is famous.

The Successor of Professor Schröder.—Privy Councillor Olshausen, of Halle, has accepted the invitation to fill the late Professor Schröder's chair of Midwifery, and will commence his lectures on May 1st.

Antithermin is the latest introduced antipyretic agent. It is allied in its chemistry to antipyrin; phenylhydrazinlevulinic acid is the chemical name.

The Virginia State Board of Medical Examiners.—The *Virginia Medical Monthly* for April, 1887, states that the object of this Virginia Board is to test candidates for practice in Virginia only upon their merits as brought out by examinations. No college professor is on the Board. The Board stands as a higher court than the college faculties; it has to pass upon the work done by the colleges. Fortunately for Virginia, the Board is composed of men well qualified for the discharge of this duty. The standard of graduation claimed by most of the reputable colleges of the country is seventy-five per cent. The Virginia Board of Medical Examiners adopts the same standard, and tests applicants solely by this standard. The Board is composed of men who possess sympathies, and who are as liberal in their markings as they should be. Without partiality to any, they are generous to all—always giving candidates the benefit of doubtfully correct replies, and even stretching their ratings as far as any proper idea of justice will allow. Not the slightest individual preference or partiality can be shown, because the examiners do not know who the candidates are. Each candidate as he enters upon the examination is given a number, but his name is known only to the Secretary of the Board. The candidate returns his examination papers only by the number assigned him, and the respective examining committees examine the papers of No. so and so, and not of Dr. so and so. Catch questions are avoided, or, if asked, are not rated; and not one who has yet presented himself for examination, so far as we have ever heard, has suggested the charge of unfairness. Some who failed in their examinations have said that some of the questions are too hard. But we publish the questions regularly, year by year, and we have not yet heard of a college professor or a practitioner of education who has said otherwise than that the candidates should be expected to answer them. And yet, in view of all this, we have just had 12 candidates rejected out of a class of 19 applicants, each one of whom is fresh from college with his diploma, and some, we learn, are *honor graduates.*'

Formidable Examinations.—The preliminary examination customary in this country, is quite a different affair in Lyons, France. The medical faculty of that city, feeling that it did not receive its due in the shape of students, began to inquire into the reason therefor. It arrived at the conclusion that it was the severity of the preliminary examination which deterred students from entering there, and, to judge from a few figures, we do not wonder at their reluctance. In 1882, 33 candidates were rejected out of 41; in 1883, 15 out of 20; in 1884, the same; in 1885, 11 out of 15; in 1886 all the candidates who presented themselves were "plucked." The faculty now proposes to petition the government to abolish the examination altogether.

The Disposal of Garbage.—The best methods for the disposal of garbage must necessarily differ according to circumstances. For some communities its utilization in the feeding of swine is a practical solution of the problem; while for others no better way seems to have been devised than to deposit it at sea, so far from land as to preclude the possibility of its return by wind or tide. Still another plan is that of its destruction by fire or cremation—a plan which theoretically is perhaps the most satisfactory from a sanitary standpoint, but one in regard to which practically there seem to be so many difficulties as thus far to have prevented its adoption in the largest cities of the United States. This problem is now being discussed at Milwaukee, Wis. One proposition is to take the garbage to the country and then to feed it to animals, another is to deposit in the waters of the lake, and a third to consume it by fire. A company proposes to erect two cremators, at an expense of $10,000, for this purpose, claiming that the running expenses will not exceed $15.50 per diem.—*Science*, April 1, 1887.

Decreasing Birth-rate of Ireland.—*The Sanitary News* of March 26, 1887, writes as follows on this subject:

The marriage-rate in Ireland is the lowest of any country in the world which keeps a record of its vital statistics, and it is constantly growing lower and lower because of the emigration of men and women in the prime of life. In that unhappy country, the excess of births over deaths is but 6.4 compared with 13.9 in Scotland, and 14.3 in England and Wales. The Irish are not the people under ordinary circumstances to have small families, hence this decrease in the birth-rate is all the more alarming. The death-rate in the United Kingdom is rapidly decreasing. Fewer children die and adults reach a greater average age. The marriage-rate declines, however, having fallen off 1½ per cent. in the period 1880–1887 as compared with the period 1875–1880. The decline in marriage-rate is not due to "hard times," for, while the population of the United Kingdom increases but 12 per cent. per decade, its wealth increases 22 per cent., its trade 29 per cent., and its ship-

ping 67 per cent. The greatest danger lies in the prospect of physical degeneration because of the decreasing death-rate, which fell off 5½ per cent. in 1881–1885, as compared with the preceding five years. With an increase of intelligence and wealth, there is always a decreasing birth-rate. France has reached that point where its births only serve to keep the population undiminished, while in our own New England, it is probable that the population would actually decrease were it not for immigration.

CHOLERA IN CHINA.—*The Sanitary Record* of March 26, 1887, describes the following successful attempt to eradicate a cholera epidemic:

At a colliery on the island of Takasima, Japan, cholera last year attacked 1500 out of 4000 laborers, and 800 died. As this was the third time the island had been ravaged by cholera, the company used sanitation as a preventive. The U. S. consul reports that this work was carried out as follows: A complete sewerage system was formed. Heavy pumping arrangements were erected on the beach, for pumping sea-water to the highest point of the island, whence by an arrangement of drains and sluices it was gravitated back to the sea, flushing for three or four hours daily every drain among the dwelling houses. An extensive fresh-water condensing apparatus was erected, turning out from 7000 to 8000 gallons of water per day. The wells on the island were closed, and water from the main land only allowed to be imported for purposes of washing, etc. A strict system of food quarantine was instituted, and all food was supplied through the company. Three digesters, each of 800 gallons capacity, were erected, beef killed under inspection being used to make soup, about 1000 gallons per day being supplied to the miners. Beef was also served out in the rations. All shell-fish were prohibited, only deep-water fish, after inspection, being allowed to be landed or sold. No deleterious vegetables of any kind were permitted to be brought to the island, potatoes, beans, and certain harmless native vegetables being the only ones allowed for consumption. The success of the system adopted has been amply demonstrated by the fact that Takasima has been the only place in Nagasaki Ken untouched by cholera during this year's epidemic.

THE CASE OF CATALEPSY NOW AT LONDON.—*Science* for April 22, 1887, describes the following case which is now exciting great interest in London:

The case of M. Chauffat, a native of Haute Savoie, who has been overtaken by a trance in a French hotel in London, has been exciting very great interest among the section of medical men devoted to psychological studies. This is the seventeenth day of his cataleptic condition, from which he shows no sign of awakening, and the administration of food is not a little difficult. Chauffat has been a patient of the famous Dr. Charcot, in the Saltpêtrière Hospital in Paris, where a large number of experiments are now being conducted upon hypnotizing. Dr. Charcot, however, particularly wishes it to be understood that Chauffat is not a hypnotized subject. The general state of his body is good, the temperature and pulse being normal, though the respiration is subject to great variation, changing from 15 to 28 in the course of a few hours. The only way in which he can be aroused sufficiently for the administration of food is by directing a strong ray of light on his eyes. An examination of them by the eminent oculist, Mr. Brudenell Carter, showed that all the vessels, both veins and arteries, were much contracted and very small. Both sides of the body are alike in their condition, though the cataleptic condition is stronger in the limbs than in the trunk. The most extraordinary feature of the case is the remarkable results obtained by gently stroking Chauffat's arm. The limb, if raised upright, remains in that position indefinitely; and, when certain nerves are stroked, the fingers clinch tightly, the blood is forced from the extremity, the hand and forearm turn slowly round to the right till the strain is so great that the muscles stand out rigidly, the limb being perfectly rigid. On the other hand, the most gentle touch or stroking of the flexor of the forearm is sufficient to relax the whole. Without doubt, Chauffat's case is one of the most remarkable of the kind that has occurred in England, although they are more frequently to be met with in France.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 26 TO MAY 2, 1887.

[illegible], James S., *Major and Surgeon.*—Granted leave of absence for 10 days, to take effect May 3, 1887.—*S. O. 98, A. G. O.*, April 26, 1887.

WOODSON, CHARLES L., *First Lieutenant and Assistant Surgeon* (recently appointed).—Ordered for duty at Fort Wayne, Mich.—*S. O. 96, A. G. O.*, April 26, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING APRIL 30, 1887.

ALLEN, W., *Assistant Surgeon.*—Ordered to the Receiving Ship "Vermont."

BROWN, CLEMENT, *Passed Assistant Surgeon.*—Detached from the Naval Academy, and to Marine Rendezvous, Phila., Pa.

[illegible], J. F. HAGY, *Passed Assistant Surgeon.*—Ordered to the Navy Yard, [illegible].

HUDSON, A., *Medical Inspector.*—Ordered to the United States Steamship "Trenton."

HIBBERT, C. T., *Passed Assistant Surgeon.*—Ordered to the United States Steamship "Trenton."

DECKER, CORBIN, J., *Assistant Surgeon.*—Detached from the Receiving Ship "St. Louis" and to the United States Steamship "Trenton."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, FOR THE THREE WEEKS ENDING APRIL 30, 1887.

GOLDSBOROUGH, C. B., *Surgeon.*—Leave of absence extended thirty days on account of sickness.—April 20, 1887.

DEVAN, S. C., *Passed Assistant Surgeon.*—Granted leave of absence for [illegible] days.—April 12, 1887.

BRATTON, W. D., *Assistant Surgeon.*—To proceed to Port Townsend, W. T., and assume temporary charge of the service.—April 21, 1887.

ORIGINAL ARTICLES.

PISTOL-SHOT WOUND OF THE ABDOMEN,

INVOLVING THE LIVER, STOMACH, SUPERIOR MESENTERIC ARTERY AND VEIN, SMALL INTESTINE, AND KIDNEY: LAPAROTOMY; NEPHRECTOMY; DEATH ON THE FIFTEENTH DAY; AUTOPSY.[1]

BY W. W. KEEN, M.D.,

PROFESSOR OF SURGERY IN THE WOMEN'S MEDICAL COLLEGE, PENNA., SURGEON TO ST. MARY'S HOSPITAL.

MISS B., in Vineland, N. J., a plump and healthy, well-developed girl of nearly eighteen, shot herself with a pistol, calibre No. 32, at 6.30 A.M., April 1, 1887. In a few minutes she was found by the family who had been roused by the shot, lying on the floor of the room next her bedroom, bleeding slightly, and conscious, and was carried to her bed. Dr. O. H. Adams who arrived in a few minutes found that the ball had entered over the liver, and after a careful search found it lying under the skin of the left flank. She was pale and weak and suffering considerable pain. Giving her one-quarter of a grain of morphia subcutaneously and directing that no food be given her, he telegraphed for me. I reached there at 2 P.M.

She was perfectly conscious, very pallid and weak, suffering moderately. Her night dress was blackened and burned over a space four to five inches in diameter. She told me that the wound was self-inflicted, hence the pistol had been almost in contact with the body, and the ball had probably passed in a straight line. The small, blackened wound of entrance was seen over the ninth rib, which was fractured, four and a half inches above the level of the navel, and three and three-quarter inches to the right of the median line. Skin not burned. The ball was located eight inches to the left of the median line one and a half inches above the level of the navel. There was moderate tenderness over the entire belly, hepatic dulness not changed, stomach resonant from fifth interspace, no cough, no râles, vocal fremitus normal, renal dulness began at tenth rib on left side, and was the same on the two sides. There was severe pain in the left shoulder. She had vomited a drachm and a half of clear, bright blood, she told me, immediately after the accident. This had been lost, but I saw what she had twice vomited later. It was ordinary mucous and bilious vomiting, streaked with a few drops of blood. About a pint of urine, the first since the accident, was drawn by the catheter. It was not bloody. Pulse 104, respiration 30. No material rise of temperature. As after consultation with Drs. Adams and Bidwell it was deemed almost certain that the belly was invaded by the ball, exploratory laparotomy was advised, consented to and begun at 3 P.M., and terminated at 6 P.M.

[1] Read at the American Surgical Association, Washington, D. C., May 12, 1887.

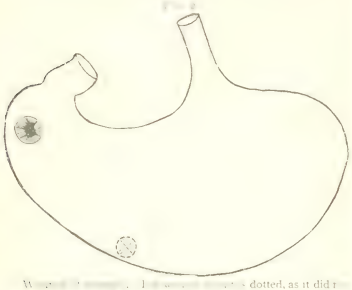
× Point of lodgement of ball.

Operation.—The instruments were in 5 per cent. solution carbolic acid, the sponges had been lying in a similar solution for five days; hands and nails were cleaned by soap and water and corrosive sublimate 1:1000; the wall of the abdomen was thoroughly washed with the sublimate solution, especially at the wound of entrance and the navel, an easy hiding-place for dirt and mischief. Plenty of towels in a warm sublimate solution were provided. The sponges were placed in the sublimate solution during the operation. Ether given by Dr. Beck. The ball was easily removed just under the skin. Neither wound could be traced positively into the belly. An incision was then made in the median line from the epigastrium downward three inches long, subsequently prolonged to eight inches, and in such a position that it crossed a line joining the two wounds, so that, if the ball had passed in the belly wall only, its track would be found. On opening the belly neither blood nor serum escaped, nor was any extravasated food or feces noticed. There was no peritonitis. Two fingers

were passed in and an effort made to discover the wound of entrance or exit without any being revealed by touch. The wound was then enlarged and the stomach drawn out. A small round wound near the pylorus was found and was closed by four sutures (Lembert) of the finest iron-dyed silk a



W[illegible] dotted, as it did [illegible]

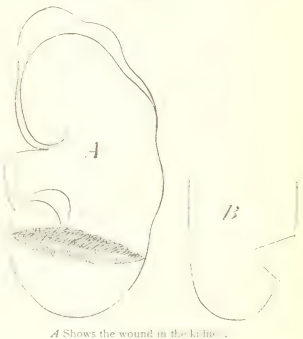
round ordinary sewing needle being used, only the peritoneum and muscular coat being caught by the sutures. This wound was practically closed by the pouting mucous membrane. As the ball had entered the stomach, search was made for the necessary wound of exit. None was to be found, but the manipulation showed that a small amount of bloody serum existed in the belly, and a large area of extravasation was seen in the mesentery. The cause for this bleeding was then sought. The bowels were carefully drawn out and placed on the belly wall wrapped in towels kept wet with the warm sublimate solution. The blood extended fan shaped in a moderately thick layer between the two layers of the mesentery, its periphery extending almost two feet along the bowel and its point being at the mesenteric attachment to the spine just below the head of the pancreas and in the line of the wound. But little blood had escaped into the peritoneal cavity. The mesentery was carefully torn through and a small artery tied. The chief bleeding came from a hole nearly one-eighth inch in diameter in a large vein, so large and lax that at first I thought it the vena cava, but its position just below the head of the pancreas convinced me that it was the large superior mesenteric vein just before it forms the portal vein. After much difficulty I seized it with hemostatic forceps and placed a lateral ligature of chromicized catgut on it.

Meantime the manipulation had revealed a moderate bleeding point in the omentum near the wound of entrance. This was tied with catgut, and the ligatured part cut off. The anterior border of the liver had been scalloped by the ball, but as there was no bleeding it was let alone. In addition, a large wound in a coil of small intestine in the left flank had been found. This was one and a quarter inches by half an inch, the long axis in the axis of the bowel, almost at the mesenteric attachment, its edges ragged, the mucous membrane pouting into the wound, but not closing it, the peritoneal wound extending beyond that in the muscular coat. No bleeding was going on. The bowel and mesentery here were carefully examined on both sides, and upward and downward, to find any other wound, but neither did the bowel nor the mesentery show the slightest lesion. A little bilious matter escaped during the closure. This was quickly caught on a

Perforating wound of the [illegible] of perforation beyond the [illegible]

sponge and the bowel carefully cleansed. Ten Lembert sutures were used in closing it.

Returning now to the stomach, a very careful search was again made for the wound of exit. Two small patches apparently of extravasation had been seen before, in the lower border, about four inches from the pylorus, and it was now found that one of these, instead of being an extravasation, was the



A Shows the wound in the [illegible]
B Shows its depth.

small, round wound of exit, obscured by a slight coating of blood. This was closed by three black silk Lembert sutures, as in the case of the other wound.

Thus far, one lesion after another had been attended to as found, and in the order of urgency. A systematic investigation was now made of the entire bowel, from the stomach to the sigmoid flexure, and no other wound discovered. Each coil as it was drawn out was examined first on one side and then on the other. The wound of exit from the peritoneal cavity next received attention, while the bowels were lying on the belly wall. It could now be found after a moderately easy search. I passed my finger in, and discovered that the left kidney was badly lacerated, and I immediately removed it, peeling it out of its capsule, and tying the pedicle with a stout silk ligature. No difficulty attended this step. On removal, the kidney was found to be ploughed through by the ball, on its anterior surface, from the hilum to the opposite border half way through its entire thickness one-third of its length above the lower end. Very little blood, and, so far as I could determine, no urine, was found at the site of the kidney. A rubber drainage tube was inserted through the wound of exit into the abdominal cavity.

Her condition by this time was such that no time was to be lost in completing the operation. The abdomen was therefore washed out by a hot sublimate solution (110° to 115°) till the water flowed out clear; the amount of blood so washed out being but little, some of which had passed into Douglas's cul de-sac. The bowels were replaced, the omentum carefully spread out over them, and the abdomen closed. This was done by nine deep silver-wire stitches, including the peritoneum, and eight intervening ones of silk. I should have sutured the peritoneum at the site of the removed kidney, and also have sutured it in front independently of the rest of the abdominal wall, but that the condition of the patient was such as to forbid the necessary delay. As a matter of fact, no added risk was caused. The wound of entrance was then cleansed, and closed by three stitches, and the wound of exit was closed by two stitches, except where the drainage tube passed out. Am Ende's sublimate gauze, rubber dam, and a wide flannel bandage completed the dressing, and she was then placed in bed with hot bottles and blankets. Pulse 175, and very weak. Some hypodermatic injections of whiskey had been given with advantage during the operation.

During the night a little cracked ice and some ice water and half a grain of morphia were given. She had had considerable pain, but had slept about three hours. At 9.30 P.M. ℥iij clear urine had been drawn, but from then till 7 A.M. only ℥ss was secreted. The morning temperature was only 99.4°; pulse 146, and respiration 18. At the request of her mother, who had mean time arrived from New York, I asked my friend, Dr. Weir, of New York, to see her. He arrived the next day and coincided in the wisdom of the course taken, especially as to the kidney.

Drs. Adams and Bidwell took charge of the case until I able to see her again with them on April 5. From their daily reports I condense her history as follows:

During the day following the operation suppression of urine was threatened, only ℥iijss being secreted. This was quite albuminous. The next day, however, the amount rose to ℥xxiv and on the third day to ℥xl, and the albumen gradually disappeared. Her temperature fluctuated between 100° and 101°, rising once to 102.5°, when a sponge bath and for a short time an ice bag to the abdomen brought it down to 101°. For the first three days, as she was so fat and hearty, nothing was given her except a little cracked ice, ice water, and a little whiskey and champagne. On the fourth day peptonized milk in frequent but small quantities was allowed with rectal enemata of the same every four to six hours, and later of "liquid peptonoids," "beef peptonoids," and "bovinine." The rectal alimentation was prevented earlier by reason of a number of watery, but not bloody stools. She had also vomited several times, once on April 4th quite violently. The matter vomited was bilious with no blood in it. She had been in a great deal of pain which was fairly controlled by morphia. For a short time on the fourth also she was delirious. Menstruation appeared regularly when due on April 3d, and ran its usual course of four days.

At my visit on the 5th of April I found her, on the whole, doing well. Her temperature had that morning fallen to the normal, pulse 114, respiration 16, but I did not like her anxious expression and continuous pain and sleeplessness. She was thirsty, but not hungry. On changing the dressings I found the wound of entrance healed. From the wound of exit, which Dr. Adams had dressed on the 4th, there was scarcely any discharge. It was healed except for the drainage tube. The abdominal wound was firmly healed at the upper and lower ends. The third, fourth, and fifth deep wire stitches had broken, presumably when the violent vomiting took place the day before or possibly earlier. The intervening silk stitches prevented much gaping. Where the gaping took place the omentum was somewhat exposed, but as it and the belly walls were well glued together, I did not disturb them save to introduce one stitch of support at the widest gap, but I did not approximate the edges, as there was a drop or two of discharge from small aseptic stitch abscesses, and I feared lest I might force it into the abdominal cavity.

At my next visit, April 7th, I found the wounds doing well, no further gaping. Six stitches at the two ends were removed, as also the drainage tube, from which there had been no discharge. The pain in the left shoulder and at the epigastrium continued to a moderate extent. There was no peritonitis or tympany. But her temperature had risen to 101.3° and the pulse to 124.

On the 8th, at noon, she had a chill lasting twelve minutes. The temperature rose to 104°, the pulse to 148, and the respiration to 32; the temperature, however, falling to 99° by 6 P.M. Her stomach and bowels had also became irritable, and much of her nourishment was lost. I did not receive the telegram calling me there till after the last train had left, so that I did not see her till the 9th. She had had another chill that morning, and her condition was most critical; temperature 104°, pulse 160, and very weak, respiration 36 and shallow. I suspected, of course, pus at some point and debated reopening the

belly, but as the most careful examination revealed no spot of special tenderness, no dulness, no fluctuation, and she was almost, it seemed, *in articulo mortis*, I did not deem it prudent to do so, lest she should die at once.

The next day, the 10th, she improved somewhat, her temperature falling to from 99° to 101.5°. She had a natural movement from the bowels with neither blood nor pus. She still vomited considerably.

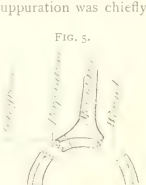
April 11. Dr. Weir saw her with me. Her temp. was 100.6°; pulse 120; resp. 24. The most careful examination showed nothing locally that would guide us in reopening the belly, either in front or flank, especially in her then bettering condition. There was no pain except on very deep pressure, which produced diffused pain; nothing in Douglas's cul-de-sac; uterus movable, not tender; no peritonitis anywhere; only the stitch wounds were tender with slight suppuration about them, and on the surface of the exposed omentum. We thought it not impossible that the chills, etc., arose from those stitch wounds, and almost hoped she would still pull through. The wound was washed and redressed as before, rubber adhesive plaster supporting the belly wall outside the dressing.

13th. I saw her again. She had had another chill, with a temperature of 105.4°, and had vomited several times, and also had some involuntary evacuations. But as her condition was fair, pulse 136, temp. 101.4°, I decided to reopen the belly and explore it. No dulness, hardness, tenderness, or œdema existed to determine any opinion as to suppuration, but I feared a possible mesenteric abscess. No ether was given, and very little pain was felt. The adhesions between the omentum and the belly-wall were broken up with very moderate force, and two fingers passed into the belly. The intestines were bright and glistening, and no peritonitis existed anywhere. Surgical bimanual examination revealed no pus or special tenderness at the site of the removed kidney, or so far as it could be located at the intestinal wound. The stomach and liver were in good condition. The fingers detected a general hard mass at the site of the wounded superior mesenteric artery and vein, but there was no fluctuation, and when withdrawn the fingers showed no pus; nor did a sponge passed into the same point show any. The wound was then reclosed by sutures, care being taken to replace the omentum and belly-walls in as nearly their former position as possible, and a glass drain inserted as a precaution. No shock followed. Her temperature fell temporarily during the evening, though it rose again during the night, and she slept nearly three hours.

During the next day (April 14) she had two bloody movements; she began to have involuntary discharges of urine as well as feces, and though her temperature never rose beyond 102.2°, she gradually failed, and died April 15th, at 1.30 P. M.

The autopsy was made by the Coroner's direction, by Dr. H. C. Smith, of Millville, twenty-one hours after death. Through his courtesy, as well as from Drs. Adams and Bidwell (for I was unable to be present), I obtained the following facts, as well as the stomach, bowel, and right kidney. There was general peritonitis, except in the pelvis, but no free pus was found anywhere. The wound in the liver was healed. Only one wound was found in the stomach near the pylorus, and this was healed, the four stitches being seen in place. The site of the other could not be found, nor could its three stitches be found anywhere. Search was made in the duodenum also, but no wound could be discovered. The duodenum, head of the pancreas, and mesentery were softened and matted together by inflammatory exudate, and the head of the pancreas was cheesy. The blood in the mesentery was disintegrating and suppurating, though no abscess existed nor was there any free pus in the peritoneal cavity. The suppuration was chiefly marked along

FIG. 5.



Section of wound in small intestine at *a* in Fig. 3, showing the site of the gangrenous spot and perforations found at the post-mortem. The wound is represented open, as at the operation.

the mesenteric attachment of the intestine. The wound in the small intestine was found entirely healed, the stitches being in place and covered with a thin layer of lymph. On the other side of the mesentery, corresponding in position to the lower end of this wound, was a spot in the bowel-wall as large as a five cent coin, which was gangrenous, and in its centre was a double perforation of bowel with pus in the calibre of the bowel. I have not received the mesentery, but I am told that it also showed local gangrene at this place. Very careful and systematic search of the entire length of the bowel revealed no wound except that discovered at the operation. No trouble was found at the site of the removed kidney. The right kidney was removed and found healthy and enlarged. Both kidneys having been in the same bottle in alcohol, the right for two weeks the left for four, their measurements are: right, 4¼ by 2⅜ inches; left, 3½ by 1⅝ inches; the right kidney is also thicker. The spleen was normal; right ovary cystic. Only the abdomen was examined.

REMARKS.—The question of doing a laparotomy was not wholly easy to decide. Besides social circumstances, which made me hesitate to assume any except urgent responsibility, neither wound could be positively traced into the belly cavity, though the nearness of the pistol made it almost certain that the ball had pursued a straight line, and if so, had penetrated the abdomen. It is worthy of note, in this connection, that when the fingers were in the abdom-

inal cavity the wound of entrance could not be felt, and later, when, by lifting the belly wall, the perforation in the peritoneum could be *seen*, when the finger was placed there it still could not be *felt*. The amount of clear blood vomited at the time of the accident was very small, and we had only the statement of the wounded girl to depend upon. Even this, as well as the streaking of blood in the later vomited matters, could come from contusion or her fall. There was no evidence of blood either by the bowel or the bladder. Her long continued and deep pallor, weak and rapid pulse pointed toward hemorrhage, but palpation and percussion did not give positive evidence of any. But, as everything seemed to point toward the *probability* of the belly's being penetrated, I determined upon an exploratory laparotomy, in order to determine the facts absolutely. In this decision my colleagues coincided. Fortunately, the presumed course of the ball crossed the proper line of incision, and I was able to decide that it had not traversed the wall of the belly by not finding its path while I was making my first incision, and before opening the peritoneum.

No food having been taken before the early hour in the morning at which the shooting occurred, fortunately prevented any extravasation of food, and none of the wounds being in the lower bowel, no feces escaped. Although it was nearly ten hours from the accident to the time when the intestine and stomach were sutured, it is worthy of notice that no intestinal or gastric juice or fluid contents escaped, even though the intestinal wound was so large and gaping, and vomiting occurred three times prior to the laparotomy. The pouting mucous membrane well occluded the gastric wounds.

The second opening in the stomach was difficult to find, and was at first mistaken for a simple extravasation, a fact already noted by Dr. Briddon[1] as occurring in a case of his own. There was, however, no doubt as to its existence, and I put three sutures in its edges. At the post mortem no evidence of its position could be found, though careful search was made both in the stomach and the duodenum, the possibility that I might have measured the wrong way being borne in mind. There is neither scar nor sutures to be found on the outer or inner surface of the stomach. The sutures in the other stomach wound are in place, and look as though they would remain for some time. Whether, in the other wound, the sutures disappeared internally after the healing of the small wound, or loosened and were lost in the belly cavity cannot be determined.

The peritonitis, found at the autopsy, did not exist on the twelfth day, when the belly was re-explored. Nowhere was the glistening peritoneum then dulled. Two sources existed for the later peritonitis—the opening in the intestinal wall opposite the intestinal wound and the mesenteric pus. The former was the most likely source. At the operation the bowel and mesentery were carefully inspected on both sides, but no such opening existed. Had it been made by the ball, peritonitis would undoubtedly have occurred quickly after the operation, and there would not have been *two* openings here, as the specimen shows. I have no doubt that the fact was that the ball contused a part of the mesentery, especially probably an arterial branch. This did not show at the time, but later on produced a limited gangrene, and perforation took place a day or two before death. Dr. Smith, also, tells me that the mesentery itself was necrosed at this place. The bloody stools preceding death point in the same direction, especially as she had had a natural movement of the bowels, with neither blood nor pus, on the ninth day after the wounding. Hereafter, however, in all cases of intestinal gunshot wound, whether single or double, I shall examine the mesentery more minutely for any possible evidence of contusion as well as perforation.

Possibly this necrotic process in the bowel, as well as the general softening of the duodenum, was promoted by the serious wound of the superior mesenteric vessels, especially the vein. The artery was a small branch, but the vein was the main trunk just below the head of the pancreas, and so large that when I first seized the bleeding point and lifted the wall I thought it the vena cava. I placed a lateral ligature upon it, seizing the margin of the small opening, as large as the lead of a pencil, and securing it by a catgut ligature. To dissect it loose and encircle it with the ligature would have required a considerable loss of time which I wished to avoid, and besides, I feared the effect on the bowel of obstructing so large a vein. Whether a thrombus formed in the vessel, and occluded it, was not examined. The blood, curiously enough, did not find vent into the peritoneal cavity by the wounds in the mesentery, save to a very slight extent, but dissected the two layers of the mesentery, and was spread out, fan-like, from its source to two feet of bowel, in a moderately thick layer, thickest at the spine. This it was impossible to remove, and I had to trust to its absorption. I was not surprised that there was trouble at the site of the wound in view of the injury done by the ball, and the necessary manipulation to get at and secure the vessels. It is worthy of note, however, that the chief trouble existed at the periphery of the clot near the bowel, where we would expect absorption most readily to take place. Probably the main absorbent trunks from this part, as they approached the spine, may have been obstructed by pressure, or have been injured by the ball or during the operation.

The kidney, I believe, has never before been removed at a laparotomy for gunshot wound, but it was clearly the right thing to do. Bloody urine is one of the most frequent signs in injuries of the kidney, and its absence here was remarkable. The wound extended entirely across the kidney, and half way through its thickness, yet the urine (℥xvj) drawn eight hours after the accident (and none had been passed), was absolutely free from blood, the injury apparently arresting the function of this kidney, while the laceration of the renal substance was such that but slight bleeding occurred. Possibly the urine drawn had been mostly secreted during the night. The day following the operation the remaining kidney worked badly, only three and a half

[1] THE MEDICAL NEWS, January 8, 1887.

ounces of albuminous urine being secreted. But the next two days dispelled all anxiety on this score, the urine rising to twenty-four and forty ounces respectively, and the albumen soon disappeared. The early and marked compensatory enlargement of the right kidney is also of great interest and importance, though, of course, now well known to follow nephrectomy.

When the chills occurred, due, no doubt, to the necrosis and suppuration of the large mesenteric blood clot, naturally the first impulse would be to open the belly, anteriorly or in the flank, and search for the pus. But I was deterred from this course by her general condition, which then threatened almost immediate dissolution, and by the fact that no peritonitis existed at the spots most likely to be the seats of suppuration. The most careful external examination revealed its absence. To this, possibly, the wounded vessels and effused blood should be an exception. Even here, however, there was no dulness, fluctuation, or hardness, and the slight tenderness that existed was to be expected. When I did reopen the belly and examine this spot I only found a general matting of the tissues, and no accumulation of pus in an abscess. What pus did exist at the post-mortem was not free in the belly, nor accumulated in an abscess, but diffused between the mesenteric layers.

I did not suture the peritoneum at the site of the removed kidney, as the patient's condition did not allow of the delay, and no harm came of it. In view of the possibility of the giving way of stitches in the abdominal wound, which occurred here, and also in a case of Dr. Bull's (and exposed the intestines), I should hereafter take time to close the peritoneum by a continuous catgut suture before suturing the abdominal wall, even if the patient's condition were bad. The avoidance of possible subsequent dangers would justify taking a certain amount of present risk.

The reason for the severe and quite persistent pain in the left shoulder, I could not determine.

THE POLAR METHOD OF ELECTROTHERAPY IN GYNECOLOGY.[1]

APPLICATION, DOSAGE, AND MEDICATION.

BY [illegible]

In this paper I shall treat of those points which are of more general interest and of practical importance in gynecological practice.

I. *Essentials for the successful use of electricity.*

II. *Manner of application, electrode, and instruments to be used.*

III. *Measurement and dosage.*

IV. *The method of applying medicinal agents, or electro-medication.*

The use of electricity is rapidly gaining in favor among gynecologists, and this is due to the *galvanometer*, mainly, hardly less to the introduction of the *polar method—i. e.*, the direct application to the tissues, and to the use of *strong, effective currents*—making it possible to apply the current without those long sittings of twenty and thirty minutes, which made it an impossibility for the busy practitioner heretofore. These are the essential features of the gynecological electrotherapy of to-day, in which the *electricity* which I advocate differs from the medical electricity which has so long remained in a very dubious light before the profession.

This questionable medium has at once become a valuable agent; a very perceptible change is taking place in the profession; the very men who, not a year ago, denied the possibility of measurement and dosage, now appear as converts: the admirers of mild currents and half-hour sittings continued for months, are hushed by the undeniable logic of facts, by the astonishing results achieved by effective currents in a few short sittings; in short, medical electricity is now emerging from the primitive condition in which it has too long remained.

Whilst commerce and industry have developed the most wonderful properties in this agent, and have utilized it to a marvellous degree, the medical profession has almost ignored it, though known for an entire century, since the time when Galvani, at sunset, on a September evening, one hundred years ago, while endeavoring to suspend the legs of a skinned frog, by a copper hook through the spinal column, to the iron railing of his garden terrace, observed the twitching of the muscles when the copper hook touched the iron railing. This event marks the first progressive step in the history of electricity since the discovery of the remarkable property of amber, 600 years B.C.

Fertile brains soon developed the discovery of the Bolognese savant, which found favor especially among the French.

The most important advance in the use of galvanism as a medicinal agent is, however, due to the labors of Remak, of Berlin, forty years ago, which we must accept as the basis of our work; upon this we build.

Physiologists have developed the science, and neurologists have applied it, but the profession at large has gained but little; indeed, we may say that the teachings of Remak have not been utilized as they should have been. Gynecologists were not successful, because they merely followed the specialists, the neurologists, who had adapted the new remedy to their own particular purposes, in a very different sphere; isolated, and even wonderful successes were reported, and created a temporary interest, which soon subsided. Even the success of Cutter, of New York, in the destruction of fibroid tumors, seventeen years ago, remarkable as it was, did not arouse emulation. The excellent results of Bruns, of Tübingen, in the treatment of goitre, and of nasal polypi, were noted by only a few and forgotten by them; the brilliant application of the electrolytic properties of galvanism for the destruction of supernumerary hair in the eyelid, made by our friend Dr. Michel, of St. Louis, would have met with a similar fate had it not been made so valuable to dermatologists by our col-

league Dr. Hardaway, so that among a limited number of specialists this one property of galvanism was thoroughly appreciated; but to the profession at large the electric current still remained the same mysterious agent, regarded with indifference, with distrust, or with awe, until Apostoli, in 1883, gave us the key to the successful application of electricity for the destruction of fibroid tumors by urging, 1. Localization, the limitation of effect to one active pole, which must be placed within the tissues; and, 2. The use of currents stronger than any hitherto applied in medical practice. Upon these fundamental laws I have based the theory and practice of gynecological electrotherapy.

Little can be said of electricity in gynecology; it has had no influence whatsoever upon the development of this rapidly progressing specialty; reference to even the latest and most thorough text-books affords the best proof of this fact.

The gynecologist, unacquainted with the varying properties of the electric current, resorted to this remedy only when all other means had failed; in the most difficult and unyielding cases he tried an agent with which he was not familiar; he naturally failed, and as naturally ascribed his failure to the remedy he used.

Need we wonder that no attempt was made to apply electricity in gynecological practice, when Sir James Y. Simpson stated that "Electrization of the uterus was all but useless, and that when uterine action had been apparently excited by galvanism it was *a mere coincidence*, or resulted from an impression made on the mind of the patient, or on the abdominal parietes by the electrode." Very little more advanced in his practice is Powell, a writer on medical electricity twenty years ago, who ridicules Simpson for this statement in his *Practice of Medical Electricity*, published in Dublin in 1869; though he tells us that the utmost care should be taken in recording cases, etc., he himself gives the following case histories: "Galvanism and faradism were applied for three weeks, and with marked benefit;" or, "he was put under a course of galvanism, and in five weeks the power of the arm began to return."

This was a time when, in the famous Guy's Hospital, patients were treated by shocks from Leyden jars passed through the pelvic regions from the sacrum to the pubis, giving the very acme of what we most cautiously avoid in its mildest form—*i. e.*, shock.

But we can go down to the very latest literature without an improvement in that vagueness which has killed electricity as a medicinal agent. What is the practice of those who in their writings urge precision in application and measurement? What is the practice of those who preach exactness, and tell us that the want of progress is due to want of precision? By their own case records we see that they themselves commit precisely the same error.

We are in a stage of transformation, light is beginning to dawn, the importance of precision in application, dose, and record, is beginning to be appreciated, but not as yet fully understood or practised; so we see one writer telling us that Apostoli applied *one and a half and two and a half ampères;* another says that whilst he formerly used only twenty-five milliampères, he now has applied as high as *ten ampères*[1] (*ten thousand milliampères!*); another is recording the strength of faradic currents in milliampères.

The state of gynecological electrotherapy is not yet clear; hence, I believe that a practical exposé is in place, and conditions are now favorable to progress since gynecologists are beginning to develop the science. Hitherto nothing has been achieved for the reason that the gynecologist has followed the neurologist, and has endeavored to follow the practice of the latter in his specialty; this led to injurious or to negative results, and the agent was condemned either as dangerous or as useless. As electricity for illuminating purposes differs from electricity as a motor, so does the electrotherapy of the neurologist differ from that of the gynecologist, and I look upon the clear understanding of this distinction as absolutely essential to the development of electrotherapy; the want of it has been one of the most effective bars in the way of progress. Success was impossible with the indiscriminate application of electricity in the various branches of medicine; in gynecology we deal with resistances of 200 and 300 ohms, as low as 40, but never above 600 or 800, whilst we use currents up to 250 milliampères, most commonly between 20 and 80 milliampères; the neurologist, on the contrary, rarely goes as high as 20 milliampères, and usually uses from 2 to 5 milliampères, and the resistance of the tissues between his electrodes is from 5000 to 10,000 ohms and over.

An essential to successful gynecological electrotherapy is a smooth current, the most complete avoidance of shock, which is, on the contrary, a valuable feature in the practice of the neurologist; we carefully avoid the effect of opening, closing, and reversing of the current, which is a highly important diagnostic and therapeutic resource in neurology.

Successful electrotherapy was impossible as long as electricity was looked upon as an agent applicable here and there in the same way, and it has been my aim to establish and develop gynecological electrotherapy: as in all matters, if we wish to succeed we must ourselves work to our own especial purposes, I have, therefore, confined my work and my writing to the subject of *gynecological electrotherapy* and I wish it to be clearly understood that I make no reference to other applications.

The conditions are peculiarly favorable for the application of electricity to the female pelvic viscera:

1. The current can be confined to the part under

[1] *Ten ampères* is the current used for the large electric lights on our streets; inside lights in hotels and stores need a current of only six ampères.

Ten ampères, through a resistance of sixty ohms, which is as low a resistance as we may expect in a fibroid, means a force of *six horse* power, this in electro-chemical force or heat would destroy the abdomen in a few moments. Any unlucky fireman who for a moment touches non-insulated parts of a wire carrying a ten ampère current is struck dead, and yet one enthusiastic electrotherapeutist claims to have applied a current of ten ampères to a living woman! Electric measurement is beginning to be appreciated, but is by no means understood.

treatment, as all the organs are gathered within the limits of the pelvis.

2. Diseased organs or morbid products can be reached directly by the electrode.

3. The low electrical sensibility of the parts makes the use of very strong currents possible. The skin, an electrically sensitive part, is not necessarily involved, and if so, only at the site of the indifferent or dispersing pole; as this is the abdomen, the current can be dispersed to any desired extent. The active electrode need never be in contact with the skin, and, however strong the current, the active intra-pelvic pole need cause no pain.

4. The polar method can, by reason of the situation of the parts, be successfully applied and fully utilized, and by this method only are speedy results possible in gynecological practice.

I. Essentials for the Successful Use of Electricity in Gynecological Practice.

As I have discussed the subject at length in my first paper, on "The Use of Electricity in Gynecology," read before the American Gynecological Association, in September, 1886, I will here only recall the important points; these are:

a. Localization of the current. The current must be localized and its effect confined as far as possible to the diseased organ or part.

b. Use of one active pole. One pole exclusively, chosen for its peculiar properties, must serve as the active agent for the application of the current, and upon this its entire effect is concentrated; this is termed the active pole.

c. Dispersing of the current. The current at the other pole must be neutralized as much as possible, and its effect rendered as little as possible perceptible; to accomplish this it is dispersed upon as large a surface as the configuration of the part will permit; hence, a dispersing electrode is used in connection with the indifferent or neutral pole, called the dispersing plate.

d. The active pole should be directly in contact with the organ or part to be acted upon, or even within its tissue.

e. The indifferent or *dispersing pole should be opposite to the active pole so as to confine the tissue to be affected between their surfaces;* it must be as near as possible to the diseased part and upon the largest and least sensitive surface which can be utilized.

f. Use of effective currents. Currents of sufficient strength to accomplish the object desired in the shortest possible time, without detriment to the patient, should be used.

The intensity of the current used in gynecological practice varies from 1 to 300 milliampères; of most general use are currents of from 20 to 80 milliamperes.

It must be remembered that I am not merely urging the use of currents as strong as possible, but of *currents strong enough to be effective.* Whilst a current of one or two milliamperes will relieve the pain of a contusion, a current of ten milliampères will aggravate it. The intensity must be commensurate with the object in view.

g. Precision in dose and measure. Knowledge of the force used and exactness in dosing it are a *sine qua non* to the effective application of electricity. It is as necessary to know the electro-motor force of the elements and the milliampère intensity of the current used as it is to know the strength of a chemical solution, and the number of grains of the drug which are to be given.

h. Use of proper instruments is as necessary to the electrotherapeutist as it is to the surgeon. The battery, by which the force is generated, is useless without proper means of dosing and of applying it, the milliampèremeter; suitable electrodes for the application of the current at the active pole, and for its dispersion at the indifferent pole, are fundamental requirements for a successful electrotherapy.

Upon the acquisition of these aids the recent progress of gynecological electrotherapy is based.

i. Recognition and proper use of the various qualities of the electric current. The electric current, both galvanic and faradic, is a most subtile agent, which may be made to serve many purposes, and which possesses numerous, greatly varying, and even antagonistic properties, which can be developed at will by the accessory apparatus and the method of application.

The following are the most important factors by which the properties of the electrical current are changed, and upon which its varying medicinal effect depends.

Galvanic.	Faradic.
Intensity; number of elements.	Intensity; distance between primary and secondary coil; influenced less by electro-motor force of generating element.
Pole; negative, alkaline, fluidifying, stimulating; positive, acid, coagulating, sedative.	Pole; slight difference; negative, more irritating, painful; positive, less painful, more serviceable for deep application.
Time of use.	Time of use.
Constancy.	Number and length of interruptions; method of increase and decrease.
Size, shape, and material of electrode.	Size, shape, and material of electrode.
Metallic for chemical effect.	Metallic for irritation.
Moist, non-metallic, for distribution and penetration.	Moist, non-metallic, for penetration.
	Length and thickness of wire in secondary coil.
	High tension, effect on nerves by long secondary coil of fine wire.
	Quality and low tension, effect by short coil of heavy wire.
	Primary current more penetrating with metallic electrode.
	Secondary current more penetrating with moist, non-metallic electrode.

The therapeutic effects developed by the various properties of the current, so changed, are numerous, and electricity may be applied to serve as a

Sedative.
Stimulant.
Counter-irritant and vesicant.
Muscle contractor.
Antispasmodic.
Tonic.

Promoter of development.
Absorbent.
Chemical cautery.
Coagulator.
Electrolytic.
Hemostatic.
Promoter of hemorrhage.
Decongestor.
And as a medicator.

II. MANNER OF APPLICATION, ELECTRODES, AND INSTRUMENTS TO BE USED.

The greatest concern is generally felt in regard to the point of least possible importance—that is, the battery itself; the question, *What is the best battery?* is so often asked that I will again repeat that *this is immaterial as regards the effect.* The current is the same, whether we use the sulphate of copper telegraph cell, the zinc and carbon telephone cell, the Leclanché cell, or any of its modifications, or the ordinary medical dip battery. The physician must adapt his battery to his convenience and to his pocket. For stationary and cabinet batteries I deem the sealed Gonda Leclanché or the Diamond the most convenient; both with muriate of ammonia, zinc, and carbon; the former with the oxide of manganese disk in place of the porous cup, which is liable to clog. This battery works steadily, and requires the addition of distilled water every six months, cleansing and refilling every year. The fluid is simple, non-corroding, and odorless. Portable batteries are now made with similar hermetically sealed cups of smaller size, and these, of course, are far more convenient than the dip batteries, which have so long ruled; of these, the Stöhrer battery was the type. It seems, indeed, strange that in this progressive inventive country, from which all electric progress comes, these filthy, corrodable batteries should so long have remained the universal favorite. The hermetically sealed open circuit battery, with dry cups, or, at least, with harmless, odorless fluid, is the battery of the future for cabinet and portable purposes.

The important instrument is the milliampèremeter, graded for general purposes from 1 to 100, for special work from 1 to 250 or 300. No work can be done without this, and it must always be in the circuit to be really useful.

The current selector I need not mention, as no battery is without one, and it is all-important that we have this means of gradual increase of the current, element by element, which I deem of more general utility, more simple, and almost as gentle as the water rheostat.

The wire rheostat to measure resistance, the interruptor, the metronome to break the current, the rheotome to change the current, the water rheostat to interpose resistance, or increase or decrease the current without even the slight jar occasioned by the insertion of single elements, are not necessary for ordinary work; but these, like the coulombmeter to measure the quantity of electricity, the voltmeter to measure the electromotive force of the elements, and the ampèremeter to measure their ampère capacity, are all demanded for progressive scientific investigation.

The *electrode*, the most simple of all the accessories, and on account of its very simplicity the most neglected, is as important as the battery itself. I blame that despicable sponge electrode in part for the neglect into which electrotherapeutics have fallen in this country; every battery was supplied with two of these abominations, and as the practitioner soon found that he could not accomplish much with them, he thought electricity useless and put aside his battery.

The sponge electrode is a filthy, current-absorbing instrument, which must be cast aside. If a small electrode is wanted, the metal plate can be used, covered with absorbent cotton soaked in warm water; this offers no appreciable resistance and is renewed without any trouble for each patient; in fact, time and trouble are saved, as it takes more time to soak thoroughly the sponge electrode than it does to cover the disk with absorbent cotton and apply this instrument, which is saturated by momentary immersion.

I propose to speak more fully of the *dispersing electrode*, as it is this which is so important, partially so from the fact that on account of its very simplicity it has been neglected. Electrodes for various purposes, for use in connection with what I call the active pole, have been devised in numerous forms to suit the locality in which they were to be used, throat, ear, uterus, or bladder, but where any but the mildest currents are to be applied these are ineffective unless the current at the indifferent pole is sufficiently dispersed; only by rendering the neutral pole painless, by dispersing the current at this pole sufficiently to render it indifferent, can the other active pole be effectively used.

For this purpose then we must have an electrode of large surface and of good conducting material, so that the resistance it offers is reduced to a minimum. The stronger the current, the more intense the effect derived from the active pole, the larger must be the surface for its dispersion at the indifferent pole, and the larger must be this surface that the peculiar effects of this pole may be neutralized and that cauterization may be avoided.

The effect of the active pole is in no way reduced thereby, as the density of the current is not appreciably diminished in applications by the polar method, whether the dispersing electrode is large or small.

The larger this is, the better; its size is limited by the surface to which it is applied, and for gynecological purposes three sizes are desirable.

No. 1. 6¼ by 9¼ inches = 58¾ sq. inches surface.
No. 2. 4½ by 6½ " 28½ " "
No. 3. 3½ by 4½ " 15⅝ " "

No. 3 is used with mild currents, and preferable when possible, as it is easily placed without disturbing the clothing, even under the corset; this should, as a rule, not be used with currents of over 15 or 20 milliampères.

Attached to a long, insulated handle, it makes a good spinal electrode, better for this purpose is one

3 inches by 5 inches, with the same surface (15 square inches).

No. 2 is still readily manipulated, though not so easily shifted from side to side and must be used with currents from 20 to 60 milliampères.

No. 1 is necessary for intensities above 60 milliampères, if the current is to be applied without giving pain; to place this the clothing must be loosened.

These three sizes will generally suffice, although I have used No. 0, 8 inches by 10 inches with a surface of 80 square inches, for the application of very high intensities in electrolysis, and No. 5 for cutaneous faradization, round, 2 inches in diameter, like the old sponge electrode.

I would urge these dimensions for general adoption, in order that that uniformity which is so desirable to an understanding may be attained.

The electrode consists of a pliable sheet of lead perforated with holes one line in diameter, one inch apart, and is covered with a layer of punk or absorbent cotton, which is held in place by a thin buckskin or kid. These electrodes conduct as well, and are in every way as serviceable as the clay electrodes of Apostoli. The cover is immaterial, if a good conductor and absorbent, but it is important that the *plate* be of *very pliable* metal, so as to adapt itself to the undulations of the surface upon which it may be placed.

The electrode must be soaked in hot water, the superabundance of which is expressed before it is placed. The water is to be as hot as it is comfortably borne by the patient; cold water must be avoided, as it lessens the conducting power of the electrode, offers greater resistance than hot water because it does not saturate the epidermis so rapidly, and because it is not only uncomfortable, but might even endanger a patient suffering from a chronic inflammatory trouble, for which we so often make these applications. Salt must be avoided; it is not necessary, as it was for the poorly conducting sponge electrode, the instrument which I suggest being a much better conductor, and salt is injurious to instrument and patient. When used upon electrodes by which currents of high intensity are applied, the electrolytic action of the galvanic current decomposes the salt, and chlorine is developed at the positive pole, by which the amount of pain may be increased and the electrode is corroded. Upon a mucous surface the effect of the chlorine generated at the positive pole from a salt water electrode is very perceptible.

The shape of the electrodes used with the *active pole* varies greatly with the object for which it is applied, and any number have been devised; important for the gynecologist and serviceable in the majority of cases are the following four:

1. A fine, pliable uterine probe, insulated up to within three inches of its end by a glass tube which can be removed (glass or hard rubber being preferable as they can be washed in acids and rendered thoroughly aseptic).

2. A heavy, but pliable uterine sound, equally insulated.

3. A needle or stylet for puncture, to be used within the tissues, with movable insulator.

4. A metal ball or oval-shaped electrode with six-inch insulated stem, for vaginal applications.

These electrodes must be so arranged that firm connection, best by a screw, can be made with the rheophore; and one of the intrauterine electrodes must be of non-corrodable metal, best of platinum, for use in connection with the positive pole; as oxygen and acids are set free at this pole, an electrode of corrodable metal is soon affected and is not only rendered useless, but is imbedded in the tissues and hard to withdraw.

It will be found convenient to have a stylet and sound in one and the same instrument, of platinum, one end straight and pointed, the other curved and blunt, which can be inserted with either end in the handle, to be used as a sound or stylet.

To be continued.

THREE CASES OF LIGATURE OF THE EXTERNAL CAROTID ARTERY, IN TWO OF WHICH BOTH VESSELS WERE TIED SIMULTANEOUSLY.

WITH REMARKS ON THE HISTORY OF THE OPERATION.[1]

BY JOSEPH D. BRYANT, M.D.,

SURGEON TO THE BELLEVUE HOSPITAL; PROFESSOR OF ANATOMY AND CLINICAL SURGERY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

I THINK it to be both proper and essential to recall, in connection with these cases, something of the early history of the operation, even at the risk of adding burdensome details to a subject that has so recently been considered by the members of this Society.

The first case, of which a definite record can be found, was operated on by M. Gensaul, at the Hôtel Dieu, September 20, 1824, while he was engaged in the removal of the parotid gland for malignant disease. There is no reason to believe that he, at that time, considered the ligature of this vessel as one of the steps to extirpation of the parotid gland. It appears, rather, that the vessel was tied during the course of the operation, without this step having been considered as a special preparatory measure. I think it safe to assume, in view of the relation of the parotid gland to this vessel, that the surgeon who extirpated the gland first was the one who first tied the external carotid artery. To Beclard belongs the credit of having furnished the first reliable account of the removal of this gland, which he himself removed in 1823. M. Gensaul repeated the operation in 1826. In both of these cases a cure was effected.

The surgeon who first tied the external carotid as a preparatory measure, of which a definite record can be found, was George Bushe, of the Royal College of Surgeons of Ireland. It was performed in a little patient of about ten and a half years of age, to check a severe hemorrhage following the removal of a pulsating nævus from the temporal region. The removal was not attempted, however, until all other recognized expedients had failed. The little patient made a rapid and satisfactory recovery, which pleased the operator so much that he expressed himself as follows:

"I shall trust in the future to ligature of the external carotid in such cases, and here I may say, that where

[1] Read before the New York Surgical Society, April 27, 1887.

the disease is not in the orbit, I cannot see the necessity of securing the common carotid for anastomosing aneurism of the face and head."

In connection with the remarks just quoted, I will call attention to the history of the first of the three cases operated on by myself.

The patient was admitted to Bellevue Hospital, August 1, 1883; aged twenty-four; family and personal histories good. About six months before admission he was struck in front of the left ear with a bottle, which was broken by the force of the blow. The wound of the scalp healed quickly under simple dressing. A short time thereafter a pulsating tumor appeared at the seat of injury, which increased in size continuously until the date of admission. On admission a well-defined pulsating tumor was found at the seat of the injury, of about the size of a hen's egg, which had a distinct thrill and bruit. The trunk of the temporal artery, together with the anterior and posterior branches, was involved directly in the growth. The trunk of the occipital artery of the same side was dilated, and its anastomotic communications with the branches of the temporal were dilated also. The patient was kept under observation for a few days to study the peculiarities the tumor might present, but inasmuch as its chief feature consisted in its rapid development, it was decided to tie the external carotid artery of the same side, with the view to arrest the growth, if not to effect a cure.

On August 7, 1883, the vessel was tied in the presence of many of the visiting and resident staff of the hospital. It was exposed in the usual manner for about an inch above the point of bifurcation. The lingual branch arose about half an inch above that point, and it was tied at once with an independent catgut ligature. After this, the trunk of the external carotid was tied with catgut at the origin of the already ligatured lingual branch. The previous tying of the lingual had provided a branchless portion of the external carotid of about an inch in extent. The ascending pharyngeal branches were sought for, but were not found. Nothing unusual was noticed during the operation, except that the internal jugular vein overlapped the external carotid at the seat of ligaturing. The ligaturing of the external carotid checked the pulsation and all other aneurismal manifesations of the growth at once, also reduced its size to about one-third of the previous dimensions.

The operation was done antiseptically throughout, and the wound had healed entirely at the end of ten days, when the first dressing was removed. At this time a slight returning pulsation could be detected in the tumor, which, however, could be controlled completely by pressure on the external carotid of the right side. On August 30, the pulsations had increased, and the thrill and bruit were again noticeable. On September 8, the pulsation, the thrill, and bruit were nearly as strong as before the operation, but they could be controlled readily by pressure made on the occipital and temporal branches of the external carotid of the right side. The temporal branch only of the external carotid of the left side gave any evidence of a return of the circulation. It then became a question of tying the external carotid of the right side, or of tying its temporal and occipital branches alone, or to attack the growth itself directly. The latter plan was chosen, and was carried into effect September 26, only about seven weeks after the primary operation.

I trust that I may be excused if I digress somewhat at this time to describe the details of the method that was adopted for the radical cure of this case. The head was surrounded by two strong rubber bands, beneath which compresses were placed at the points where arteries passed to supply the scalp. By this means the arterial circulation of the scalp was controlled admirably. The growth was then nearly circumscribed just outside of its limits by a U-shaped incision, made through the healthy tissue of the scalp, down to the bone. The stem of the flap was made about an inch and a half in width, and it extended down to the zygoma, and the centre of its long axis corresponded to the course of the temporal artery. The loss of blood was not severe, since a bleeding point could be readily controlled by pressing the vessel against the underlying skull, while its open extremity was being secured. The bleeding points were closed by catgut applied directly to them, when possible. If this could not be accomplished, they were closed by the overhand continuous suture of catgut carried around and through the borders of the divided tissues. The flap and the surface from which it had been raised were kept separated with antiseptic gauze until granulation took place; then they were fastened in apposition by adhesive straps. They united quickly, and a permanent cure resulted one month after the operation.

The following interesting practical facts are presented by this case:

1. The ligaturing of the external carotid of one side had but a temporary effect on a vascular growth that involved the branches of the ligatured vessel.

2. Pressure on the branches of the opposite external carotid artery interrupted the characteristic aneurismal manifestations that were present in the growth at its recurrence.

3. The ligaturing of all the vessels that passed to the growth, except the one of the pedicle of the flap, followed by independent granulation of the surfaces and their subsequent union, resulted in a rapid and complete cure.

I find eight additional cases of ligature of the external carotid for the cure of aneurismal tumors of the head, face, and parotid gland, in two of which both vessels were tied simultaneously. The latter procedure is not reported to have been successful in either instance. Traumatic aneurism of the parotid gland, varicose aneurism of the ear (two cases) are reported to have been cured by ligaturing the external carotid of the diseased side. It appears, however, that the last two cases received other and decided local treatment, which might have had quite as much to do with the cure as the ligaturing of the external carotid. This fact is emphasized by the recollection of the unsuccessful cases just mentioned of a practically similar nature, in which ligature of both external carotids alone failed to effect a cure. Of a total of nine cases, but one, traumatic aneurism

of the parotid, was cured by ligature alone. These facts force the conclusion that ligaturing of the external carotid of the diseased side, and even of both external carotids, can be considered only as palliative, and cannot be recommended as a means of cure for vascular growths of the head and face, except in connection with other measures.

I do not think it to be a justifiable step to ligature the common carotid alone, nor in connection with ligature of the external or internal carotid for cases like the preceding, since the rate of mortality for ligature of the common carotid is 40 per cent., while that for ligature of the external carotid is 3.62 per cent. This opinion is expressed notwithstanding the fact that the rate of cure for non-orbital anastomotic aneurismal formations is reported by Dr. Wyeth at 28½ per cent. from ligature of the external carotid. It seems to me from these facts that some errors must exist in the primary reports of these cases, since the reverse of these figures would be more consonant with the anatomical bearings of the collateral circulation of the two operations.

Ligature of the common carotid should not be entertained except when from the contiguity of the morbid process the application of a ligature to the external carotid becomes impossible, or when ligature of the external carotid has failed to afford its possible relief; a contingency that is to be anticipated only when the morbid growth is developed at the location of a free anastomosis of the branches of the external carotid and the intracranial circulation, as in intraorbital formations especially.

The second authentic ligaturing of the external carotid, as a preparatory measure, was practised by John Lizars in 1830. It was done to lessen the hemorrhage attendant on removal of the superior maxilla. Preparatory ligature of the external carotid for removal of the superior maxilla, is not necessary for the safety of the patient, except in such cases as, when the patient is ill able to withstand the loss of blood that ordinarily attends this procedure; or to bear the loss that may arise from the removal of the morbid growth that prompted the operation. I am certain, however, that ligature of both external carotids and their ascending pharyngeal branches prior to the removal of large vascular growths involving the superior maxilla and the pharynx, or retro-pharyngeal growths of a similar nature, requiring the preliminary removal of the superior maxilla, should be earnestly commended to the profession. If the growth be of a malignant nature, this plan will not only lessen the hemorrhage attendant on its removal, but may likewise delay the return by lessening the activity of the nutritive processes at its site.

The third case of preparatory ligature of this vessel was performed by Dr. Valentine Mott, about the year 1831, for extirpation of the parotid gland. The swelling of the soft parts contiguous to the diseased gland, complicated the operation somewhat; still, the patient suffered no ill effects from it, but died in less than two months thereafter from a return of the disease.

The rate of mortality of ligation of the common carotid for reputed malignant disease of the parotid gland, antrum, and face (not of orbit), is, according to conclusions of Dr. Wyeth, 44 per cent. from the operation alone, with 15 per cent. of cures resulting therefrom. I have collected nineteen instances of ligature of the external carotid for so-called malignant growths located in practically similar situations, with the loss of but one patient, who died of hemorrhage caused by sloughing of the growth. This case will be fully reported in the course of this paper.

Twenty-six per cent. of these so-called malignant growths are reported as "cured" by ligature of the common carotid. This seems inconsistent in view of the nature of the disease, a fact that was appreciated by Dr. Wyeth when he collected them. It is fair to assume, however, that if ligature of the common carotid will cure malignant disease of the face, ligature of the external carotid should lead also to a similar result. If the idea be to starve a growth, then truly, from anatomical reasons alone, ligature of the external carotid is the far more rational measure; because if the external carotid be ligatured, but comparatively little blood can reach the diseased part except by way of the opposite external carotid, provided there be no unusual anastomosis of the ligatured vessel. If the common carotid be tied for disease associated with the branches of the external carotid of the same side, then blood can reach the diseased part, not only through the opposite external carotid, but also by way of the circle of Willis, and the pervious internal trunk of the ligatured vessel.

With a full knowledge of these anatomical facts, and with the great difference in the death-rate of the respective operations, I fail to find an excuse even for ligaturing the common carotid for disease of the region supplied by the branches of the external carotid, except when ligature of the latter vessel is impracticable.

I will now present for consideration the history of two cases of my own, in each of which the external carotids were tied simultaneously for malignant disease involving the inferior maxilla, the floor of the mouth, and more or less of the tongue. In each of these cases repeated operations had been performed for the removal of the disease. A rapid recurrence had taken place in each instance, until the direct application of the knife seemed no longer feasible. The starvation plan appeared to be then the only one to offer any chance for delay to the course of the growth, combined with the greatest degree of comfort for the patients.

Recalling the fact that in the aneurismal growth, upon which I had previously operated, the collateral circulation from the opposite external carotid had reëstablished the circulation of the ligatured side within two months, and believing that it would likewise exercise the same influence in a similar operation for malignant disease, it was determined to tie both external carotids simultaneously, which was done in the first case on February 2, 1885. The incisions for ligaturing were made in the usual situations, and the enlarged lymphatic glands that were found in their course were removed. When the carotids were reached, most unusual anomalies were found. The right common carotid bifurcated be-

neath the posterior belly of the digastric muscle, which was divided to admit of the more easy application of the ligature. On the left side the bifurcation was located behind the hypoglossal nerve, which was drawn down and then the ligature was applied just below the posterior belly of the digastric. On the right side the superior thyroid branch was thought to be seen to arise from its usual position. No branches were found above the point of bifurcation for the distance of one inch, and a catgut ligature was applied at the middle of this space. The lingual and facial branches were not seen on the right side, a fact that caused no apprehension, for I had been informed that the facial had been tied some months before, during the removal of the diseased submaxillary gland of that side. I thought also that the lingual might have been associated with the facial, since this arrangement exists in about 25 per cent. of dissections. On the left side the branches of the external carotid were normally arranged. The lingual was ligatured at its origin, and the trunk of the external carotid was ligatured just below this.

No annoyance took place during the operation other than that due to the slipping off of a catgut ligature from the proximal extremity of the purposely divided facial vein, that had covered the artery in the line of the operation. The operation was done antiseptically throughout. The malignant growth diminished in size rapidly; the pain ceased; the discharge became scanty, thin, and watery, and the ability to speak and to swallow improved rapidly. On the fifth day a portion of the tumor on the right side, corresponding to the former site of the submaxillary gland, sloughed out, leaving an opening an inch in diameter, bounded by sloughing tissue, at the bottom of which could be seen necrosed bone of the lower jaw. It had been ordered that the patient be constantly watched from a fear that hemorrhage might occur. On the night of the 11th, nine days after the operation, the patient was discovered deluged with blood, and he died from its loss before morning, in spite of every possible effort of Dr. Pinkerton, the house surgeon. Even transfusion with saline solution was employed.

It was found that the hemorrhage had taken place from the site of the slough before mentioned. An abnormality of the circulation was suspected at once, and the suspicion was confirmed subsequently by a careful dissection. The facial and lingual branches of the right side arose from a common trunk at the bifurcation. The fatal hemorrhage had been caused by sloughing of some of the starved diseased tissue, into which the stump of the abnormal facial artery had passed. The vessels on the left side were not uncommon in their arrangement. The operation-wounds themselves presented no appearances of an unusual character.

It is seen at once that this case presents very rare anomalies of the circulation. It is very rare indeed that the common carotid arteries do not bifurcate at, or between, the upper border of the thyroid cartilage and the greater cornu of the hyoid bone. I can find no record of the lingual or facial ever having arisen from a similar point, as in the above case. Dr. Wyeth, in his report of 121 consecutive dissections of the external carotid and its branches, found but four instances in which the lingual branch was given off at a fourth of an inch above the bifurcation, and in only one of these did it arise independently of the facial branch. In one instance it arose an eighth of an inch above the bifurcation by an independent origin. The average origin of the lingual in 121 cases was 0.68+ inch above the bifurcation. In these same dissections the facial arose at an average of 0.92+ inch above the point of bifurcation. In no instance did it arise independently within less than a fourth of an inch from this point. In one instance only the lingual and facial arose by a common trunk an eighth of an inch from the bifurcation. I have no doubt that if I had tied the branch at the bifurcation which I had supposed to be the superior thyroid, but which was, in fact, the common trunk of the facial and lingual, the patient would not have died from hemorrhage.

The result of this case emphasizes some important facts, viz.:

1. The tying of the external carotids robbed the growth of so much of its vitality that, notwithstanding it was presumably supplied in part by the lingual of the right side, and also by branches of the pervious stump of the facial of the same side, the diseased tissue sloughed and involved thereby the stump of the facial itself.

2. The branches at the bifurcation should be tied when it appears that neither the lingual nor the facial arise from the first inch and a half of the external carotid.

3. The feasibility of simultaneous ligature of both external carotids for the starvation of malignant growths of the regions supplied by their branches, is emphasized by the effects on the growth in this case.

The number of deaths from ligature of the external carotid alone that may be justly attributed to the operation itself, is somewhat indefinite. Dr. Wyeth reports 67 cases of ligaturing, with two deaths occurring after the operation; but, inasmuch as these two patients were still suffering at the time of their death from the gunshot wounds for which the operation had been performed, it is certainly not proper to charge these deaths to the operation alone. I am able to add to this list 16 others, and in but one of these (my own) did the subsequent death of any bear the least relation whatever to the operation itself.

The amount of objection that may be raised to ligature of the external carotid by reason of the death just reported—a death clearly dependent on abnormalities of the circulation not before described—is a matter that I will leave to others than myself to express. Hemorrhage at the seat of the operation has never as yet proved fatal, and it has, as a rule, been controlled easily by simple means, as pressure, styptics, etc. In a number of instances hemorrhage has taken place at the seat of the injury or of the disease, for the relief of which the vessel was tied, and it has required ligaturing of the common or internal carotid of the same side to control it. But, in no instance, can I find that the opposite external carotid has been tied with the same view.

The second case was performed in Bellevue Hospital, May 10, 1885. It pursued subsequently, in all important respects, a similar course to the first, except that no hemorrhage or sloughing occurred. The patient was discharged from the hospital in one month, much improved, with instructions to report at intervals of a week. He reported at the hospital as requested for the next two months. During this time the growth showed but a little tendency to increase in size. The pain and difficulty in swallowing did not return. However, in the meantime he had developed a profound cancerous cachexia, attended with emaciation and loss of strength. No evidences of internal cancerous involvement were discovered. Finally, he disappeared suddenly, and was not again heard from by myself, even though his recorded address was visited and a thorough inquiry was made to ascertain his whereabouts.

The main objections that are raised against ligaturing the external carotid are the following: 1, the difficulty of the operation; 2, the danger of secondary hemorrhage at the seat of the ligature. It is no doubt true that ligature of the external carotid is not as easily accomplished as that of the common trunk, but this is no reason why it should not be practised in preference to the latter when the comparative results of the two are considered. The linear guides of the two vessels are equally simple. The primary incisions of both are alike uncomplicated, provided the region of the external carotid is not invaded by disease. The deep guides of the external are as plain and unvarying as can be wished. The digastric muscle and the hypoglossal nerve are constant in their relations to this vessel. The lingual vein, the facial vein, and its connections, are obstacles to ligaturing of the external carotid; but, with care, they can be displaced, or they may be divided between two ligatures, and turned aside. The internal jugular vein sometimes encroaches alike on both vessels. The external carotid may be mistaken for the common, as for the internal carotid. The points of origin, size, and direction of the branches of the external should enable the distinction between it and the common trunk to be easily made. The difference in the origin, course, and depth of the two vessels, to say nothing of their differences as to branches, should discriminate between the internal and the external carotids. Finally, if a doubt exists after the ligature is passed, raise the vessel gently from its bed by means of the ligature, and study the effects of the ligature pressure on the branches of the external carotid, and on the trunk of the internal carotid.

Care should be taken not to pass the ligature around both vessels at the bifurcation. This is an error to which the relations and appearances of the vessels in this situation add but little that is reassuring. However, to state the liability of the error should be to signal the danger with sufficient acuteness to prevent its occurrence. It is proper to add in this connection that if ligature of the external carotid be associated with removal of the parotid gland, it should be ligatured as near to the gland as circumstances will permit.

In conclusion I respectfully submit the following propositions:

1. Ligature of the external carotid artery, together with independent ligature of the branches arising from the first inch of its course, is a safe and commendable operation.

2. When the facial and lingual arteries do not arise singly, or by a common trunk from the first inch of the course of the external carotid, the branches arising at the point of bifurcation of the common carotid should be tied.

3. Simultaneous ligature of both external carotids is a rational preparatory measure for operations involving the parts supplied by their branches when dangerous hemorrhage is feared. If the pharynx be involved, the ascending pharyngeal branches should be ligatured also.

4. Simultaneous ligature is advisable as a final expedient to diminish the rapidity of the development of extensive malignant growths when they are nourished by the branches of the external carotids.

5. Ligature of one or both of the external carotids for the cure of aneurismal formations of the branches of the same is not feasible as an independent curative measure.

6. Ligature of the common carotid should not be done for the cure or for the arrest of morbid conditions involving the external carotid or its branches, except as a final resort.

MEDICAL PROGRESS.

POINTS IN THE DIAGNOSIS OF BRAIN DISEASES.—NOTHNAGEL, in an article read recently before the College of Physicians of Vienna, gave the following diagnostic points on the value of headache as a symptom of brain disease:

1. In brain tumors headache is of very little value in diagnosis; we know that the cerebral substance is not sensitive; the pia mater but little sensitive, and the dura mater only, of the cranial contents, is sensitive. Headache occurring in cases of cerebral tumor is explained by tension upon the dura caused by the bulk of the tumor.

2. Headache is present in inflammatory processes situated in the meninges, and more frequently in lepto-meningitis than in pachymeningitis; in lepto-meningitis the headache frequently changes its characters.

3. Headache is present in chronic cerebral hyperæmia and also chronic anæmia; it is questionable whether anæmia alone is the important element in chlorosis, as we see most marked cases of pernicious and intensive anæmia caused by carcinoma in which headache is absent. Headache is rarely present in insular multiple sclerosis; in cerebral abscess its presence and character are extremely variable. The location of the headache gives no certain diagnostic point for the determination of the location of the lesion, although in general terms it may be said in the majority of cases the lesion is where the headache is.

Vertigo, while common in various cerebral diseases, is of little importance; when it is excessive and accompanied by incoördination, such as occurs in diseases of the crura of the cerebellum, it has decided import.

Vomiting is rarely of great value in diagnosis; it aids chiefly in the location of lesions. It can be present in cases in which the amount of blood in the brain is abnormal, and an irritation of the centre of emesis in the medulla oblongata exists.

We are aided by this symptom in diagnosticating lesions of the tissue in the posterior fossa of the skull; for example, tumors which originating in the cerebellum press upon the medulla; or tumors of the medulla or pons.

Fever is an important symptom in but few cerebral diseases. The highest temperature is present in meningitis, especially in its infectious form. But as peritonitis without fever is often observed, so meningitis may run its course without marked rise of temperature. Fever occurs in cerebral abscess and septic phlebitis of the cerebral sinuses; it has then more often the characteristics of septic fever with pyæmic chills, and does not depend directly upon the phlebitis, but upon pulmonary embolism. Fever also occurs in the course of progressive paralysis. The pulse gives no certain criterion for the diagnosis of a given cerebral disease. It is often, however, of value in the abnormalities of its rhythm in beginning meningitis, in the form of regularly occurring *arythmie* (first described by Nothnagel), where a certain periodicity in the variations of the pulse frequence occurs; the increased number of beats endures but a few moments, and is caused by an irritation of the pneumogastric nerve. The respiration gives no information in the diagnosis of brain diseases.

Regarding disorders of speech, aphonia is seldom present, and the location of the lesion which could cause it, in the medulla oblongata, is such that death generally results speedily in these cases. Speech is affected most often in progressive bulbar paralysis, and frequently in multiple sclerosis in patches. Speech is also implicated in progressive paralysis when the origin of the hypoglossus is affected; also in cortical disease of the lower portion of the central gyrus.—*Wiener medizinische Presse*, No. 13.

Peptone Suppositories.—Sauter prepares these suppositories with cacao butter, each containing twenty-five grains of peptone; they are mixed and kept cold to prevent the fat from becoming rancid. In cases where patients cannot be nourished in the normal manner they serve an excellent purpose, fifteen grains of dried peptone equalling two and a half drachms of meat in nutritive value. Children may be given one suppository four times daily; grown persons, two three times daily. The suppository should be lubricated with olive oil, and the rectum previously cleansed by an enema. —*Pharmaceutical Record*, No. 5.

Treatment of Typhoid Fever at Roosevelt Hospital.—Dr. Asta-Buruaga reports, in the *New York Medical Journal* of April 30, 1887, the treatment of forty-five cases of typhoid fever in this hospital as follows:

The treatment was mainly expectant. Equal parts of milk and lime-water constituted the sole diet as long as the fever lasted. Forty grains each of subnitrate of bismuth and pepsin, divided into four doses, were given in the milk daily. Stimulants in the shape of whiskey were ordered according to requirements.

The convalescents were allowed solid food, commencing with tenderloin steak on the tenth to the twelfth day after the subsidence of the fever, and were generally allowed to sit up about five days later.

Small doses of Fowler's solution of arsenic were given, with good results, when the fever was protracted.

Antipyretics were required in several cases. Antipyrine, antifebrine, the cold pack, the cold bath, and the abdominal water-coil were used.

The mortality was 8.88 per cent.

Microbe of Yellow Fever.—Freire, Gibier, and Rebourgeon describe the microscopic appearances and behavior of this bacillus as follows: The microbe is very mobile; grows rapidly in bouillon when taken from the blood and urine; a dark substance, like black vomit, and having its odor, forms at the bottom of the tubes of culture. Inoculation with the blood of those dying with yellow fever produces an identical disease. Culture liquids undergo spontaneous attenuation in a few days. Inoculations with attenuated cultures have been very successful in the hands of the writers.—*Gazette Hebdomadaire*, No. 12.

The Bacterial Treatment of Phthisis.—Filipovitch reported before the Medical Society of Odessa six cases of phthisis treated by Cantani's cultures of bacterium termo in bouillon. Liquid containing the bacteria was flavored with mint and inhaled. Of the six patients three died, two went from the hospital unimproved, one remained. The results obtained were an abundant growth of the bacilli inhaled in the lungs of the patient. The treatment was useless at best; in some cases harmful.—*Les Nouveaux Remèdes*, No. 6.

Formula for Oil of Male Fern.—

℞.—Ol. filicis mar. . . . . ♏45.
Tinct. vanillæ . . . . ♏45.
Syrup. terebinth. . . . . ʒ 6¼.
Gummi arab. pulver. . . . gr. 30.
Aquæ destillat. . . . . ʒ 6¼.—M.

This should be taken at one dose, with an equal amount of milk. Castor oil should be given several hours afterward.—*Journal de Médecine*, April 17, 1887.

How to Evacuate Psoas Abscesses.—Dr. Owen, of London, describes his method as follows: The method of evacuating psoas abscess, which I have adopted in a large number of cases, and which I recommend with confidence, is by a free anterior as well as posterior opening, and by then washing and draining the cavity right through. The first opening I make close above the outer end of Poupart's ligament, using the scalpel until about an inch of the length of the fibres of the aponeurosis of the external oblique has been exposed. I then scratch through the fleshy attachment of the internal oblique and transversalis, and, keeping well below the level of the peritoneum, thrust the director into the swelling. Pus escapes, and the opening is enlarged by the dressing forceps and the finger. A stiff probe is then passed through the abscess cavity and made to project beneath the skin on the outer side of the erector spinæ. With this as a guide, a counter-opening is made in the loin. The large cavity

is then flushed perfectly clean with a warm antiseptic solution, and a drainage tube of the size of a penholder is laid through the chasm for a few days, being afterward replaced by a silk thread. The parts are liberally covered with bulky pads of wood-wool and finely picked oakum in gauze bags; these are kept in position by a towel arranged as a binder, which, for the sake of compression is tightly drawn and fixed with safety pins. Next day the cavity is again washed out, under chloroform, if necessary, the wounds being dressed as before. After this, the less it is interfered with the better; if the temperature do not rise, and the discharge do not soak through, the dressings may be left for three or four days, or longer. From the first day the discharge becomes thin and watery; suppuration in the ordinary sense of the word is at end, and the cavity steadily contracts into a narrow passage.

If the abscess be so small that the surgeon does not feel inclined to attack it from the front, he may readily work down on to it above the iliac crest, on the outer side of the erector spinæ. The scalpel is needed only for the skin incision, the rest of the operation being performed with equal ease and safety by the use of a steel director and the ring dressing forceps—at any rate in children.—*Lancet & Medical Journal*, April 23, 1887.

A SEDATIVE HYPODERMATIC INJECTION.—

℞.—Caffeine . . . . . gr. ½.
Morph. sulphat. . . . . gr. ½.
Atropiæ sulphat. . . . . gr. $\frac{1}{150}$.
Aquæ camphorat. . . . . ♏ xv.

Its use is said to be without the disadvantages of morphia alone.—COCHRANE in the *Revue de Thérapeutique*, March 15, 1887.

OIL OF ERIGERON.—DR. BARTHOLOW writes as follows in the *Physician and Surgeon* for April, 1887:

That oil of erigeron is entitled to the repute it had at one time as a remedy for certain kinds of hemorrhage, I am well assured by recent experiences. Some time since, casting about for a remedy in a case of metrorrhagia that had severely tried my resources, I fell on erigeron oil, but with a rather despairing sense of its probable inutility. I was proportionally pleased to find that it acted admirably. As one case can no more establish the value of a remedy, than one swallow can make a summer, I have since made numerous observations with the view to ascertain its real powers. I am accordingly in a position to re-affirm the statements formerly made, and to express my belief that in oil of erigeron we have a valuable remedy for certain cases of menorrhagia and metrorrhagia, and probably, passive hemorrhages in general. In some cases of *neurasthenia*, it now and then happens that menorrhagia becomes an embarrassing complication; but I have found erigeron oil to act very efficiently, and while it has moderated the flow to proper dimensions, has improved the general condition, and lessened the nervous irritability.

For the most part, the uses of oil of erigeron for the conditions above mentioned are not novel. Finding, however, that it is a really effective remedy in menorrhagia and metrorrhagia, I then had recourse to it in those conditions having their origin in albuminuria, and then it was I ascertained that it checked remarkably the waste of albumen. From this point it was but a step to observe how far this remedy affects the course of Bright's disease—or such chronic forms of albuminuria as are due to tubal and interstitial nephritis and the cases combining these two morbid processes. No attempt was made to arrive at an exact differentiation, if indeed such be possible. It suffices to state that the chronic cases of nephritis united by the common symptom—albuminuria—were included. In the chronic form of Bright's diseases, erigeron oil lessens the amount of albumen, lowers the abnormal vascular tension, and improves the general condition; it has also seemed to have a most favorable action on the headache, the nausea, and other symptoms of uræmic character. Whether it be actually curative in cases not too far advanced, can be determined only by careful and sufficiently protracted trials. Thus far it can be said to promise well.

Oil of erigeron also acts in a very beneficial manner in cystitis, lessening the irritability of the bladder, and diminishing the catarrh. In a case of prostatic disease with very great irritability of the bladder and much catarrh, it seemed to have an excellent effect.

In catarrh of the bronchial tubes, chronic bronchitis, and in cough of a nervous character, I have seen very considerable relief given by it. Indeed, in these affections it has seemed to me to afford as much relief as *terebene*, which has been much vaunted of late, and with justice.

In administering it, I have usually directed it in five drop doses every three or four hours. It may be conveniently dropped on a lump of sugar. It appears to me to do better in moderate doses rather frequently administered, so as to maintain a constant impression, than in occasional larger quantity.

PHTHISIS IN FAMINE.—DR. PORTER, of the Madras Medical College, writes as follows in the *Indian Medical Gazette*, No. 2: In 459 consecutive autopsies made during the Madras famine of 1877–1878, tubercular deposit was found in one or both lungs in thirty men, 13.3 per cent., twenty women, 12.8 per cent., and in one child. The deposit was present in both lungs in eighteen of the men and in sixteen of the women, was confined to the right lung in three of the men, the child, and three of the women, and to the left lung in nine of the men, and in one woman. The disease was latent in eighteen men, thirteen women, and in the child; death having been due to alvine flux in all these, except two men who died from dropsy, and one who died from starvation apparently. In the remaining twelve men, 5.3 per cent., and seven women, 4.5 per cent. of the total, death was due to phthisis pulmonalis, and these are the cases of which it is proposed to treat here. It may be noted that in nine thousand two hundred and sixty-six admissions to the Royapettah Hospital, two hundred and sixty-two, or 2.8 per cent., were from this cause.

A PRESCRIPTION FOR AFTER-PAINS.—GUÉNIOT, of Paris, gives the following prescription:

℞.—Aquæ tiliæ (linden flower water) ℥ 22½.
Tr. digitalis . . . . gtt. 12.
Aquæ lauro cerasi . . . ♏ 15.
Syrup of codeia . . . . ℥ 6½.—M.

This should be taken in three doses in the course of the night, commencing at 9.30. When febrile reaction follows delivery, the prescription is modified as follows:

℞.—Aquæ tiliæ . . . . ℥ss.
Tr. digitalis . . . . gtt. 15.
Aquæ lauro cerasi . . ♏ 15.
Syrup codeia . . . ʒss.
Tinct. aconit. rad. . . gtt. 6 to 10.

Syrup of codeia will be recognized as not belonging to the U. S. Pharmacopœia; the alkaloid codeia is in use in the muriate, sulphate, and phosphate; doses of ⅛th of a grain hypodermatically, ¼ of a grain by the mouth, have been given; 10–15 grains have been given in one day in the treatment of diabetes. The rule usually observed in using codeia is that its dosage is about double that of the morphine salts.—*Les Nouveaux Remèdes*, March 24, 1887.

Long-continued Use of Caffeine as a Heart Tonic.—Huchard in *Revue Générales de Thérapeutique*, April 7, 1887, recommends the following formula:

℞.—Caffeine,
Sodii benzoat. . . . . aa gr. 45.
Ext. stigmat. maidis . . . gr. 90.
Ol. anisi . . . . . gtt. 3.
Ft. pil. 60 in num.
Sig.—Four to six pills daily.

Cataract Produced by Sound.—Von Stein, of Moscow, has performed the following interesting experiments, which are quoted in the *Ophthalmic Review* for April, 1887:

The experiments were made upon guinea-pigs. Careful observation in every case showed that the media of the eye were clear at the outset, thus excluding the natural opacities sometimes observed in very young animals. The animal was placed in a box to which an electric tuning fork was attached. Here it was kept for several days before the fork was set in action, in order to exclude the possible influence of the confinement in the box, which admitted no light.

Experiments, eighteen in number, were made upon very young animals, with a positive result in every case.

In the first case detailed the animal was two days old. The tuning-fork gave the note D, 100 vibrations per second. The animal was at first restless, and squeaked. Pulse and respiration quickened. From three to four hours later the pupils were widely dilated and sluggish. After about twelve hours the posterior lens surface showed a stellate opacity, the rays of which were feather-like, especially toward the equator; there was also a general slight cloudiness of the lens. These appearances lasted about twenty-four hours. Gradually the central portion became clearer, while the star faded and finally disappeared. Meanwhile, however, three grayish-white triangular opacities made their appearance at the equator, and gradually extended toward the centre, but did not reach the latter. In four or five days all these changes had vanished, the fork acting continuously meanwhile.

With a three days' old guinea-pig, and a fork of 250 vibrations, a stellate figure appeared on the anterior lens surface at the end of twenty-four hours, and on the posterior surface the following day; the further course was the same as in the former case.

With a five weeks' old animal, and a fork of 100 vibrations, white opacities appeared after about forty-eight hours around the whole equator of the lens; all opacities disappeared in a week.

In eyes enucleated for examination was found sometimes anterior stellate cataract, sometimes posterior stellate cataract, sometimes posterior cortical cataract, or all these varieties in combination.

In adult animals no changes were produced. The phenomenon was exhibited to nearly all the oculists in Moscow.

The author expressly declines to advance any hypothesis to account for the facts observed, but we may permit ourselves some speculative consideration of the matter. An analogy at once suggests itself between the effect of this terrifically loud music on the newborn guinea-pig and the lental disturbance which is known to follow convulsion in the human infant. There is much evidence to show that the tender growth of the human lens may be disturbed or arrested *in utero* by shocks to the system of the mother; and there can be little doubt that the nutritive disturbance which occurs during infantile convulsions suffices to damage the lens fibres then in process of formation. We can well imagine that twenty-four hours' confinement in the resonator of a tuning-fork would powerfully impress the nervous system and the nutrition of a more vigorous being than a newborn guinea-pig; during the period of infancy a lental opacity seems a not improbable expression of such disturbance. It is not necessary, we imagine, to regard the cataract as a direct vibratory disturbance of the lens. It would be interesting to know whether the infant animal was separated from its mother during the ordeal, whether its temperature was maintained, whether it obtained and willingly took a normal supply of nourishment during the period in question, and whether any other signs of perturbation were present. Whatever be the explanation, the fact is most interesting.

A Vermifuge Powder.—

℞.—Calomel . . . . . gr. 2¼.
Santonine . . . . . gr. 1½.
Sacchar. lactis . . . . gr. 15.—M.

This powder should be given in the morning, when the stomach is empty, in a little honey. The dose is for a child four years old.—Boymond, in *Journal de Médecine*, April 17, 1887.

Vaccinations against Yellow Fever.—Freire, Gibier, and Rebourgeon, report their results as follows (6524 patients were treated):

The mortality in Rio Janeiro, from January, 1885, to September, 1886, was 1675, of whom only 8 had received preventive vaccination; mortality rate among the non-vaccinated, 1 to 100; among the vaccinated, 1 to 1000.

The official bulletins show no epidemic during this time, a result not obtained for thirty-five years previous. The vaccination was gratuitous, and wholly inoffensive. —*Gazette Hebdomadaire*, April 8, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,
PER ANNUM, IN ADVANCE, ... $ [illegible]
SINGLE COPIES, ... 10 Cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding [illegible] letter.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MAY 14, 1887.

TYPHOID FEVER IN DRINKING WATER.

THE value of any source of supply of drinking water has been shown by Koch's recent researches to depend largely upon the number of bacteria the water contains, and the present great desideratum of the water analyst is a simple, unmistakable test for their identification. It will be remembered that Dr. Prudden, in his recent biological study of Hudson River ice (THE MEDICAL NEWS, March 26, 1887), while he found large numbers of various bacteria in the water, failed to discover any pathogenic microorganisms, although he strongly suspected their presence. DR. THOINOT, however, we learn from a recent number of the *Gazette Hebdomadaire*, has been more fortunate, and has detected the bacilli of typhoid fever in water taken from the Seine very near the point at which the supply for the city of Paris is obtained.

The French have given much attention recently to the contagion of typhoid fever, and they have especially studied its bacillus. Our readers will recall the recent interesting case of a family at Pierrefonds near Paris, who were inoculated with the bacilli after a single use of contaminated water (MEDICAL NEWS, December 11, 1886), and the epidemic, in 1885, at Plymouth, in our own country, by which nearly a whole village was decimated by the careless emptying upon the ground of the undisinfected excreta of a single typhoid fever case (*Ibid.*, May 16, 1885), as well as the investigations of Chantemesse regarding the influence of disinfectants upon the typhoid germ (*Ibid.*, April 30, 1887). The persistence of life and the continued virulence of the typhoid bacilli after exposure to the atmosphere and the mechanical effects of a body of flowing water are questions of the greatest importance. It is well known that the diffusion and oxidation of inorganic poisonous matter in running water is Nature's greatest provision for maintaining its purity; but whether poisonous protoplasm undergoes like destruction is not so certain. We may hope that ptomaines developed in an infectious disease and voided with the dejecta will be readily oxidized and decomposed, but if the bacilli of such diseases are to survive their transit through various channels until they appear as living and virulent bodies in our water supply, the danger of infection is greatly increased.

Prudden's investigations upon the presence of bacteria in ice have dispelled the common belief that freezing purifies water. Similar investigations in Germany have yielded identical results. As Sternberg has found the death temperature of the typhoid bacillus to be 132.8° F. (THE MEDICAL NEWS, April 30, 1887), the most rational and convenient germicide at our disposal is heat, and should the slightest suspicion exist regarding the purity of a water to be drunk it should be thoroughly boiled.

It is still safer, however, to strike directly at the source of danger by disinfection of excreta immediately upon their discharge. For this purpose the standard solutions of chloride of lime or of bichloride of mercury and permanganate of potassium, recommended by the Committee of the American Public Health Association, in THE MEDICAL NEWS of April, 18, 1885, should be in common use, and nurses and attendants should be familiarized with the simple procedures necessary for disinfection.

The examination of water to determine its fitness for drinking purposes is becoming recognized as largely a bacteriological study; and it will be one of the most substantial achievements of the bacteriologist when tests for pathogenic bacteria in water are brought into common use.

THE AFTER-TREATMENT OF CATARACT.

IT has recently been alleged that a revolution has occurred of late in the after-treatment of cataract operations, and in the last report of the Presbyterian Eye, Ear, and Throat Charity Hospital of Baltimore, Dr. J. J. Chisolm presents the most enthusiastic statement concerning it. He says that

"In May, 1886, eight months since, a series of experiments were commenced at this hospital, having for their object the doing away with much of the restraint deemed heretofore needful for the successful treatment of cataract patients. At that time in all parts of the world there was a uniform method of treatment in the hands of all eye surgeons. Immediately after an operation every cataract patient had both eyes bandaged with heavy compresses so as to exclude all light. They were then put in dark rooms confined to bed, lying on their backs, with instructions to keep very quiet. They were restricted in their diet, and food was given

to them lying down. . . . . The revolutionary treatment which was instituted at this hospital consists in substituting a strip of the thinnest isinglass plaster for the thick bandages and compresses. . . . . Light sufficient to permit of reading to patients was admitted into the chambers. Patients were not confined to bed, but were permitted to dress daily and eat their usual meals, in this way removing all restraint as to their diet. . . . . The experience of this hospital were published in a medical journal, and so important was it considered that it was copied from one to another till it went the rounds of the medical press abroad as well as at home. . . . . The good work done at our Charity Hospital is evidently not restricted to Baltimore or even the surrounding States. It is far-reaching, extending to very distant countries and to people who speak in unknown tongues their gratitude for release from over-careful, and at all times very annoying, treatment, now proved to have been always injurious."

While this statement may be well calculated to awaken the enthusiasm of the friends and patrons of the hospital, for whose reading it seems, primarily, to have been prepared, and will serve to refresh and invigorate "that local pride which is peculiar to London, Paris, Timbuctoo, and Little Pedlington," when placed before the profession it is likely to call forth criticism as to its accuracy.

What are the facts? For ten or fifteen years, as he states in the *Archives of Ophthalmology* for September, 1886, Dr. Charles E. Michel, of St. Louis, had "discarded bandages and darkened rooms, closing the eye with a single piece of gold-beater's skin one and a quarter inches long by one-half inch wide," and, he says, "I never had any bad results supervene which I could reasonably suspect were even remotely due to this mode of treatment."

When Dr. Chisolm was in St. Louis in May, 1886, at the meeting of the American Medical Association, he stated, by request, before the Section on Ophthalmology, one afternoon, what he had learned that morning, of Dr. Michel's plan of treatment, adding that he thought it seemed reasonable, and that he proposed to give it a trial when he returned to Baltimore.

While we may credit originality to Dr. Michel, he cannot establish any claim to priority in the matter. Twenty years ago, Dr. Levis, in his services at the Pennsylvania Hospital and Wills Eye Hospital in this city, and in private practice, discarded the use of the bandage, substituting adhesive plaster applied to the lids, and keeping patients in undarkened rooms. His plan of dressing and treatment was described in the *Archives of Clinical Surgery* for 1876, page 76, by Dr. John B. Roberts; and we know that Dr. Levis and Dr. Roberts have employed it ever since. Moreover, at the last meeting of the American Ophthalmological Society, Dr. C. R. Agnew said:

"Thirty years ago, coming back from abroad, I adopted the plan, learned of Wilde, of Dublin, and employed also in the Royal London Ophthalmic Hospital, of closing the eye after cataract operation or iridectomy with two narrow strips of isinglass plaster, each one-fourth of an inch wide, placed across the centre of the palpebral slit. For many years I used that method exclusively, It was not until Gräfe so influenced us that I resorted to the use of a modified method of bandaging. In my experience it has never been the practice to incarcerate patients, after a capital operation on the eye, in a dark room, The institutions with which I have been connected have always been as light as any other hospitals."

It seems scarcely necessary to pursue this subject further; we have no desire to rob Baltimore of her due. We freely admit that the change referred to may have constituted a great improvement in the treatment of cataract cases in the Presbyterian Eye, Ear, and Throat Hospital. Unquestionably, to the genius of Baltimore belongs the credit of first calling this change of treatment a "revolution," and of so proclaiming it to "very distant countries;" and we earnestly desire that the stream of gratitude "in unknown tongues" may continue to pour upon her, to the honor of her institutions and the emolument of her surgeons. But as to the after-treatment of cataract cases, a conscientious regard for the truth compels us to say that some good surgeons dispense with the bandage, and have done so for thirty years or more; a larger number of good surgeons prefer to use it; and the amount of restriction advisable is not fixed, but varies with the circumstances of each individual case.

DEATH FROM ELECTRICITY.

SINCE electricity has become the winged Mercury of our time a familiarity has arisen which has bred a partial indifference to the dangers of the electric apparatus now in common use. Within the past week two cases of sudden death from such cause, occurring within two or three days of each other, have been reported.

While our knowledge of the phenomena caused in the human body by electricity is not inconsiderable, we know comparatively little regarding death from electric shock. We find that practical electricians recognize a marked difference in the susceptibility of different persons to electricity, and only employ men to work upon the electric light, who, after trial, are found to be not shocked by the ordinary manipulations which are deemed entirely safe. At the inquest upon a recent fatal case, a workman was brought before the jury, who had severed a circuit of forty-eight lamps, possessing an electric force of over 2000 volts. Although made insensible by the shock, and fastened by muscular spasm to the wires, he was rescued by his comrades. The length of time that he was subjected to this tremendous shock, which was not only the primary current but the current of reaction as well, was several minutes. He recovered consciousness very soon, and although

his hands were severely burned, he made a good recovery.

In one of the recent fatal cases, the workman was splicing a circuit: a projecting piece of severed wire at the junction of the positive and negative wires is supposed to have touched his face while his hand upon the other wire completed the circuit. He thus "shunted" a current of about 2700 volts, from fifty-eight lamps. When we remember that the resistance of the human body, from one hand to the other, is seven or eight times that of the Atlantic cable, and that from the side of the face to the opposite hand is about 5000 ohms, while the resistance afforded by the circuit of fifty-eight lamps on which the man was working was not more than 300 ohms, the reason of the shock is apparent. The shock received in this case was much less than that in the first accident, where the circuit was deliberately cut and the powerful current of reaction was added to the original force. It is possible that had the workman in the second case been promptly removed from the wire he might have been resuscitated; but the influence of individual susceptibility must be an important factor in recovery.

Acting upon this fact, it is the invariable rule of one of our largest electric lighting companies, that when a workman goes upon a pole, or applies tools to the mechanism, the wire or lamp is to be touched by the finger tip; if an unpleasant shock is received, work is not to be done at that time, or extra precautions are to be observed. It is also a rule that the circuits are tested at a certain hour each day so that workmen upon the line may avoid the lamps at this time. Machinery becoming disabled is not to be investigated by its attendant workman, but the superintendent is to be notified. With these precautions work upon electric machinery is not more dangerous than upon other mechanisms. As to its mortality, the superintendent of the company above referred to, was able to recall but nine deaths in different American cities, and in various companies in seven years, and most of these, he said, were caused by carelessness.

As to the *modus operandi* of the shock, the post-mortem examination of the recent case in this city revealed extensive fluidity of the blood, and the disintegration of its corpuscles as the most noticeable condition present. At a meeting of the French Academy of Sciences, on April 4, 1887, ARSONVAL reported, according to the *Gazette Hebdomadaire*, of April 8, 1887, some recent studies upon the mode of death by electricity, which showed that its action was—

1. Direct or disruptive, causing instantaneous, irremedial death by disintegrating effects upon the nervous, vascular, and muscular tissues, which lose instantaneously their physiological properties.

2. Reflex, exciting the bulbar centres in a manner similar to mechanical irritation. In this category is the action of the generators of electricity used in various industries. This reflex action is accompanied by the phenomena of "action at a distance," studied by Brown-Séquard under the names of inhibition and dynamic generation. These phenomena are thought to be the cause of the variation in the effects and lesions produced by the electric shock in different organisms.

Death by shock from generators used in industrial mechanics is thought to be due to reflex arrest of respiration and resulting asphyxia; and the practical deduction from the observations made, is that artificial respiration and other resuscitating measures should be employed in such cases, and with reasonable hope of success if aid be given with sufficient promptness.

PILOCARPIN IN LUNG AFFECTIONS.

THIS well-known alkaloid of jaborandi is experiencing the fate which has befallen so many medicines introduced to the profession with too laudatory statements. For three or four years after its discovery in 1876, the journals were full of observations, experimental and clinical, relating to its virtues, and it was felt that a really valuable addition had been made to the Pharmacopœia. Of late it has lost favor, and there are large institutions in which it is not given once in six months, and we know practitioners who have not ordered a dose for two years. This disuse has arisen in great part from the unpleasant symptoms which occasionally follow its administration, particularly the collapse and vomiting, with depression of the circulation; but too much has perhaps been made of these untoward effects. At any rate, we are glad to see in *Berliner klin. Wochenschrift*, No. 15, 1887, that RIESS, the former Director of the Berlin City Hospital, calls attention to its value in certain lung diseases. In 1880–81 he first employed pilocarpin for the purpose of increasing the secretion of the bronchial mucous membrane, and has ever since made use of it with the most satisfactory results. In cases of old and obstinate emphysema and bronchitis, with dry catarrh and attacks of asthma, the hypodermic administration of $\frac{1}{2}$ to $\frac{1}{7}$ of a grain usually caused a copious secretion from the bronchial mucous membrane, and brought relief after two or three injections. In cases with dyspnœa of a paroxysmal character the action was often remarkably prompt. Possibly also in true bronchial asthma it would be of service, inducing relaxation of the mucous membrane by the copious transudation.

In pneumonia, Riess has used pilocarpin in the stage of resolution, to hasten the removal of the exudate. In six cases the injection was begun the

day after the crisis, and repeated for six days. Resolution took place rapidly, with the expectoration of a copious frothy sputum. In two instances of delayed resolution the action was very prompt.

In the whooping-cough of older children $\frac{1}{7}$ of a grain daily for from eight to fourteen days was followed by a reduction in the frequency and intensity of the spasms, and the thick, tenacious mucus was more readily expectorated.

In a prolonged experience with the drug, Riess has not seen any dangerous results, though vomiting may occur after the first dose. In the above-mentioned conditions the indications point clearly to its use, and in this direction the remedy is worthy of a more extended trial than it has heretofore received.

Dr. Alfred Meadows died suddenly at London, on April 19th, from heart failure caused by acute abdominal pain: he was aged fifty-five.

Among many important positions which he held he was physician-accoucheur to St. Mary's Hospital, and lecturer on midwifery and the diseases of women and children. He had been very active as secretary of the Obstetrical Society, and in 1884 was first president of the British Gynecological Society. He was the author of a manual of Midwifery, and translated and compiled several important works.

The sixth German Surgical Congress, which met last month at Berlin, elected Volkmann, President, and Bergmann, Vice-President, and Billroth and Spencer Wells, honorary members.

Dr. Brown-Séquard has just been elected President of the Société de Biologie, to serve for five years.

REVIEWS.

Medical Electricity. By Roberts Bartholow, A.M., M.D., LL.D., Professor of Materia Medica, General Therapeutics, and Hygiene in the Jefferson Medical College of Philadelphia, etc. Third edition. 8vo. pp. 304. Philadelphia: Lea Bros. & Co., 1887.

The fact that this work has reached its third edition in six years, and that it has kept fully abreast with the increasing use and knowledge of electricity, demonstrates its claim to be considered a practical treatise of tried value to the profession.

The matter added to the present edition embraces the most recent advances in electrical treatment.

The author's experiments have led him to believe that the direction of currents of galvanic and faradic electricity has less influence than the strength of the currents in producing given effects; this fact is of importance in estimating the effect of currents upon the vaso-motor and sympathetic systems.

The German nomenclature for the normal formulæ of electro-physiology is adopted in the present edition.

The interest which the recent study of neuritis has excited will be gratified by a description of its electrical treatment. Apostoli's treatment of chronic metritis and endometritis is described, and the value of electricity in gynecology is clearly set forth. In extrauterine pregnancy the author considers electrical treatment incomparably superior in the hands of any but an accomplished laparotomist, to laparotomy. Newman's treatment of urethral stricture receives full exposition. The galvanocautery and lamp, and the "electric osteotome" of Dr. Roberts, of New York, are fully described. Newman's recent treatment of enlarged prostate and villous granulations of the bladder, is quoted in the language of its originator; and a description of the electric light in its recent applications to medicine, and apparatus for producing heat, with a discussion of thermo-electricity, close the volume.

The illustrations are abundant and clear, and the work constitutes a full, clear and concise manual well adapted to the needs of both student and practitioner.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, April 27, 1887.

The President, Charles McBurney, M.D., in the Chair.

CASE OF FRACTURE OF THE FIFTH CERVICAL VERTEBRA, WITH RECOVERY.

Dr. Gerster presented a patient who had recovered from this injury, and related the following history: E. H., æt. thirteen, while bathing at the seashore on August 6, 1886, dove into shallow water and struck his head so violently against the bottom that he was stunned. He was taken from the water by his playmates and was carried to a neighboring hotel. The local physician found that there was paralysis of the left upper and lower extremities, and of the bladder and rectum. There was also paralysis of the right upper extremity (with the exception of the shoulder-muscles) and paresis of the corresponding leg. He saw the boy in consultation on the 8th of August, and found, on examination, that the spinous process of the fifth cervical vertebra was depressed and gave marked crepitus on stretching the patient's neck and then letting go of it. The spinous process of the fourth was abnormally prominent. The head could not be held up without support, and when released it fell over to one side if the boy was supported in a sitting posture. Not knowing that his neck was broken, the family had him sit up in bed, when he complained of severe pain in his head. Weight-extension was applied, and the bladder was emptied by catheter. On the 10th of August he was able to pass his water naturally. By the 25th there was a marked improvement in the right side. The patient was then brought to the city and was placed under Dr. Lange's care at the German Hospital. In October he began to walk with crutches, and he has continued to improve ever since. His gait is still atactic, while the left arm exhibits evidences of ulnar paralysis, especially the "main en griffe," the

extension of the hand on the arm is incomplete, and as soon as we let go of it it at once recovers its former position. The muscles of the arm and forearm are atrophied and their condition has been but slightly improved by massage and galvanism. No abnormality of outline was to be detected in the neck now, the fracture having become firmly consolidated, while the irregularities observed in the projection of the spinous processes had been smoothed down by the callus. A symptom frequently described by authors—*i. e.*, priapism, had not been present.

DR. PETERS asked how the extension had been obtained.

DR. GERSTER replied, by means of Glisson's apparatus, and also by elevating the head of the bed. In reply to other questions, he said that the patient had experienced relief within thirty-six hours after extension was applied; that a prominence had been felt in the pharynx, which was quite distinct. The patient probably recovered because there was no interference with respiration. There was no paralysis of sensation. No displacement at present could be felt.

CASE OF OLD THORACIC FISTULA CURED BY ESTLANDER'S OPERATION.

DR. GERSTER presented a patient with this history: J. S., æt. twenty-one, a clerk, had empyema of the left side for upward of a year. When he came under his care he had lateral curvature, a large fluctuating swelling, and a sinus in the back, from which issued a profuse, fetid discharge, while he was much emaciated, and suffered with hectic, sweating, etc. On August 25, 1879, Dr. Gerster incised the extensive burrowing abscesses of the thorax, resecting portions of the seventh and eighth ribs, in order to gain room for a large-sized drainage tube. There was a rapid improvement in the patient's condition, but the cavity did not close. On January 3, 1880, he exsected portions of the third, fourth, fifth, sixth, and seventh ribs in the axillary line, making a vertical incision, the exsected pieces increasing in length from above downward. The wound was packed with gauze, to prevent too rapid repair of the ribs, and a wide bandage was applied. On April 11, 1880, the patient was discharged cured, the cavity having healed, leaving a deeply depressed cicatrix. At present there is no lateral curvature, the ribs have entirely reformed, and make normal respiratory excursions, and there is proper expansion of the left lung.

DR. BRIDDON asked if Estlander did not make a longitudinal incision.

DR. GERSTER said that he did, but the important point was the principle of removing the ribs; it seemed better to make a single vertical incision rather than a number of horizontal ones.

DR. BRIDDON remarked that he had once removed five ribs by a single vertical incision, and had been criticised at the time for so doing, on the ground that there was more hemorrhage than there was when the incision was longitudinal.

DR. GERSTER thought that the amount of hemorrhage was not determined by the length of the incision alone. In his own case there was but slight bleeding, since the principal vessels could readily be seen and secured before they were divided. In reply to a question by D Sands, he said that the piece removed from the upper rib was not over one and a half inches in length, that from the lower rib about two and a half inches. The thickened pleura was not removed.

DR. SANDS asked Dr. Gerster if he had any idea as to the nature of the nerve-lesion in the case of fractures of the vertebra.

DR. GERSTER replied that, since sensation was not impaired, he was disposed to believe that the motor roots of the cervical nerves on the left side had been subjected to crushing or pressure by fragments, portions of the trunks supplying the left upper extremity, probably being destroyed in their continuity. The transient paralysis of the bladder, rectum, and the extremities of the right side seemed to have been dependent on pressure by bloody effusion. It was very doubtful that weight extension caused the disappearance of these paralyses; it was more probable that absorption of the effused blood was followed by improvement. However, the patient derived a great deal of comfort from the fixation afforded by the extension.

DR. J. D. BRYANT read a paper entitled

THREE CASES OF LIGATURE OF THE EXTERNAL CAROTID ARTERY, IN TWO OF WHICH BOTH VESSELS WERE TIED SUBCUTANEOUSLY.

(See page 542.)

DR. SANDS remarked that he had listened with interest to the paper just read, but that he could not agree with some of the conclusions arrived at by the author. It was doubtless well to reiterate the fact that, on the score of both safety and efficiency, ligature of the external carotid artery should often be performed in preference to that of the common trunk. But the principles advanced of resorting to ligature of the external carotid as a preliminary step to the excision of tumors have long been regarded as unsound. The formal ligature of the external carotid, although quite practicable, is not an easy operation, and ought not to be performed unnecessarily. Experience has proved that large tumors of the face, and especially those situated in the parotid region, can be successfully removed without adopting the precaution referred to. Moreover, it has been shown that the preliminary ligature of the principal trunk does not always have the desired effect of preventing hemorrhage, which is maintained by the anastomotic branches.

Dr. Sands also dissented from the proposal made by the author of the paper to tie the external carotid with the view of preventing or retarding the progress of a malignant growth. The anastomotic channels are so numerous and free that little or no benefit can be expected from such an operation, and he believed that the uselessness of this practice has been freely demonstrated.

DR. WEIR agreed with Dr. Sands in his last criticism. Practically he thought that it must very rarely happen that the surgeon was obliged to tie the external carotid before excising the jaw. He had never thought of doing this in cases of maxillary tumors, because it is possible to ligate vessels as they are exposed, or the facial artery may be compressed by means of a clamp introduced into the mouth. The gush of blood that follows the first incision seems very large at first, but the hemorrhage is soon checked.

DR. STIMSON testified to the fact that in one of the cases reported there was a rapid diminution in the size

of the growth, and also in the amount of the discharge, when the lingual was not tied, although the tumor was within the mouth. Hence the diminution of a growth does not seem to be dependent on the diminution of the blood-supply.

DR. BRYANT said that he was aware that ligation of the artery for the arrest of morbid growths is not always successful. There are many cases on record in which the hemorrhage attending excision of the jaw has been diminished by preliminary ligation of the external carotid. In his own case the disease rapidly recurred, and the use of the knife did not seem to be justifiable. After ligation of the arteries, whether less blood was supplied to it or not, the vascular morbid growth became anæmic, sloughing occurred on the right side, and the patient recovered the ability to swallow and articulate. One tumor was kept under observation for two months, during which time it did not increase in size. There is no reason, he added, why, if we can prevent blood from going to a part by tying the artery, we can not delay the growth of a tumor by diverting the blood from it.

DR. SANDS called attention to the fact that there is no true analogy between the operation of tying an artery for the cure of an aneurism, and the same procedure as practised for the arrest of a malignant growth. In the former case, the object aimed at is to prevent, or retard, the current of blood in the aneurismal sac, and thereby to accomplish by coagulation a complete and permanent cure. But the tying of an artery in the case of a growing tumor can at best be regarded as a palliative measure; and its value, in this respect, is certainly problematical. We should not confound cause with effect. The growth of a tumor is not determined to any extent by its supply of blood. On the contrary, the supply of the latter is generally equal to the demand, the vessels enlarging to keep pace with the rate of growth. When the anastomotic channels are free, ligature of the main vessel may have very little influence in diminishing the vascularity of the parts to which its branches are distributed. He once noticed, after tying the common carotid, that pulsation could be felt six hours later in the temporal artery on the side of the operation. He referred to a case cited by Erichsen in which both common carotids and one vertebral artery had been gradually obliterated from disease and operation combined; yet the nutrition of the brain was maintained by the remaining vertebral. Opinions expressed in regard to the retardation of a growth, caused by the ligation of an artery, are usually so vague as hardly to be within the limits of scientific inquiry. The utility of the practice was evidently not demonstrated in the case of Dr. Bryant's patients, one of whom died from hemorrhage after the operation, while the other continued to be unrelieved.

DR. STIMSON desired to place on record the fact that he had tied the external carotid, several years before, in order to arrest the growth of epithelioma of the mouth; the patient lived for several weeks after the operation, but there was no evidence that any benefit had resulted from it.

CASE OF PAROVARIAN CYST THAT DEVELOPED EXTRAPERITONEALLY.

DR. GERSTER exhibited a specimen, and related the following facts concerning the case: The patient from whom it was removed was a young married woman, æt. twenty-one, who became pregnant about four months after marriage, and had an abortion. Examination at that time revealed a sessile tumor occupying the right iliac fossa. The patient was seen by a gynecologist, who advised waiting until a pedicle should form. The reader examined the lady in March, and found that the cyst in question was about the size of a child's head, and filled the right iliac fossa; it was immovable, and seemed to be generally adherent. On the 6th of April Dr. Gerster performed excision of the tumor. On dividing the tissues in the median line, down to the usual situation of the peritoneum, that membrane could not be found, but the cyst was exposed and tapped, a clear, yellowish fluid being withdrawn. The sac was then enucleated with the fingers, adhesions being successively ligated and divided, until the pedicle was reached, deep within the pelvis, near the right cornu of the normal uterus. The cyst was of the parovarian variety, and had grown outward between the layers of the broad ligament, until it reached the parietal peritoneum, which it had dissected up from the iliac fossa, following the course of an extraperitoneal abscess. A piece of peritoneum, about one-third of a square foot in area, was excised. Two drainage tubes were introduced, and the wound was closed with plate sutures.

On the day following the operation the patient, who had reacted well, suddenly developed tympanites, while her pulse became very rapid, and her respirations rose to forty; in fact, she appeared to be in a condition of shock similar to that observed after severe blows upon the abdomen. The tympanites was spontaneously relieved on the fourth day; her pulse improved under stimulation by enemata of brandy and hot water, and she subsequently made a good recovery, her temperature falling from 101.7° to normal. Bloody urine and some uterine flow were observed for a few days. The patient was out of bed on the thirteenth day.

The interesting feature in the case was the sudden development on the second day of symptoms of shock, although there certainly could not have been what is commonly called shock at such a late period; neither could peritonitis have appeared and disappeared so rapidly. There were no evidences of septic trouble, no vomiting or abdominal tenderness, but the main disturbance seemed to be in the circulation. The reader suggested, as a probable explanation, the occurrence of a localized coagulation—necrosis in the widely detached peritoneum, leading to hyperæmia of the contiguous serous covering of the intestines, which resulted in paralysis of the gut, with consequent tympanites. There may have been an attempt at the formation of adhesions; because, when the patient's bowels were moved on the fifth day, by a saline cathartic, she said that "something seemed to give way."

DR. SANDS asked if the symptoms might not have been due in part to the pressure of the bandage, which became tightened in consequence of the tympanites. The reporter said that the dressings were quite loose, and that, moreover, there was no change after they had been removed.

DR. GERSTER, in reply to an inquiry, said that all the sutures had held. Four of them were removed on the fifth day, together with the drainage tubes.

Dr. Weir thought that some of the sutures might have given way. He had noticed that silver wire sutures occasionally gave way soon after the operation, perhaps in consequence of change in the metal.

Dr. Briddon could not believe that necrosis of the peritoneum had occurred, and been so quickly arrested.

Dr. Gerster explained that the existence of this condition seemed quite probable, in view of the fact that such a large piece of peritoneum had been detached. Dead tissue within the abdominal cavity might be absorbed, provided that it remained aseptic, as was frequently noticed after the removal of pieces of omentum. The nerves of the peritoneum, which were closely related to those of the solar plexus, might be so affected by these aseptic necrotic changes, that serious symptoms might be produced. In reply to a question by Dr. Briddon, he said that this nerve-irritation would have accounted for the symptoms presented in the case under discussion.

Dr. Stimson could hardly see how such a transient necrotic process could exist.

Dr. Briddon thought that the fluid removed from the cyst presented an appearance different from that usually observed in parovarian cysts.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, [illegible], 188[illegible].

H. Augustus Wilson, M.D., in the Chair.

Dr. H. M. Fussell read a paper on

DIAGNOSTIC VALUE OF TUBERCLE BACILLI IN SPUTA.

He said that his personal observations enable him to confirm the conclusions of numerous authorities, that the presence of tubercle bacilli in sputa is diagnostic proof of the presence of tuberculous phthisis. In the examination of his cases he used a modification of Gibbe's method suggested by Prof. William Osler. The sputum was spread as thinly as possible on a clean cover-glass, allowed to dry in the air, and passed quickly two or three times through the flame of a spirit lamp. The cover-glass was then immersed in solution of magenta, manufactured by Beck & Co., and allowed to remain fifteen minutes after first slightly heating. It was then decolorized in alcohol, acidified with hydrochloric acid (four or five drops to a watchglassful of alcohol), and examined under a moderately high power. In this manner the whole proceeding can be done in less than half an hour. If bacilli were not found by the rapid method, however, the glasses were allowed to remain in magenta over night, and then examined as before. The power used at first was Hartnack No. 9 immersion, afterward 7 objective, 4 eyepiece. Lower power may be used, however, by one perfectly familiar with the bacillus. He has used a Zentmeyer one-fifth with A eyepiece.

The sputa from 100 cases of lung disease were examined.

The sputa of 84 cases contained tubercle bacilli. In 79 of these there were evident physical signs of phthisis. In 5 there were few or no physical signs of phthisis. The diagnosis was made by the presence of bacilli in the sputa.

In 16 cases tubercle bacilli were *not* found in the sputa. In 8 of these phthisis was *not* suspected from the physical signs, and no bacilli were found; and in 8 the physical signs led to a suspicion of phthisis, but the absence of tubercle bacilli and the subsequent history proved it to be absent.

It is in these doubtful cases that the presence or absence of tubercle bacilli in the sputa is of such practical value.

Dr. William Osler said that the importance of the tubercle bacillus in the sputum as a means of diagnosis is not sufficiently recognized by the profession. The technical skill required is not very great, and the time required with the rapid methods of staining is not more than fifteen to thirty minutes. He had succeeded in demonstrating the bacillus within five minutes of the time that the sputum was put upon the slide. This examination is particularly serviceable in just those cases where the evidences of disease are very slight. Only within the past few weeks there was in the University Hospital a man without any pulmonary signs, who had been failing in health and had slight fever. The condition was attributed to some obscure abdominal disease. Finally a suspicion arose that there might be some trouble with the lung, and the sputa were examined and the bacilli found. The signs of phthisis have since developed. The power required for these examinations need not be, as Dr. Fussell says, very high.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May [illegible], 188[illegible].

The President, A. Jacobi, M.D., in the Chair.

Dr. Newton M. Shaffer read a paper prepared by himself and Dr. R. W. Lovett, of Boston, on

THE ULTIMATE RESULTS OF THE MECHANICAL TREATMENT OF HIP-JOINT DISEASE; AN ANALYSIS OF FIFTY-ONE CASES OCCURRING IN THE SERVICE OF THE NEW YORK ORTHOPÆDIC DISPENSARY AND HOSPITAL.

All the cases were taken exclusively from dispensary cases; all private patients and all hospital cases being left out of the account. All cases of excision were also eliminated. Having referred to the difficulties met with in sucessfully carrying out a course of treatment among dispensary patients in any chronic trouble, he said that these difficulties were especially marked in cases of such affections as hip-joint disease, where the treatment was a matter of years and involved the use of mechanical apparatus. In private practice the results obtained were, of course, much more favorable.

No case was considered which had not been treated exclusively in the service of the Orthopædic Dispensary.

No case was considered which had not been discharged cured; nor which had not been cured at least four years—that is, in which at least four years had elapsed since the patient had been discharged cured; nor which had not been under treatment for at least two years. *All* the cases which came under these exclusive conditions were reported.

The period studied in the investigation was the five years from 1877 to 1882, and during this time there were

treated at the institution altogether 778 cases of hip-joint disease. Of these 168 cases, or 21 per cent., were discharged cured, 261 discharged relieved, 49 discharged for neglect of orders, and 6 discharged as incurable; while 64, or 6.4 per cent., died. Of the deaths, 20 were due to tubercular meningitis, 5 to amyloid degeneration of the kidneys or other organs, and 3 to phthisis. It was the practice to discharge patients at first experimentally cured; watching the effect of leaving off the apparatus for a time. In some of them it was necessary to apply the splint again for a longer or shorter period before they could be discharged permanently cured.

The plan of treatment adopted in all cases was to apply the long Taylor splint, and instruct the parents or friends in its use. Unless the recumbent posture was required by the special circumstances of the case, the patient was allowed almost unlimited exercise in the open air, and once a week the patient was expected to report at the dispensary.

The aims of the treatment were as follows:

(1) To overcome by mechanical means any existing deformity.

(2) To protect the affected parts from traumatism.

(3) To secure free out-door exercise.

(4) To maintain that position of the limb in which there would be the least amount of deformity in case ankylosis should result.

No operations were performed with the exception of occasionally evacuating an abscess, and little medication was resorted to. Much credit, Dr. Shaffer thought, was due to the capable and energetic assistant surgeons of the institution for their faithful attention to the cases. The long splint used was made without any joint at the knee. He thought that the results would probably have been even better than they were if an intermediate apparatus had been employed, as was usually done in private cases; but on account of the additional expense involved, the institution was unable to provide this.

Of the 51 cases on which the paper was based, 4 were ascertained to have died. 2 of the deaths were due to tubercular meningitis, and the other 2 to acute pneumonia; the latter patients having been in good health up to the time of the attack which carried them off. Of the remaining 47, 6 had relapsed. 1 of these patients remained well two years, 2 three years, 2 four years, and 1 five years; and in 1 of these cases the relapse was due to a fall from a cart. In 1 of the cases excision of the hip had been performed, and the patient was still in bed at the end of a year. In the other 5 the traction treatment had been resumed, and of these 2 were cured a second time, 2 were now nearly well, and 1 was slowly improving.

Passing on to speak of the difference in the length of the two lower extremities, Dr. Shaffer said that the amount of shortening did not seem to depend on the presence or absence of abscesses; although there was a larger proportion of cases of shortening with abscess than of those without. The influence of age on the amount of shortening was quite marked; the greatest amount of shortening occurring in late cases, that is, when the patients were over ten years of age when the trouble commenced. It was a fact worthy of note that the difference in the length of the limbs almost always increased slightly after the case had been discharged cured.

As to the difference in the circumference of the two thighs, in the majority of instances it was between one and two inches; and when the result was the most perfect this was never less than one inch. No relation was observed between the amount of shortening and that of atrophy. The atrophy of the calf of the leg was more marked than that of the thigh in after years. A study of these cases seemed to show beyond a doubt that the muscular growth of the limb received a shock from the occurrence of hip-joint disease from which it never afterward fully recovered. The atrophy might doubtless have been diminished by massage and other appropriate treatment especially directed toward this end; but in dispensary practice this was impracticable, and, consequently, no special efforts of this nature were made.

In nineteen of the cases recovery took place with ankylosis, and three of the patients had perfectly free motion in every direction. The presence or absence of abscess seemed to have little influence on motion. An investigation of these cases showed that the amount of motion, as a rule, grows less instead of greater, as time goes on; and in no case did the motion increase after the discharge of the patient. A careful examination was made in regard to the presence of lateral curvature of the spine, and it was found that in only one out of fifty cases was there anything at all approaching true rotary lateral curvature. In this case, however, the latter condition was not really present. It was found that after cure the limb on the diseased side does not grow as rapidly as the unaffected one, and Dr. Shaffer thought this was no doubt the reason why the difference between the length of the two limbs so often became greater as time went on. In case of ankylosis, adduction, rather than flexion, was the thing to be most avoided.

In conclusion, he stated that these cases showed that, aside from the danger of the operation, conservative methods of treatment gave better results than excision. Excluding the four cases which died and the six which relapsed, there was not a single individual among the patients who was incapacitated for active occupations, and none were affected with tubercular disease or other serious trouble.

DR. LOVETT stated that, as a part of the work included in the present investigation, he had visited and examined these patients at their homes, and he had found that, taken altogether, they were an exceptionally healthy set of people. There were only five who were not in robust health. One of these was a boy, who was the only one of the number who used a crutch or cane; and the other three were young women who, while anæmic and inclined to be delicate, presented no signs of phthisis. There was very few who wore high soles on the affected side; although quite a number had tried this for a time, but eventually found that they could get along better without this device. As had been remarked, adduction was the most unfortunate deformity resulting from hip-joint disease. It made the gait ungainly, gave rise to pain in the back, and rendered the practical shortening of the limb a great deal in excess of the actual bone shortening. Nearly half of all the cases complained of more or less pain in the affected limb during damp weather; but in not a single instance was there the slightest reason to suspect any return of the disease.

Dr. J. F. Ridlon said that by this paper the claim was substantiated that hip-joint cases could be successfully treated in dispensary practice. Having been for six years connected with the institution referred to, three of which were spent in the outdoor department, he was perfectly familiar with the whole matter. So far as he understood Dr. Shaffer's opinion, it was assumed that all the cases were of a tuberculous nature; but personally he believed that many cases which were supposed to be of strumous origin were in reality due to traumatism. He also thought that a considerable proportion were due to inherited syphilis. It, therefore, seemed only right that the causation of the trouble should modify the treatment adopted to a very considerable extent. In traumatic cases where there was more or less dead bone present, he thought it good surgery to cut down and remove it. If such cases were allowed to go on without operation they were very apt to end fatally; while in instances of this kind where even a very large fragment of dead bone was removed he had seen the patients make a perfect recovery. If a diagnosis of inherited syphilis was made, anti-syphilitic remedies should be employed in addition to the usual splint. He had, indeed, seen one or two syphilitic cases get well under anti-syphilitic treatment, without the use of mechanical means at all. He was convinced that many cases which were supposed to be of tuberculous character by orthopædic surgeons were in reality syphilitic, and he knew of one case of this kind which was treated with simply a hip-splint for two years, when a syphilitic eruption appeared. The mother and a younger child were also affected with a similar eruption. As to whether there was any way of deciding whether a case was tuberculous or syphilitic was a matter, he thought, worthy of careful investigation; and it seemed to him advisable to try the effect of internal remedies in addition to mechanical treatment. All were familiar with the difference met with between private and dispensary patients, and the more speedy cures among the former he believed to be largely due to this cause.

Dr. Samuel Ketch said that he thought Dr. Ridlon was mistaken in the statement that it was assumed at the New York Orthopædic Dipensary that all cases, without exception, were of tubercular origin. It was also a fact that quite a number of cases, in addition to mechanical appliances, were treated with such remedies as iron, cod-liver oil, and hypophosphites. His personal experience with the mechanical apparatus employed, led him to consider that with it we had a most satisfactory method of treating hip-joint disease. Not only were good limbs secured, but also relief from suffering; and many of the cases were saved from the knife.

Dr. Louis A. Sayre said that the conclusions of Dr. Shaffer corresponded to a great extent with the views which he had taught for the last thirty years. If proper mechanical treatment were carried out the patient usually recovered. Whether a predisposition to tuberculous, syphilitic, or other dyscrasia were present or not, he had observed that in almost all cases an exciting cause, however trifling, had been required to develop the trouble in the hip-joint; this traumatic influence serving to fix the diseased process at this particular point. If any hereditary taint were present, of course, a very slight injury was required for the development of the disease. With proper mechanical treatment and the use, in appropriate cases, of such measures as blisters, leeches, and the hot iron, a fair result could usually be obtained, and there were scores of his patients in this city and elsewhere, who now had perfect motion of the limb. Many of these he had seen in consultation with such surgeons as Mott, Willard Parker, Van Buren, and Hamilton, and the results were so successful that it would never be suspected that they had ever had hip-joint disease at all.

If we could succeed in arresting the disease, Dr. Sayre went on to say, mechanical treatment was all that would be required. The moment that the apparatus was applied there was instant relief from pain. But, in spite of suitable mechanical means and the internal use of cod-liver oil, bichloride of mercury, or other remedies that seemed to be indicated, there were a certain number of cases which, instead of improving as time went on, only kept growing worse. If, therefore, caries went on increasing, with long-continued suppuration which was liable to result in amyloid degeneration of the kidneys and other organs, then the knife was the proper thing to resort to. Instead of letting a case go on for eight years, as had been done in some of those reported in the paper, with the health becoming all the time more and more broken down, he thought exsection was infinitely preferable. So far as results were concerned, these would be incomparably better than in serious cases of this kind in which it was not resorted to. In this connection Dr. Sayre referred to two patients in whom he had performed exsection, one of whom had afterward become a champion foot-ball player and college athlete, while the other had won a pair of silver skates for his agility in skating. Yet these were cases in which he believed death would have resulted if he had not performed the operation.

For a number of years he said he had only been allowed to do exsections in those who were already condemned to die, so strong was professional opinion against the procedure; and, consequently, his statistics were not as favorable as they would have been if he could have selected his cases. A certain number of cases had been referred to this evening as incurable, but he thought it was a great mistake not to give them the chance which exsection offered. Of the seventy cases in which he had performed the operation, many were of this apparently hopeless character. As regards the condition of the spine in the subjects of hip-joint disease, while there might not be present true rotary lateral curvature, it was undoubtedly true that there was more or less lateral distortion in many of the cases.

Dr. V. P. Gibney considered the statistics presented in the paper a valuable addition to surgical literature, and particularly as regards the questions of ultimate motion and ultimate atrophy. It would seem from them that the common impression was an erroneous one, that motion increases, and atrophy becomes less and less marked as time goes on. These were very important points, and they would serve to help us in our prognoses. Personally, he had gained increasing confidence in the value of mechanical treatment. With it there were no exacerbations, there was immunity from suffering, and the children grew hearty and robust.

Dr. A. B. Judson said that the limb would take the position which was the most convenient to the patient. Adduction was particularly undesirable, and he thought

that patients should be drilled so as to spend as much time as possible with their weight on the affected limb.

Dr. L. H. Sayre said that as long as the patient showed improvement, however slow, mechanical treatment should be persevered in; but, if instead of improving, he steadily lost ground, he believed it was good surgery to remove the dead bone at once. He did not believe, however, in early exsections, and did not think the results thus obtained would at all compare with those of mechanical treatment.

Dr. Shaffer, in closing the discussion, stated that he did not wish to be at all dogmatic in his views in regard to tuberculosis and syphilis. The only way that he could distinguish between the two was by the test of treatment; some cases getting well under antisyphilitic remedies, and some not. In the early stages he did not think that we could make the distinction. It was important to remember that the paper was devoted exclusively to the results of mechanical treatment among dispensary patients, and he thought that these had unquestionably demonstrated the fact that one adequately equipped dispensary could do the work of three or four hospitals among this class of cases, and at a far smaller expense. In regard to medicines, the Orthopædic Dispensary, on account of the large expenditures which it had to make for mechanical appliances, was not able to furnish these. In private practice, however, he was in the habit of using internal remedies wherever they seemed to be indicated.

He did not wish to bring up the question of mechanical treatment *versus* excision. The cases which were spoken of as incurable, were those which were incurable as regards deformity, and not the disease itself. Patients with chronic suppuration and sinuses were not given up at all, but followed up until they died; and in his private practice some of his best results had been in cases of this kind. If he could have the entire control of the child, and the parents would give it the benefit of fresh country air and other needed hygienic conditions, a good result could almost invariably be obtained, provided amyloid degeneration did not occur. In his experience there were fewer deaths and better general results from mechanical treatment, with this special oversight on the part of the surgeon, than from excision. In the patients which had been referred to in the paper as living eight years under treatment, the eight years were not spent in combating sinuses, but in getting the best ultimate position and most serviceable limb. These were mostly cases of dry caries. He was not opposed to excision, but he believed that it should be resorted to only very rarely. In cases of which he had the entire control it was seldom or never necessary.

CORRESPONDENCE.

SULPHURETTED HYDROGEN INHALATIONS.

To the Editor of The Medical News,

Sir: My attention having been attracted by an article, entitled, "Sulphuretted Hydrogen Inhalations," in your issue of May 7, 1887, in which are described the methods employed at Allevard, France, I respectfully desire to call your attention to the fact that these identical methods have been in operation in Sharon Springs, N. Y., since June, 1884, and are described in Dr. Beverly Robinson's *Nasal Catarrh and Allied Diseases* (second edition, page 141).

During the past three years I have had occasion to use them in my own practice, in many cases of diseases of the respiratory organs, and with gratifying success. As the use of sulphuretted hydrogen is now receiving marked attention from the profession, it seems to me eminently proper that medical journals, while directing special notice to results obtained in foreign lands, should not ignore the employment of the same means in our country, and within easy access of those of their readers who may not be able conveniently to cross the sea.

Respectfully yours,

G. A. Williams, M.D.,
Sharon Springs, N. Y. Resident Physician.

Direct Inoculation of Tuberculosis in Alaska. —Dr. Pitcher relates the following personal observation among the natives of Alaska:

The native population is, and has been for some time, steadily decreasing. It is true that an epidemic of smallpox some years since contributed largely to that end, but not to such an extent that the ravages of consumption were lost sight of. The sudden onset of the more alarming symptoms in the respiratory and circulatory organs may be in a measure explained by the almost universal prevalence entailed in "packing" immense loads upon the back by means of a band passed across the chest horizontally, and attached to bands at either extremity, passing from the load, under the arms, in front of and over the shoulders, back to the load again. This, as a matter of course, renders breathing a difficult feat. The dampness of the climate, lack of good hygienic surroundings, intermarriage with Russians, existence of syphilis and scrofula, may explain the existence of the disease, but not its rapid spread and presence throughout whole families. One would expect to find among a people accustomed to a climate from infancy, taking plenty of out-door exercise, living extensively upon a diet of fats and oils, and remarkably free from gastric disturbances of any type, a certain percentage free from it, but such is not the case; it is the exception, rather than the rule, to find a man, woman, or child free from it. After examining a large number of cases, young and old, it struck me that some unusual agency must be at work, but look where I would, no remarkable explanation could be found, until I chanced to be in a house visiting a patient during the preparation of the evening meal. The klutchman (wife) was assiduously chewing a mass of something, spitting it, when thoroughly moistened, into a spider. Watching more closely, the substance chewed proved to be a sea-weed, prepared in the fall by pressing into square cakes and drying. This she picked to pieces and thrust into her mouth, masticating it as described. The spider at last becoming full a quantity of seal or herring oil was poured over it, a few hot coals stirred in and later warmed slightly over a fire. Of this delicate dish the entire family partook briskly. This klutchman was a consumptive, and the patient (her son) was also suffering from the same complaint.—*Medical Age*, April 25, 1887.

NEW HYGIENIC MUSEUM IN BERLIN.—A large hygienic museum has recently been opened in Berlin. The rooms on the first floor, of which there are sixteen, contain exhibits relating to fire, building, heating, ventilation, lighting, water-supply, and road and street making. On the second floor are eighteen rooms, in which are shown objects used in civil and military nursing, clothing, baths, education, asylums, prisons, etc.—*Sanitarian*, April, 1887.

NUMBER OF AMERICAN MEDICAL STUDENTS IN VIENNA.—For the year 1886–87 there were ninety-five Americans studying medicine in Vienna.

PRIZES IN THE FRENCH ACADEMY OF MEDICINE.—The Academy offers $2000 (10,000 francs) for the best essay on treatment of urethral stricture, or other diseases of the genito-urinary tract. Meynot has contributed $14,000 for essays in otology and ophthalmology.

A NEW TECHNICALITY.—In view of the great confusion arising from the indiscriminate use of various words and phrases to denote the same operation, Dr. Reeves proposes the single word "*ventrotomy*" to express the operation of opening the abdominal cavity, for whatever purpose. Operations with incisions in various parts of the abdominal walls are designated median, anterior, lateral, and posterior or lumbar ventrotomy. In accurately describing a gastrotomy done through the linea alba, he would say "median gastro-ventrotomy."

A LETTER FROM PASTEUR.—*Science* for April 22, 1887, publishes the following extract from a letter by Pasteur:

Pasteur, who is now sixty-four years old, was, last winter, sent by his physician to Italy for his health, and is only just returning to Paris. Under date of April 1st, in a letter to his friend, Mr. Jules Marcou, of Cambridge, which the latter kindly permits us to use, he writes from Arbois in the Jura, that he hopes to live to welcome the earliest publications of the Institut Pasteur, and adds, "We have just purchased eleven thousand square metres of land, and the subscription has reached the sum of nearly two million francs; it is, however, very insufficient, for, if we spend twelve hundred thousand on land and buildings, the income from the remainder will be much too small. Oh! if only some American millionaire were inspired with an enthusiasm for this work! I hope that when we are incorporated, and this will be soon, we shall be better endowed. We shall then be able to receive legacies. To proceed suitably and with full independence, we should have, according to my estimates, three and a half million francs. I am confident. The future is ours. The prophylactic treatment of rabies continues to do well. Very, very rarely are there failures, and all in cases where exceptional circumstances appear. There has been but one failure since the first of January, and more than five or six hundred cases treated, a multitude having been most severely bitten. If we could only attack diphtheria, phthisis, etc., with success. We are going to attempt it. It is at least a step toward discovery to have confidence, and to hope in the result of obstinate labor."

OBITUARY RECORD.—Died at New York, on Monday afternoon, May 9th, E. DARWIN HUDSON, M.D., aged 43 years.

Dr. Hudson was an earnest worker in the field of medical science, and a frequent contributor to medical literature. He held the professorship of Medicine and Diseases of the Chest in the New York Polyclinic; he was Visiting Physician to Bellevue Hospital; and was one of the original members of the Association of American Physicians.

—— at Philadelphia, on the 9th instant, of typhoid fever, ELLIOTT RICHARDSON, M.D., Lecturer on Clinical and Operative Obstetrics, and Demonstrator of Operative Obstetrics, in the University of Pennsylvania.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MAY 7, 1887.

SHAFER, JOSIAH, *Assistant Surgeon.*—Detached from the "Minnesota" and to the "Despatch."

SIMON, W. J., *Surgeon.*—Ordered to the U. S. Steamer "Boston."

HENRY, C. P., *Assistant Surgeon.*—Detached from Hospital Philadelphia, and to the "Boston."

MEANS, VICTOR C. B., *Assistant Surgeon.*—Detached from Hospital Mare Island, and to the Hospital New York.

SIMONS, MANLY H., *Passed Assistant Surgeon.*—Detached from Naval Academy and to the "Constellation."

DILLIE, OLIVER, *Passed Assistant Surgeon.*—Detached from Hospital New York, and to the Hospital at Philadelphia.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 3 TO MAY 9, 1887.

FRYER, BLENCOWE E. *Surgeon.*—Ordered for examination by Army Retiring Board at San Francisco, Cal.—*S. O. 101, A. G. O.*, May 2, 1887.

STERNBERG, GEORGE M., *Surgeon.*—Assigned by the President to the special duty under the Treasury Department of "investigating the merits of the method practiced in Mexico and Brazil for preventing yellow fever by inoculation." Relieved from duty as attending surgeon and examiner of recruits in Baltimore, Md.—*S. O. 101, A. G. O.*, May 2, 1887.

MIDDLETON, J. V. D., *Major and Surgeon;* HAPPENSETT, J. C. G., *Major and Surgeon;* AINSWORTH, F. C., *Captain and Assistant Surgeon.*—Appointed to assemble at U. S. Military Academy, West Point, N. Y., on June 1, to examine into the physical qualifications of the members of the graduating class and of the candidates for admission to the Academy.—*S. O. 102, A. G. O.*, May 3, 1887.

LONSIG, LEONARD Y., *Captain and Assistant Surgeon.*—Sick leave of absence still further extended six months, on Surgeon's certificate of disability.—*S. O. 103, A. G. O.*, May 4, 1887.

BIART, VICTOR, *Captain and Assistant Surgeon.*—Sick leave still further extended one year, on Surgeon's certificate of disability.—*S. O. 99, A. G. O.*, April 29, 1887.

PAGE, [illegible] *First Lieutenant and Assistant Surgeon.* Ordered from Fort Leavenworth, Kansas, to Fort Lewis, Colorado, for temporary duty.—*S. O. 100, A. G. O.*, April 30, 1887.

ORIGINAL ARTICLES.

MEDICO-LEGAL ASPECTS OF CRANIAL AND HEART WOUNDS.[1]

BY D. HAYES AGNEW, M.D.,

PROFESSOR OF SURGERY IN THE UNIVERSITY OF PENNSYLVANIA.

Is it possible for an individual, with suicidal intent, and in quick succession, to inflict a perforating shot wound of the head and another of the chest implicating the heart? Or, reversing the proposition, Is it incredible that a person, bent on self-destruction, can, with his own hand, shoot himself in the heart, and in the head? These questions have a medico-legal bearing of no small import, and have been suggested as the subject of the present paper, by a murder committed during the spring of 1886, in the town of Newport, Rhode Island.

A colored man, long a resident of Newport, well known both to the permanent inhabitants of, and to many of the transient visitors to, this place of fashionable resort, was found one morning in his house dead under the breakfast-table, having in his mouth some food unswallowed, and with a bullet wound in his head and another in his chest. A coroner's jury, after holding an inquest, brought in a verdict of suicide, and the body, under this finding, was interred. Some weeks later, through the suggestion, I believe, of one of the local physicians, that it was impossible for the deceased to have inflicted these double wounds with his own hand, both involving vital organs, the authorities ordered the body to be disinterred and the inquest to be reviewed. The autopsy revealed a perforating shot wound of the skull, the pistol ball (22 calibre) having entered the right parietal bone about two inches above and anterior to the ear, making a clean-cut perforation of the skull and lodging in the posterior part of the left half of the cerebrum, having passed from left to right, and from before backward. Another ball had penetrated the thorax at a point three inches to the right of the left nipple, and two inches to the left of the median line. "The ball," as was stated, "was found to have passed through the left ventricle of the heart, entering the base and emerging at the apex." It is probable that the exact point at which the ball entered the chest was not accurately noted, as it would have been an anatomical impossibility for the missile, entering the thorax at the position stated, to have traversed the heart from base to apex, the base of the organ being on a level with the second costal cartilage.

The finding of the coroner's jury, based on the evidence developed by this second examination, was murder by some person or persons unknown. Suspicion now fell upon the son-in-law of the dead man, who lived in the same house with his father-in-law. This colored man, named Dorsey, was a graduate of Lincoln University, and had attended two courses of instruction in the Medical Department of the University of Pennsylvania. He was immediately arrested, imprisoned, and held to answer for the murder. He stoutly denied any participation in, or knowledge of, the crime, and as the young man had, both during his student life at Lincoln University and at the Medical Department of the University of Pennsylvania, borne a remarkably excellent character, and as no possible or sufficient motive, at the time, could be divined for such an act, many of his friends were disposed to regard him as innocent. These convictions were strengthened by the rumor that Burton, the murdered man, was hopelessly embarrassed financially, and had, I understand, on the very morning of his death, a note at maturity, and without the means to cancel it.

At the trial of Dorsey the prisoner, five medical experts were examined on behalf of the prosecution. One witness testified that either wound must have caused nearly instant death; or, if the brain received the first ball, such a degree of unconsciousness would have ensued as to incapacitate the victim for inflicting the second wound.

A second witness declared that the wounds were entirely inconsistent with the idea of suicide. The three remaining witnesses testified that if not more than one minute elapsed between the shots, the case was one of homicide and not suicide. Such were the answers as given to me by the prosecuting attorney in the case.[1] Entertaining a different view from that expressed by the medical experts, Dr. William Hunt, one of the surgeons of the Pennsylvania Hospital, and myself, at the urgent solicitation of the friends of the prisoner, went to Newport on the last day of the trial. We arrived at the place in the night, expecting to go on the stand the following morning, but in the meantime the trial was brought to a sudden termination by the confession of the prisoner's wife, in which both her husband and herself were concerned in the murder; and now the question recurs, Are such wounds as those described entirely inconsistent with the idea of suicide?

If the testimony given by the medical experts in the case just detailed, is to pass unchallenged, then it follows that an innocent person arrested and tried for murder in a case where a shot wound of the head

[1] Read before the American Surgical Association, May 11, 1887.

[1] Since this paper was written I have had the pleasure of meeting one of the medical experts in this trial, Dr. Richardson, of Boston, who informed me that the evidence given by himself and others of his colleagues, as to the wounds being homicidal and not suicidal, was based upon certain facts brought out in the case which rendered the former more probable than the latter.

and of the heart existed, might be condemned to death, even though the other evidence did not raise the connection of the prisoner with the deed, above a mere probability. In examining this question I shall assume that it is possible for a shot wound of the head and of the heart to be suicidal, and as to precedence of injury, the head or the heart, it is not essential to the case.

First, however, let us consider the subject in the order of a shot wound of the head and of the heart. There are two conditions which would disqualify an individual bent on self-destruction from inflicting the second wound in the chest, namely, the suspension or loss of consciousness and paralysis, partial or complete, of one or both upper extremities. The loss of consciousness, in a given shot wound of the brain, is not due to the mere passage of the missile through cerebral matter; you can thrust a finger, a trocar, or a knife, into portions of the brain, without at all affecting either sensibility or consciousness. It is due generally either to fragments of bone carried before the vulnerating body and buried into the cerebrum, to some large vessel or sinus being opened, causing a profuse hemorrhage, or to transmitted vibrations resulting from the impact of a ball against the skull, thus causing a molecular disturbance of its contents, and momentarily deranging the orderly operation of the intellect. Indeed, I believe that the sudden suspension of consciousness in many of these shot injuries of the head is due more to this contact of the missile with the cranial wall, than to its passage through the brain.

It is common to see a person fall to his knees or prone upon the ground when struck upon the head by a pebble or a fragment of a stone, but in an instant he is again on his feet, the fall does not necessarily imply loss of consciousness, though it does mean an interruption to muscular coördination. Every surgeon can recall instances of the most dreadful injury to the skull and brain without destroying the conscious volitions of the patient.

During the winter of 1885 Dr. William Hunt and myself were called to see a man who had been run over by a street-railway sweeper in the night. He was seen to arise immediately after the accident, and walk to his house on Spruce Street, two squares from the scene of injury. Opening the door with his deadlatch key, he passed up stairs to his room on the second story and went to bed. The family in the morning found him unconscious. On examination portions of the parietal and temporal bones were found driven deeply into the brain.

A prominent physician of Philadelphia was run over by an unmanageable horse, and dashed against the corner of an iron pillar, causing a frightful compound comminuted and depressed fracture of the frontal bone, tearing the membranes of the brain, and injuring its substance. I applied the trephine in two places, and removed twenty-seven fragments of bone, and yet, though unable to stand, neither motility nor consciousness was destroyed, as the patient gave intelligent instructions in reference to being carried to his home.

I recall another case of still more extensive damage to the skull; one in which, by the bursting of a fly-wheel, quite one-half of the frontal bone was carried away, and with it a considerable portion of the prefrontal lobes of the cerebrum. Only for a few moments was the man dazed, and ultimately made a good recovery.

The famous case, occurring in the practice of Dr. Harlow, and figured in some of the books on surgery, is another one in point. A bar of iron having entered the face below the zygoma, passed through the skull, emerging near the vertex, without destroying personal consciousness.

A private,[1] named Solomon, Co. G., New Jersey Volunteers, received a shot-wound at the battle of Bull Run. The ball entered the skull below the tip of the left ear; the man fell, but retained his senses. The surgeon passed a probe two inches into the brain in the supposed track of the ball.

In a letter received recently from Sir William MacCormac, of London, the writer says that he thinks it entirely within the bounds of possibility for an individual, with suicidal intent, to shoot himself in the head and in the heart, or in the heart and afterward in the head, and furnishes the following cases, which render such a statement entirely feasible. The first was that of a suicidal case under the care of Mr. Hulke, where the bullet traversed the head from temple to temple, but did not emerge. The patient lived fourteen days, but did not lose his consciousness until a short time before his death, and was fully able to inflict any other wound had he been so disposed. In a second case, under the care of Dr. Smith, a bullet traversed the skull from temple to temple. The patient not only preserved his consciousness, but finally recovered.

A soldier at the Battle of Pultuska, in Poland, as related by Hennen, received a remarkable wound of the brain. A ball carried away the bayonet of a musket, which entered the right temple of the man, two inches above the orbit, and passing backward and downward, emerged through the maxillary sinus of the left or opposite side. The soldier, aided by his two comrades, tried in vain to withdraw the weapon; the Surgeon-Major, M. Fordeau, made a similar attempt and failed, when at length the task was accomplished by a strong soldier placing the man's head on the ground and his foot upon the head, while traction was made on the missile. The patient ultimately recovered, and as it is distinctly stated that he joined his own efforts with those of his fellow soldiers in their attempts at extraction, it follows that neither consciousness nor motility was lost.

The *second* disqualifying condition for inflicting another wound after one in the head is paralysis.

The very great advance made in the last few years in regard to the functions of the brain and the topographical relations existing between the exterior of the cranium and definite cerebral convolutions, enables us to locate with considerable accuracy intracranial lesions from the symptomatic phenomena which may be present. The local areas or centres of muscular power have, for the most part, been clearly established.

It will, I think, be conceded that so long as the

[1] Surgical History of the War, Part I.

middle portion of the ascending frontal and corresponding portion of the ascending parietal convolutions remain uninjured, the power to use the arms is retained, and the same may be affirmed of the lower extremities, so long as the upper end of the ascending parietal convolutions and that part of the posterior parietal lobule immediately behind remain intact. The motor centres are all grouped about the fissure of Rolando, and unless a shot or other missile trenches on these special regions, motility remains; though it may, after a time, be lost by the extension of hemorrhage or from inflammatory products. So common is it to see shot and other wounds of the brain occurring without material impairment of muscular motion, that I do not think anyone will challenge the statement. Indeed, the cases already cited in support of personal consciousness after wounds of the brain, are, most of them, equally pertinent when applied to the maintenance of motility. Nor does the fact that a man falls, or is unable to rise after a perforating shot wound of the skull, prove that the power to use his arms is lost. The missile may damage the leg-centres and not affect the arm-centres.

Let us next change the proposition by changing the order of wounds—the heart wound taking precedence.

The unconsciousness and loss of muscular power which follow wounds of this organ, are due to hemorrhage; the vessels of the brain and other nerve centres being suddenly emptied of their blood, fatal syncope ensues; hence wounds of the heart are generally considered to be instantaneously fatal. Yet there are many, very many, exceptions to the rule. Fischer, in an analysis of 452 cases of wounds of the heart, gives no less than 35 recoveries; 72 were shot wounds with 12 recoveries. Dr. Purple, in his collection of heart wounds, states that in 42, 12 of which were shot wounds, death did not take place immediately.

While it is true these statistics are not altogether free from criticism, yet they possess an intrinsic value in establishing the general statement, that these injuries are not necessarily, or immediately fatal in all instances. The following cases culled from different sources will go to sustain the object most needful for my present purpose. In the *Surgical History of the War*, Part I., pages 530 and 531, there is recorded the case of Private Lanning, Co. A, Pennsylvania Volunteers, who was shot in the chest, the ball entering the right auricle. The patient persisted in sitting up, and walking about his room. He lived for fourteen days.

The same author mentions the case of a private named Wright, Co. C, Fourth Regiment of the Veteran Reserve Corps, shot at Quincy, Ill., and who lived forty-six hours. The ball passed through the lung, the left auricle, the auriculo-ventricular septum, and the left ventricle.

A private, Charles T., 1st Maryland Potomac, Home Brigade, was shot in an affray with the Provost Guard at Frederick. The ball passed through the left ventricle and right auricle. Death did not follow for twelve hours.

In two instances given by Jamain, the patients lived six months after a shot wound of the left ventricle. Ferrus mentions a case in which a man lived twenty days with a skewer through his heart.

Sir William McCormac writes me that Mr. Durham had a case of bayonet wound of the heart in which the patient survived fifty-six hours. The wound implicated both ventricles, the septum, and auricle, and the man walked some yards after receiving the injury.

Dr. Andrews reports a case under the care of Professor Bergman, of Dorpat, where the injured man travelled fifteen miles to Dorpat, and finally recovered.

In the *Lancet* of January, 1879, a case is reported where a man received a perforating shot wound of the left ventricle which did not prove fatal for fifty-four days, the patient having in the mean time returned to his work.

In Rankin's *Abstract of Medical Sciences*, vol. 31, page 165, Mr. Jackson reports a case of a man who received two shot wounds, one of the balls passing through the right ventricle. He lived for three and one-half hours, and was able in the mean time to make a deposition and name his assassin.[1] A case of assassination was tried before a British court in India. A native named Kadir was shot through the heart June 2, 1873, while lying on his cot. It was stated in evidence that the victim, after receiving the fatal wound, recognized and denounced his murderer, a man named Meera Khan. On the strength of this testimony the assassin was found guilty. An appeal was made, and the case carried to another court, and the verdict reversed, on the ground that death must have been instantaneous. Mr. W. Curran, Brigade-Surgeon, in commenting on this case, stated that the decision of the former court was, in his judgment, the more correct, as in his own personal experience shot wounds of the heart were not necessarily immediately fatal.

In the *Lancet* for April 9, 1887, page 725, there is reported the case of a groom, who, while adjusting his master's foot in the stirrup accidentally discharged a pistol which was in the holster of the saddle. The ball entered the chest, on the left side two and a half inches to the right and one-half inch below the nipple, and pierced two chambers of the heart. He survived the injury fifty-two hours.

On May 11, 1812,[2] Mr. Percival was shot by Bellingham in the heart. At the trial Mr. Smith testified that after the firing he saw the murdered man rush hastily through the crowd toward the place where he was standing, looking first in one direction and then in the other, and, after making a few steps more, reeled and fell to the ground.

The tragically affecting case of the Duke de Berri is to the same point. While leaving the theatre in company with the Duchess, he was approached by a man, who, placing his hand on the shoulder of his victim, drew him to his side and plunged a dagger into his chest which pierced the heart through, making a wound of some inches in length. The Duke lived until six o'clock in the morning, in the mean time begging that his assassin might be forgiven, and also speaking words of comfort to the Duchess.

[1] Lancet, April 2, 1887, page 628.
[2] Ibid. April 2, 1887, page 674.

I may also mention the case of a woman brought into the surgical ward of the Pennsylvania Hospital during my term of service. The left ventricle had been pierced by a butcher's knife. She survived two and three-quarters of an hour, and for at least one-third of that time her mental condition was perfectly clear. Can anyone doubt that in most of the cases cited, these patients, had they been so disposed, could have inflicted a shot wound of the head?

And now, third and last, are there any instances in which a suicide has actually inflicted the two wounds which I have been considering. Dr. Macleod, Professor of Surgery in Glasgow University, Scotland, furnishes me the case of a suicide which came directly under his observation. A student shot himself in a water-closet, the ball entered the head. Finding that he had not accomplished the work of self-destruction, he went to his bedroom along a passage and shot himself in the heart. He lived only a few moments after this last injury. Prof. Macleod entertains no doubt in regard to the feasibility of these double wounds being self-inflicted.

In turning to the records of the Coroner's physician, Dr. Formad, I am able, through the kindness of this efficient and careful officer, to furnish the following cases:

1. A policeman shot himself, first through the head, the ball, entering the right temple, was found lodged in the cranial vault on the opposite side. A second shot was fired into his chest, the bullet cutting the right side of the heart. Death from internal hemorrhage followed in about five minutes. This was done in the presence of witnesses.

2. A boy aged nineteen, inflicted four shot wounds from a revolver on his own person. The first bullet entered the forehead, and after taking a circuitous route, lodged about the middle of the left temporal lobe. A second ball was fired into the chest, and passing through the sternum, cut through the left ventricle of the heart, on a level with the mitral valve. A third shot passed into the abdomen, and the fourth into the neck. Death ensued from pericardial hemorrhage.

3. A grocer was found dead in his room, having locked the door. A pistol was still clutched in each hand; one bullet had passed through the brain, and a second through his heart.

4. A man committed suicide in the Park, one bullet entered the brain, and a second the chest. In all these cases the suicide was not assumed, but proven beyond a reasonable doubt.

From the foregoing facts which are thus hastily thrown together, I think I am at liberty to draw the following conclusions:

First. That it is possible for a ball to enter the brain without destroying consciousness, though it may for a few moments cause some mental confusion.

Second. That a ball may traverse the brain without causing muscular paralysis.

Third. That a suicide may, with his own hands, if so disposed, first shoot himself in the head, and within the lapse of a minute inflict a similar wound on the heart, and that there are a sufficient number of cases on record to establish the feasibility of the self-infliction of the two shots; and

Fourth. That a suicide may first discharge a ball into the chest, wounding the heart, and immediately after send a second ball into the brain.

THE MORTALITY OF PRIMARY LAPAROTOMY IN CASES OF EXTRAUTERINE PREGNANCY; ITS CAUSE, AND THE DIFFICULTIES WHICH LIE IN THE WAY OF REDUCING IT.

BY ROBERT P. HARRIS, A.M., M.D.,
OF PHILADELPHIA.

UNDER the present accepted classification, a laparotomy to be entitled to the term *primary*, in a case of ectopic gestation, must be performed not only while the fœtus is living, but after it shall have reached a viable period of gestation; in other words, when it can be undertaken in the interest of two lives. When the fœtus is dead, it may be a few hours or a few days, the gravity of the operation will be unchanged, but the classification will be; as the laparotomy is then performed in the interest only of the mother, it is to be classified as a *secondary* operation. The period of limit attached to the primary operation, and the functional activity of the placenta, must always render it one of great gravity. But the time for the secondary operation is not limited, except as to when it may commence. It may be performed (but very unwisely) a few hours or days after fœtal death; or it may be postponed for months, or years, until it becomes a matter of necessity for the saving of life. Operations after three months will save a large proportion of mothers; but during the first month are, on the contrary, very largely fatal, the exceptional cases being late in the month, and very slow in recovery.

This is not according to the classification (1860) of Mr. Jonathan Hutchinson, of London,[1] who made the term *primary* to apply to all cases in which there had not yet formed an abscess opening through the abdominal wall; and *secondary*, where such an opening had already formed. In his tabular record,[2] he gave fifteen cases of what he denominated *primary* with six recoveries, but did not introduce one case of what is now regarded as the *true primary* laparotomy, although at the time of writing (1864) his second paper in Holmes's *Surgery*, there had been performed five of these operations, with the saving of three children.

The late Dr. John S. Parry, of Philadelphia, wrote in 1875, a work upon extrauterine pregnancy, in which it is evident that he prepared his table of twenty primary operations with six recoveries, after the classification of Hutchinson. This will account for the fact, as noticed by Litzmann, Lusk, and others, that there was not a primary case, as we understand the term, among the six saved. At the time Dr. Parry published his work there had been eight true primary operations, saving one woman

[1] Medical Times and Gazette, July 21, 1860, page 59.
[2] Holmes's Surgery, 1864, vol. iv. p. 514.

and four children, the successful one being then of very recent occurrence, and probably unknown to him. It is very evident that our accepted classification has been introduced as a matter of necessity. The operation for the removal of a decomposing fœtus after the spontaneous discharge of an abscess through the abdominal wall is of very ancient date. That of laparotomy for the removal of a dead fœtus where the abdominal wall is sound is of more recent introduction, dating back to the year 1594. What is now regarded as the primary operation was first performed, so far as can be ascertained, in Berlin, in 1813, and has in seventy-four years been executed twenty-five times, with twenty-three deaths, and a loss of thirteen children.

We are especially interested in this operation just now, because Dr. Joseph Price, of Philadelphia, recently performed it in Camden, New Jersey, the child living four hours and the mother fourteen days; the death of the latter resulted from hemorrhage. This operation has been performed only twice in the United States, in all her history, and both of the cases proved fatal. One other operation it is true was performed, in 1870, by Dr. E. Paul Sale, of Aberdeen, Mississippi, but in this case the operation was followed by the Cæsarean section thus complicating the removal of the extrauterine fœtus by an intrauterine one. The woman died of septicæmia, and the children, one at six months, and the other at twelve months, of measles and broncho-pneumonia respectively.

The twenty-five operations upon record were performed by twenty-four operators, only one, Dr. Hildebrandt, of Königsberg (1882), having had two cases. Of the twenty-three women lost, only three lived longer than that under the care of Dr. Price, viz.: Case 2, under Dr. Novara, of Italy, thirty-three days; Case 3, Dr. Matfield, twenty days; and Case 16, Prof. Litzmann, Germany, sixteen days. Seventeen of the women died before the completion of the fourth day, and of this number twelve did not live through the second day, seven of them surviving twenty-four hours or less. Thirteen children perished within fifty hours or less after their extraction. In six of the twenty-five cases, peritonitis existed at the time of the operation, and in three of these rupture of the cyst had taken place. Four other women were regarded as *in extremis* when operated upon.

Causes of death. Hemorrhage is the most frequent, and may occur by itself, or be complicated by the existence of peritonitis, septic infection, or both. Heart-clot is probably a more frequent complication than has been noticed. Twelve women died of hemorrhage, alone, or complicated, as mentioned. Peritonitis alone, or mainly, caused death in four; septicæmia in two; heart-clot in one; and in four death was attributed to collapse, or to shock and exhaustion.

Location of the placenta. In about one case out of six or seven, the placenta will be found implanted upon the abdominal wall. When this is central, and in the line of incision, death soon results. The placenta may also be found in the Douglas cul-de-sac, as was the case in the two operations under Hildebrandt. It may cap over the superior strait, as in the case which recovered under Mr. Jessop, of Leeds (Case 8), in 1875. It may be located over the iliac fossa; be attached to the uterus and its appendages; be implanted over the lumbar vertebræ, or kidneys; be attached to the small intestine, stomach, or liver, and has even been found within the uterine cavity. In all of the locations except the last, there can be no contraction of the placental basis after the fœtus has been removed, and the process of exfoliation must produce more or less hemorrhage. To remove a placenta from its attachment to the viscera during the operation, must be necessarily fatal, and it has not been attempted in this class of cases, so far as known, for forty years.

The primary and secondary operations are performed in exactly the same way, from the taking up of the knife, to the suturing of the abdomen, and the difference of gravity in the two cases is due to the danger to be apprehended when placental separation begins, being infinitely greater in the former, because of the open condition of the placental sinuses. Thus far, the mortality by the primary operation has been at least ninety-two per cent., and will foot up higher than this, when the cases of 1883, 1884, and 1885 come to be reported.

The secondary operation, when performed not earlier than three months after fœtal death, has of late years been one of comparative safety, as there is only a moderate risk of secondary hemorrhage, and septic infection can be largely controlled by abdominal irrigation. Much will depend upon the location of the placenta in determining the final result. This will account for some patients recovering when operated upon only a month after the death of the fœtus, while others have died of hemorrhage after four months delay. The immunity under the secondary operation is due to the changes that take place in the placental circulation after its functional activity ceases.

If the primary operation is ever to be one of diminished risk, it must be made so by one of two methods: 1, the ligation of the vessels that supply the placenta and its removal with the cyst, as was done in Case 20 (1881), by Dr. August Martin, of Berlin; or 2, by an antiseptic treatment of the placenta, to prevent its decomposition and separation. If the placenta is implanted over the iliac fossa, a solid immovable base, this experiment might be tried: tie the cord and cut it off close to the placenta, wash out the cyst cavity with corrosive sublimate water, turn in the cyst opening so as to bring the serous surfaces in contact, and stitch them in apposition by the uninterrupted suture of Apolito or Gély, and finally close the abdominal wound without drainage. In Case 11, under Dr. Gervis, of London, the placenta was thus located, and the operation performed in the usual manner, resulted in death from hemorrhage in fifty-six hours. The antiseptic plan cannot do worse than this, if it should entirely fail to maintain placental vitality and adhesion. This plan can only be tried crucially, in a case where there has been no preceding peritonitis, rupture of cyst, sepsis, or hemorrhage.

THE POLAR METHOD OF ELECTROTHERAPY IN GYNECOLOGY.[1]

APPLICATION, DOSAGE, AND MEDICATION.

By GEORGE J. ENGELMANN, M.D.,

[redacted]

III. Dose and Measure.

For proper *dosage* the following elements are re[illegible]

Galvanism.	Faradism.
[illegible] of current.	Strength of current by distance between primary and secondary coil [illegible].
[illegible] by which quantity of electricity used is determined.	Number of interruptions.
[illegible] electrode, for record of	electrode.
	Tension and quality of the current as determined by the [illegible] wire in the secondary coil.

Other measures by which all details of the application are recorded with precision for scientific research, though not necessary for simple treatment, are the following:

Galvanism.	Faradism.
Resistance of the tissues and electrodes in ohms.	Resistance of the tissues and electrodes in ohms.
Density of the current.	
Quantity of electricity used expressed in coulombs.	
Electro-motive force of the elements used in volts. Ampère capacity of the elements used in ampères.	Electro motive force of the elements used in developing the current and their ampère capacity in ampères.

The galvanic current, thanks to its commercial value, can now be measured and dosed with the utmost precision, and all its practically important characteristics can be more accurately recorded than those of any other medicinal agent. For all practical purposes—I am speaking only of the application of galvanism by the polar method, in gynecological practice—we need only know the *intensity* of the current in milliampères, the *time* of application, and the *site, nature, and size of the electrodes*.

The *resistance* of the tissues in ohms is not practically necessary, as in gynecological practice we know that the resistance varies between 60 and 800, usually between 200 and 300 ohms, and this is more closely indicated by the location of the poles, as the physician who applies electricity judiciously and scientifically should know about what the resistance of certain parts generally is.

The *density* of the current, however important in other methods or in other localities, varies but little in gynecological treatment by the polar method, as it is practically the same in all but the intrapolar applications, as, for instance, to the ovaries. The active pole being always small, either stylet or ball, the effect sought in its immediate vicinity differs but little whether the current is dispersed upon a large or small plate. Still I have named the location and size of the dispersing electrode among the elements necessary for dosage and record; by means of this the density can be calculated, though I have included it, not for this purpose as much as for the convenience of the physician to facilitate repetition.

The practically important elements for record and dosage of faradic currents are the electro-motive force of the generating element, with the distance between the coils, the character of the secondary coil, and the number of interruptions per minute; but this will only be possible with perfect standard instruments, which are not yet made in this country, so that this is as yet impossible, and the utility of this form of electricity is very limited, on account of the imperfect apparatus in the hands of the profession.

The determination of the milliampère intensity of a faradic battery is more than useless, it is deceptive, as the ampère intensity carries no conception of the true force of this kind of electricity, which is produced by induction, and by frequent making and breaking of the current.

If passed through a coil of long wire the milliampère intensity is greatly reduced, and yet the effect of the current is increased. I mention this only to prevent entanglement by the erroneous ideas advanced by some.

Measure and Dosage of Galvanism.

The milliampèremeter. Upon the use of this instrument, absolutely essential to successful practice, the present advance in gynecological electrotherapy is based. The instrument may be either horizontal (tangent) or perpendicular, and for gynecological purposes should indicate from 1 to 250 milliampères. Whilst the neurologist may need one with more exact reading from 1 to 10, enabling him even to distinguish one-half or one-quarter of a milliampère, the gynecologist must have wider scope, and, as a rule, exactness to a single milliampère is not essential; the intensity usually employed is from 10 or 20 to 60 or 80 milliampères; in rectal, urethral, and vesical applications, the want of an instrument plainly showing fractions of a milliampère is sometimes felt, as two or three milliampères only are used, but in general use this is unnecessary.

The high intensities are needed for purposes of electrolysis or cauterization.

Time of application is noted in minutes, and from this the quantity of electricity applied in the entire séance can be determined in coulombs, the unit of quantity.

For ordinary purposes the record of time only is needed. The importance of this element in determining the effect is self-evident.

Density. Square surface of dispersing electrode. This should be recorded to facilitate repetition, and, if desired, to determine the *density* of the current, which is of extreme importance in certain methods of application.

To simplify record, and further an understanding, it is very desirable that practitioners should adopt standard sizes of this important instrument; uni-

[1] Read before the [illegible]

formity in size and even in conducting powers of dispersing electrodes is essential, as it is difficult to calculate with ever-varying factors, but if a standard be adopted this difficulty is obviated.

The three sizes I use I would suggest as most convenient for gynecological purposes:

No. 1. 59 square inches surface (6¼ by 9¼ inches) for higher intensities.

No. 2. 28½ square inches surface (4½ by 6¼ inches) for intensities from 20 to 60 milliampères, still applicable to the abdomen without difficulty.

No. 3. 15⅔ square inches (3½ by 4½ inches), easily manipulated and readily slipped under the clothing upon any part of the abdomen, can be used for all milder applications, and even with 40 milliampères if the patient be not too sensitive and the resistance low.

Resistance of the tissues and electrode in ohms. The ohm is the unit of resistance, and is measured by the rheostat. Upon the resistance of the tissue depends the intensity of the current possible and necessary.

The *greater the resistance* the *less the possible working intensity* of the current, but the *greater the electromotive force* and *ampère capacity of the generating battery* required. Hence the possibility of successful application of galvanism in gynecological practice; the resistance offered by the tissues is small, usually 200 or 300 ohms; and under these circumstances the patient can stand 100 or 200 milliampères; in percutaneous applications, as required in neurological practice, the resistance of the tissues is rarely as low as 1000 ohms, often 5000 and 10,000 ohms, and 5 milliampères is then a great intensity requiring strong battery force. In neoplasms and effusions, in which the highest intensities are required, the resistance is sometimes reduced to as low as 40 ohms, and at most it is never above 600 or 800 ohms. The resistance of the moist tissues is very low, and the nearer the electrodes can be approached to each other the less it is, as the amount of tissue is diminished.

The greatest resistance is offered by the dry epidermis, and in gynecological applications this is only to be encountered once, and not in all treatment; then the epidermis on the abdomen is not so thick and hard, and the surface is so located that it can be well saturated. When both poles are intrapelvic the resistance is naturally lessened, and very little ampère capacity of battery is required. The resistance in these applications is also lessened by the approximation of electrodes, the one in the vagina, in the uterine cavity, or in the tissue, comes very near to the other, over it upon the abdomen. Most effective, however, is the succulence of the tissues in reducing resistance, and these tissues, with the exception of the abdominal walls, possess low electrical sensibility. For these reasons the use of effective currents, inapplicable in other parts, is possible in the pelvic viscera. This is best explained by an example: In an electro-cauterization of the endometrium, with one pole, the sound, in the uterine cavity, and the other, the small plate, upon the abdomen, I can use 30 milliampères with but little pain, and may need 6 elements to develop these 30 milliampères through a resistance of 250 ohms. If I place the same small abdominal electrode on the back of the hand, and in place of the uterine sound, at the other pole, a round electrode in the palm of the hand, I will find a resistance of 3500 ohms from palm to back of hand, and I will need 24 of the same elements to obtain 4 milliampères, and these 4 milliampères will cause as much burning as the 30 milliampères through less resistance, and in a more sensitive spot.

For an exact determination of the resistance of the tissues, the resistance of the electrode must be noted. That a knowledge of the resistance of the tissues under treatment is necessary, is evident from the influence of this factor upon the result. For general purposes of gynecological treatment, however, it can be dispensed with, as this resistance varies within known and narrow limits; but for other applications it must be noted, as the variation is very great, and so much depends upon it.

I myself have recorded the resistance in the cases treated, for the sake of study and observation, and believe that this should be done for the purpose of scientific observation, that rules of practice may be developed.

It is to the low resistance and slight degree of electro-sensation that gynecology owes the possibility of successful electrotherapy; 250 milliampères can be applied for electrolysis in a uterine fibroid, because the resistance may not be over 60 milliampères, and this can be accomplished without excessive pain, or the use of great battery force; whilst 250 milliampères sent through the body from hand to hand would cause instantaneous death; and no battery—nothing but a dynamo—sends such a current through a resistance of 15,000 ohms (at which I roughly estimate the tissues from hand to hand).

Density of the current. The greater the density of the current the more intense the effect, and, as we have seen, in gynecological electrotherapy and the polar method, the greatest density is attained, as the effect is derived from the surface of one small pole, and the density of the current in the tissue surrounding this active pole varies but little, whether the dispersing electrode be large or small; hence, as has been stated, for mere working purposes, the record of this factor is of no value in gynecological electrotherapy, however important it is in other applications. The density has been expressed by the milliampère intensity divided by the square electrode surface, $\frac{1 \text{ milliampère}}{\text{square surface of electrode}}$. It is an element which can be dispensed with practically in dose and record of gynecological electrotherapy; though of interest for investigations of scientific precision, and application to other parts. It is only in ovarian and similar intrapelvic intrapolar applications that we must take into account this element of density.

Quantity of electricity used. The coulombmeter. The coulomb is the unit of quantity, and is represented by the quantity of gas developed by a current of one ampère in one second of time, or by the amount of water displaced by the gas evolved by a current of one ampère in one second of time; in other words, a coulomb is the quantity that passes

in one second of time against one ohm of resistance under the electro-motor force of one volt. One coulomb will decompose 92 microgrammes of water, and upon this decomposition the instrument for measurement is based; though not scientifically exact, like the milliampèremeter, it is sufficiently so for practical purposes.

In gynecological practice it is sufficient to calculate the amount of electricity used, which is easily done if the intensity of the current and time of application are known: As one ampère for one second of time equals one coulomb, $\frac{1}{1000}$ of an ampère, or one milliampère, will equal $\frac{1}{1000}$ of one coulomb, in one minute, 60 seconds, will equal $\frac{60}{1000}$ or $\frac{6}{100}$ of a coulomb, and in five minutes, $\frac{300}{1000}$ of a coulomb. The current used in an ordinary application, for instance, 20 milliampères for 5 minutes, equals $20 \times \frac{300}{1000}$ or 6 coulombs; the same as if a current of 100 milliampères was applied for 1 minute, or of 1 ampère for 6 seconds.

I have made the measurements and calculations in my case records for the sake of observation and comparison, but I do not deem it necessary if milliampère intensity and time of application are given; it is merely one of the methods of measuring the galvanic current in all directions for precise determination. If a milliampèremeter is not at hand, the quantity may be measured by the coulombmeter, and, the time being known, and the resistance, the milliampère intensity may be calculated.

Electromotive force; the voltmeter. This is one of the measures used for determining the initial force of the agent, the power of the battery, or of the cells used in the treatment. One volt, the unit of electro-motive force, is a force sufficient to produce a current of one ampère through one ohm of resistance—that is, about equal to that of one chloride of silver, or of one Daniell, element.

The voltmeter used for measuring the electromotive force is an instrument similar in appearance to the horizontal galvanometer, indicating the force in degrees of deflection of a needle, which is impelled by the current passing through a coil of high resistance underneath the pointer. This instrument is of service in determining the value of a battery for galvano-caustic purposes, and for recording the force of the elements used, but is superfluous in galvano-therapeutics for all but exact scientific work; it is not necessary for determining or recording the electric dose, but serves rather to define the status of the battery and of the elements used in the treatment; it tells us whether they are in perfect working order, whether they are deteriorating, and how they have been influenced by work or exposure.

The ampèremeter is used to determine the ampère capacity of the battery, or of the elements used in a given treatment; by this instrument, which is similar to the tangent galvanometer, the intensity of the current used for galvano-caustic purposes is determined, and it is our best means of recording this. In galvano-therapeutics it is useful for control of the battery and its elements, and by it the ampère capacity of the elements used for a given application, or the initial intensity of the current may be determined. It is, of course, not kept constantly in the circuit, like the milliampèremeter, but is inserted in place of the body and milliampèremeter, after the application has been made, to show the intensity of current as coming direct from the battery. It is of no importance to the practitioner, but cannot be dispensed with for a complete determination of all elements; by the ampèremeter, knowing the milliampère intensity of the current in an application, we can calculate the resistance of tissues and electrodes, and, as by the voltmeter, we can record the condition of the elements before and after a *seance*.

This instrument takes the place of the milliampèremeter in all cases in which no such high resistance, as in medical treatment, is interposed. In gynecological electro-therapy this measure is unnecessary for practical work, as the efficiency of the treatment cannot be determined by the battery-force used, on account of the great resistance interposed, it serves us only for an understanding of the working power of the battery, and of the currents used in treatment, but for electro-cauterization and for mechanical purposes this is the gauge by which the work is measured. The ampèremeter is for the machinist, the electroplater and electro-lighter what the milliampèremeter is to the medical practitioner, who employs but an infinitesimal part of the electric intensity needed by the former.

Faradic Dosage.

The only precise measure applicable to faradic electricity is the electro-motive force and ampère capacity of the generating element, but these affect the therapeutic result too little to be considered in dosage. They are recorded only for scientific purposes.

For purposes of dosage we must as yet content ourselves with a rehearsal of the conditions by which the effects of the faradic current are determined.

Strength of the current is indicated by the distance between primary and secondary coil, as shown by the scale, but until a uniformity of instruments is achieved, this is of value only to the operator himself.

Time of application, of course, determines the effect and should be recorded.

Number of interruptions, which in my instruments, for instance, vary from 50 to 3000 per minute, is an important feature of the application and must be noted as one of the determining factors.

Size, shape, and material of the electrode affect the result greatly, and should be noted.

Tension and quality of the faradic current are perhaps its most important therapeutic factors, as the effect varies greatly with the nature of the secondary coil by which these are produced, hence this must always be noted.

A coil of long and fine wire gives high tension and little quality, whilst a short coil of heavy wire gives greater quality and less tension. By a current of tension the pain of cellulitis will be relieved, but the pain and swelling from a contusion will be aggravated; by a current of quality and low tension

the pain of a cellulitis would be aggravated, the pain, œdema, and venous distention of a contused surface will be alleviated; the former is used mainly for nerve, the latter for muscular effects.

Resistance of the tissues is of no practical importance, as we have no measure of faradic intensity corresponding to the ohm as the ampère does. It is noted only for experimental purposes and future possibilities.

Nomenclature. I will here again call attention to the nomenclature which I have employed and which I have urged for general adoption, in my first paper, so that the recording of cases may be simplified and a general understanding facilitated.

The method of application is described by the location of the poles, the site of the active pole being named first, that of the indifferent or dispersing pole following.

Thus, in speaking of a *utero-abdominal faradization,* I refer to the application of the faradic current with the active pole in the cavity, and the indifferent pole on the abdomen; by *intrauterine galvanism* I have indicated the bipolar treatment—that is, both poles in the uterine cavity. If the word negative or positive precedes, this always refers to the character of the first named, the active pole, viz., *positive recto-abdominal galvanism* tells us that the active positive pole is in the rectum.

The application of the bare metal pole to a surface with higher intensities of current is termed a cauterization. Thus, a *positive electro-cauterization* of the uterine cavity expresses in a concise form the application of the bare metal electrode, connected with the positive pole, to the uterine cavity, an intensity above 20 milliampères being used, whilst the current is dispersed at the negative pole upon the nearest available surface, the abdomen. When the cauterizing metallic pole is replaced by a non-metallic pole, such as a cotton-wrapped applicator, I term this treatment *positive utero-abdominal galvanism.*

Puncture is the introduction of the needle or stylet, the metallic pole, directly into the tissues with dispersion of the current upon the nearest available surface; a *negative electro-puncture* of a fibroid is the electrolysis by a stylet in connection with the negative pole inserted into the tissues of the fibroid, the current being dispersed upon the abdomen in the positive electrode. If this puncture is made *per vaginam,* we speak of a *negative vaginal electro-puncture.*

Record of dose. I have stated that intensity of current in milliampères, time of application, and square surface of dispersing electrode are necessary for determination of dose; to make this still more exact, I have always added a description of the active pole. An electro cauterization of the uterine cavity I have thus precisely recorded:

—E. C. 20 milliampères, 5 min. Fine probe. II. Plate.

i. e., 20 milliampères were applied for 5 minutes with the fine—Sims's—probe as negative pole in the cavity, and II. plate with a surface of 28½ square inches, as the positive dispersing pole, on the abdomen.

This is the therapeutic application and dose fully defined.

In cases recorded for research with scientific precision other data are added; these I have arranged in the following manner:

—E. C. 8 Gonda Leclanchè elements 10⅔ volts, 0.63 ampère. Sims's probe, II. Plate; 20 milliampères, 5 min., 6 coulombs. 600 ohms resistance (tissues 586 ohms, II. Plate, 14 ohms).

This, in addition to the data essentially necessary for dosage, tells us that for this treatment 8 Gonda Leclanchè elements were used, with an electro-motive force of 10⅔ volts, and an ampère capacity of 0.63 ampère; that the quantity of electricity used in the treatment with effect upon the patient was 6 coulombs; that the entire resistance offered these 0.63 ampère of current, which allowed the use of 20 milliampères effectively on the patient, was 600 ohms, which is essentially referable to the tissues, but an examination of the dispersing plate shows that this offered a resistance of 14 ohms, which leaves 586 ohms for the tissues, the resistance of the apparatus and rheophores being trifling.

The dose of a faradic application I have recorded in the following manner:

+V. A. Faradism, 4 min. 6 cm., 1500 I. Fine coil.

Or, in other words, the positive cotton-covered ball electrode in the vagina, the small dispersing plate on the abdomen, used for four minutes, the secondary coil 6 cm. from the primary coil, 1500 interruptions per minute, a current of great tension and little quality, the long coil of fine wire as secondary helix.

When I first advocated attention to measure and dose, being myself deeply impressed with the importance of the principles advocated by Apostoli, many of the ablest practitioners, who had long felt the want of precision as the check to progress, readily accepted the idea, but were unable to procure the necessary instruments—I am speaking of gynecologists; others, especially those who have assumed prominence heretofore in electro-therapeutic science, denied the practicability of such measure, and in the face of my claim for a progressive move and effective doses, urged mild applications. A change is rapidly being effected, the demand for instruments of prcision has created a supply, and whilst but a year ago hardly a milliampèremeter was to be had on this side of the Atlantic, and the galvanoscope was sold as a galvanometer, the market is now being supplied,[1] and the working members of

[1] Milliampèremeters of American make are now offered the profession, but I regret to say that, though I have tested several, I have not as yet found one which is perfectly accurate; some indicate *twice* the proper intensity, ten milliampères when they should indicate five milliampères, some two-thirds of the real strength of the current, etc. Every physician should test his galvanometer or have it tested by an expert electrician.

The most delicate test of the correctness of the instrument is the test of the intensity of the current by the amount of silver (or copper) deposited by it in a given time.

The simplest test, and sufficiently correct for instruments such as are used in medical practice, is by Ohm's law, $I = \frac{E}{R}$. Every physician can thus test his own galvanometer, if he has a rheostat

the profession are beginning to test the value of galvanism applied with precision and judgment, and those who not many months ago still upheld the theory of mild currents tested on the tongue, and long applied, are beginning to vaunt the effective strong current measured in milliampères. Erb and others have long since urged the importance of dose and measure, but a standard had not been adopted; the weber would not yield to the ampère or the Siemen's unit to the ohm, the instruments were rare and costly, and, above all, those who urged precision and measure did not themselves set the example. In but few instances do we find case histories so recorded that the dose is stated with precision. Apostoli gave us the milliampère intensity, this was a most important step forward, also time of application, and the size of the electrode could be inferred. All the essentials were indicated, though not given for the purpose of thus noting dose; these I have systematized, and I believe that I can say that a correct and serviceable dosage has thus been attained.

If the good results of faradism, applied with scientific precision, were equally appreciated, the profession would also be supplied with effective faradic apparatus; but as yet this is only to be seen in the laboratory, and has not been accessible to the practitioner, hence it cannot be tested, and faradic electricity will slumber on as galvanism has done, until some enterprising mechanic gives a suitable instrument to the profession. With the apparatus now in the market, satisfactory results cannot be accomplished; a regulating interruptor, a sliding scale, and a series of graduated coils are wanted.

(*To be concluded.*)

and a cell of known electro-motor force and known internal resistance, and if the resistance of his galvanometer be known.

Resistance consists of resist[illegible] R, of galvanometer plu[illegible] ternal resistance of cell plu[illegible] must be in a milliampère test, 1000 times E less (galvanometer R + internal cell R). Thus, if I take my Gonda-Leclanché cell

E = 1.3 volts.

R of my galvanometer = 0.4 ohm.

1.3 volts.

1.3 volts / 1300 ohm = 1300 ohms = R = R' of cell + R

1.3

To the neurologist, who deals with resistances in the human body of 3000 to 35,000 ohms, this galvanometer R of 60 or 130 [illegible] difference; in his treatment of the pelvic tissues, which offer a resistance of from 60 to 300, a galvanometer R of 130 is an important factor.

Why waste as much battery force in overcoming the galvanometer R as is needed to overcome the R of the tissues? It is a needless loss of power, and herein lies the great advantage of the Griffe galvanometer, which offers an R which can be practically overlooked,—less than one ohm.

MEDICAL PROGRESS.

Poisoning by Tyrotoxicon in Cream Puffs.—Dr. Stanton, Health Officer of Cincinnati, recently reported to the Cincinnati Medical Society several cases of poisoning by cream puffs. That these were the source of the toxic element was inferred from the fact that all the persons affected had partaken of puffs purchased on the same day at one bakery. All of the cases of poisoning occurred on Saturday or Sunday, April 2 and 3, but they first came to his knowledge on the Wednesday following, when one of the puffs was brought to the health office with a report of three of the cases. That the puff had undergone considerable decomposition, was shown by its sour, offensive odor, but no doubt much of the change had taken place after purchase, but that they were not as fresh as a delicacy composed of milk and eggs should be, might be inferred from the fact that one lady, when putting them upon the table on the evening of the day of purchase, remarked that she thought them stale. However, as all purchased by that family were eaten, they were probably at that time not so much changed as greatly to affect their taste.

So far as he had learned, four families were affected by the puffs from the one bakery. In one family there were five poisoned; in two families three each, and in one family two.

The patients all presented about the same symptoms, differing somewhat in degree, one patient being for a time seriously ill. The symptoms were those of an irritant poison. In most of the cases, in from one to three or four hours after partaking of the puffs, nausea came on, followed soon by vomiting, and later by purging. In some cases these symptoms were persistent. There was in all a sense of burning in the throat, stomach, and bowels, and great thirst. In the severer cases there were headache, and a disinclination to take food for some time.

Believing that the symptoms in the cases here referred to were due to tyrotoxicon poison, he made some chemical analyses according to the methods Prof. Vaughan has followed, and succeeded in isolating needle-shaped crystals which answer the description he has given of tyrotoxicon. He had not at hand the means of applying chemical tests to prove the identity of these crystals with that poison, nor had he time to get them before decomposition of the product rendered this impossible, for, like tyrotoxicon, it was very unstable; but he found by experiment upon himself that the residuum after evaporating the ethereal extract produced a sense of burning in the mouth and stomach, and nausea, such as are produced by tyrotoxicon. A larger amount would, no doubt, have produced vomiting and purging. The microscopic appearance, the unstable nature of the crystals, and the effects, convinced him that the poisoning in the cases here referred to was due to tyrotoxicon.

The method followed in testing the cream puffs was that recommended by Prof. Vaughan. A portion of the custard from one of the puffs was mixed with water. It was intensely acid. Potassium hydrate was added in sufficient amount to render the mixture slightly alkaline. An equal amount of ether was added, which, after separation, was removed by a medicine dropper. This was allowed to evaporate, and the residue dissolved in dis-

tilled water. This aqueous solution was again agitated with ether, and after separation the ethereal solution was dropped upon a microscope slide, and allowed to evaporate, the tyrotoxicon crystalizing in long, needle-shaped crystals. There were also visible on the slide some crystals of cholesterine, some phosphates, and other crystals, which were probably salts of potassium with some acid of decomposition soluble in both water and ether.—*Lancet-Clinic*, April 23, 1887.

Treatment of Lachrymal Tumor.—Grandmont treated a tumor of the puncta lachrymalis, with occlusion of the duct, as follows:

In the beginning he bathed the puncta in the following fluid:

Chloral. hydrat.,	
Sodii salicylat.	āā gr. 8.
Aquæ	ʒ 5.

He then dilated the duct with a sound.

If an abscess formed it was opened, and bichloride of mercury, in solution, was used as an antiseptic.—*Les Nouveaux Remèdes*, April 24, 1887.

Therapeutic Uses of Pyridine.—Dr. Dandieu, of Paris, has recently published a monograph on the use of pyridine and other allied bases (collidine, etc.) in which he states the following conclusions, supporting those already reached by Prof. Germain Sée:

1. Pyridine is indicated in attacks of angina pectoris. Its action is prompt. Its use prevents fresh attacks.

2. In asthma, whether of nervous, emphysematous, or catarrhal origin, inhalations of pyridine are to be preferred to subcutaneous injections of morphine; their effect is more lasting, and is unattended with danger. It is not only palliative, but truly curative.

3. In asthmatic attacks resulting from the inhalations of irritating gases, it is also an efficient agent.

4. In the dyspnœa of phthisis, and in that from affections of the larynx, its action is prompt.

Prof. Sée employs pyridine in the following manner: The patient is placed in a small room, about nine feet square. The pyridine, a teaspoonful, is simply poured on a plate, and set on a table in the room, where it evaporates spontaneously, impregnating the air with its vapor. In urgent cases, the pyridine may be inhaled directly, four or five drops of it being placed on a handkerchief and held before the patient's face.—*American Lancet*, May, 1887.

Formulæ for the Hypodermatic Use of New Remedies.—The following are from *A Manual of Hypodermatic Injections*, by Bourneville and Bricon:

1. Acid. chrysophanic	gr. $\frac{1}{2}$ to 1.
Aquæ destillat.	♏ 15.

Employed successfully in eczema, lichen, prurigo, psoriasis, and urticaria.

2. Acid. osmic.	gr. 1½.
Aquæ destillat.	ʒ 2½.

For interstitial injections in the treatment of tumors; in the treatment of obstinate neuralgia (Billroth, Neuber), from 8 to 15 minims of the solution may be injected in the vicinity of the affected nerve.

3. Agaricin.	gr. ¾.
Alcohol. absolut. . . .	♏ 70.
Glycerinæ	♏ 85.

The contents of an ordinary hypodermatic syringe, 20 to 30 minims, may be given for the night sweats of phthisis.

4. Antipyrin. hydrochlorat. . .	gr. 15.
Aquæ destillat.	♏ 15.

Solution should be aided by heat. Huchard has used the drug with benefit as an antipyretic.

5. Cicutin pur.	gr. 15.
Ether. acetic.	ʒ 1.

The contents of a hypodermatic syringe may be injected and repeated in fifteen or twenty minutes, or every hour, for obstinate diarrhœa, intestinal ulceration, in cirrhosis, and alcoholism. May be used in cholera, night sweats.

6. Kairin. hydrochlorat. . . .	gr. 1½.
Aquæ destillat.	♏ 15.

A powerful antithermic; antipyrine is preferable.

7. Alcoholic solution trinitrin, 1 to	
100	gtt. 30.
Aquæ destillat. (lauro-cerasi) .	ʒ 2 ♏, to ʒ 2½.

This should be injected into the muscles of the back or nates. To be given in angina or cerebral anæmia.

8. Paraldehyde,	
Aquæ lauro-cerasi . . .	ad ♏ 75.
Aquæ destillat.	ʒ 3¾.

The syringe should be plunged into warm water before giving the injection, to heat the fluid moderately. Paraldehyde is hypnotic and sedative.

9. Peterin. hydrochlorat. . . .	grs. 15 to 30.
Aquæ destillat.	ʒ 5.

Dose from 1½ to 6 minims in intermittent fever.

10. Thallin. sulphat. . . .	grs. 15.
Aquæ destillat. . . .	♏ 75.

The solution should always be warmed. One and a half grains of thallin, given hypodermatically, are sufficient to produce a fall of temperature of $2\frac{1}{10}°$ to $3\frac{1}{10}°$ in from six to nine hours.—*Journal de Médecine*, April 3, 1887.

Irrigation of the Knee-joint.—Dr. Culver reports in the *New York Medical Journal* of May 7, 1887, a case successfully treated, as follows:

The outer side of the knee at the place selected for puncture was injected with a four per cent. solution of cocaine into the skin itself, taking care that it did not get into the subcutaneous tissue; the joint and surrounding parts were scrubbed with a nail-brush, using the bichloride of mercury soap and a solution of the bichloride (1 to 1000), and we were then ready for the operation.

We had provided a fountain syringe with a metal nozzle, and a large-sized trocar and canula, the nozzle made to fit into the latter, all the steel instruments having been boiled in a carbolic solution, and everything else thoroughly antiseptically cleansed, also 1000 grammes of a 1 to 30 solution of carbolic acid made from distilled water, carefully filtered and warmed to 80° F.

The technique of the operation is to plunge the trocar into the lower and most distended portion of the synovial pouch, the assistant meanwhile making careful pressure over the whole joint with both hands, so that the serous fluid may first flow nearly out, and then the joint is to be carefully distended with the irrigating fluid, and by pressure gently emptied, and this is to be repeated until the fluid comes out clear, using from 450 to 1000 grammes (1 to 3 pints) of the irrigating fluid.

OVER-DISTENTION OF THE RIGHT VENTRICLE RELIEVED BY LEECHES.—DR. F. C. SHATTUCK, of Boston, reports, among others, the following interesting case:

M., aged eleven years, entered the House of the Good Samaritan, May 17, 1886, for mitral disease, the result of rheumatic endocarditis the previous winter. September 10th she was sent to the Convalescent Home connected with the institution, and stayed till November 20th, when she came back. Under absolute rest, careful feeding, and digitalis, she improved for a time, but grew worse again.

January 31, 1887. She was vomiting everything she took; there was marked cyanosis, and some ascites, anasarca, and hydrothorax; the jugulars and the liver were pulsating distinctively; the pulse was 129–130; the daily amount of urine had fallen to ℥2–3. Six leeches were ordered over the liver, and, with the subsequent bleeding, the amount of blood lost was estimated at ℥8. Immediate relief followed; the vomiting ceased, she had a good night, the next day the venous pulsation was scarcely to be seen, and she ate a good breakfast with relish. The amount of urine rose to 10 ounces on February 1st, to 9 ounces on February 2d, 10½ ounces on February 3d, 123 ounces on February 4th, 60 ounces on February 5th.

The pulse fell on the 3d to 90. It is only fair to state that on the 2d, she was ordered tincture of strophanthus ♏j. t. i. d. I do not doubt that this drug contributed to the diuresis and continued improvement, but from my experience with other cases I am persuaded that without the previous leeching it would have been useless. Since then I have pushed the strophanthus up to ♏vi, t. i. d., the pulse remaining at 108 all the time. There was an interval of a fortnight between the time the strophanthus was omitted and resumed.

The child is now up and dressed all day, and is steadily improving in weight and strength. I believe that her life was saved by the leeches.—*Boston Medical and Surgical Journal*, April 28, 1887.

CREASOTE IN PULMONARY TUBERCULOSIS.—FRANTZEL prescribes creasote as follows in the treatment of phthisis:

℞.—Creasote . . . . . ℈ 10.
[illegible] . . . . . ʒ ss.
Spts. vini rect. . . . . ʒ 7½.
Vini verici . . . . . ad O 2.—M.
Sig.—Daily two or three tablespoonfuls—after meals.

This treatment is best suited for cases of beginning phthisis, in which the progress of the disease is slow.

The treatment may be long continued. The results are a general improvement in the condition of the patients. The bacilli are not affected. Inhalations of creasote are useless (Koch and Gaffky).—*Berliner klinische Wochenschrift*, April 25, 1887.

INOCULATION FOR YELLOW FEVER.—DR. BUSTAMENTE, of Cucuta, South America, is quoted as follows by the *Boston Medical and Surgical Journal* of April 28, 1887:

"Dr. Urricoechea, surgeon of the frontier battalion, inoculated, by way of experiment, and with good results, five of his soldiers. Twenty minutes after the operation the temperature gradually ascended to 40° C., accompanied with all the symptoms of yellow fever. This lasted forty hours, at the expiration of which the fever and all attendant symptoms had disappeared. This operation was effected in a place called Moras, three leagues from Cucuta, and where a body of troops is stationed, who have not come to the city for fear of the fever. At present, the inoculated soldiers are here, exposed to the action of the focus of infection. As in Moras, no case of the epidemic has as yet presented itself." Dr. Bustamente, in his letter, says, "as yet my labors in the field of inoculation as a preventive of yellow fever are only, it may be said, mere experiments, which, although they may satisfy me with a well-founded hope of successful and complete result, cannot be of genuine utility until the best and most efficacious method is decided upon. I am thinking, however, of making an abstract of my observations, together with the method pursued, the results obtained, and everything that may be useful in the premises. For the present, I will confine myself to the statement that, in more than forty persons whom I have inoculated, a fever, with many of the characteristic symptoms of yellow fever, has presented itself; this fever, developed by inoculation, varying several tenths of a degree, and, in some cases, ascending to 41° C., but never presenting the most grave symptoms of yellow fever. The result of my observations permit me to state positively that the fever produced by inoculation is attended with no danger; and it is safe to inoculate, as I have already done, from children of two years to the oldest individuals. Many of the persons inoculated have come to this city, and in no case has the yellow fever attacked them, which gives me hope of a final result completely satisfactory. The municipality, assisted by the merchants, sent to Mexico, January 10th, a commission composed of two physicians, in order to study the inoculation of the fever."

TERPINE AS A DIURETIC.—LEPINE prescribes as follows:

℞.—Terpinal,
Sodii benzoate . . . . . aa gr. 15.
Sacchar. alba. . . . . q. s.
Ft. pil. 10 in num.
Sig.—From five to ten pills daily.—*Journal de Médecine*, April 10, 1887.

ICE POULTICE.—Spread a layer of linseed meal, three-fourths of an inch deep, on a cloth of proper size, and put pieces of ice the size of a marble on the meal at intervals of an inch; then sprinkle lightly with the meal; cover with a cloth, and turn over the edges; apply to the thick surface to the skin. The meal protects the skin and excludes the air from the ice, thus preventing melting.—*Technics*.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE $5.00

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in registered letter.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MAY 21, 1887.

HÆMATEMESIS IN TYPHOID FEVER.

IN no disease does the unexpected happen more frequently than in typhoid fever, and, therefore, every possible complication, no matter how rare, must be borne in mind as something that may, at any moment, assume a primary importance. Hæmatemesis in the course of typhoid fever from ordinary causes, such as simple or malignant ulceration and cirrhosis of the liver, is a very rare event, but decidedly more common than that occasioned by the specific typhoid deposit in the gastric mucous membrane. A few cases of this latter sort have been reported, in one of which, that of Millard, the diagnosis was confirmed by the necropsy. On the anterior wall of the stomach, near the pyloric end and a little below the lesser curvature, was an oval ulcer one inch and a half long by three-quarters of an inch wide, with an irregular border, extending in depth to the serosa. Directly opposite, on the posterior wall, were two small superficial ulcerations.

In 1834 Chomel referred a hæmatemesis in a case of typhoid fever to a specific typhoid ulceration of the stomach, and Murchison, quoting this case, admits the explanation.

The most recent contribution to this subject is by WEISS, of Prague, who, in the *Wiener medizinische Presse*, Nos. 13 and 14, 1887, reports the case of a soldier, aged twenty-two, who succumbed to profuse gastric hemorrhage at about the beginning of the third week. This was preceded by intestinal hemorrhage. In the absence of a post-mortem examination the diagnosis was based on the following facts. At the time of the attack of fever the patient was in excellent health, and had never suffered from any symptoms of gastric disturbance. He was not a drinker, had never had syphilis, and the heart and lungs were sound. There were no petechiæ in the skin and there had been no epistaxis, and, finally, a careful inspection of the naso-pharyngeal cavity revealed no lesion whatever. The source of the fatal hemorrhage was, therefore, the duodenum, the lower portion of the œsophagus, or the stomach, and its cause, considering the previous physical condition of the subject, was presumably typhoid ulceration.

Numerous authorities are quoted by Weiss to prove that typhoid processes in the stomach and its immediate neighborhood are more common than is generally supposed, and that symptoms usually regarded as functional, are often due to structural changes. Louis and Jenner have observed typhoid ulcers in the lower portion of the œsophagus. Röderer and Wagner have described an œsophagitis follicularis as common in an epidemic in Göttingen, and Eichhorst and Reimer have observed similar changes.

Rokitansky has noticed infiltration and even necrosis of the so-called lenticular glands of the stomach, and Chauffard and Cornil have described an infiltration of the mucosa and submucosa with lymphoid cells which may proceed to the formation of miliary abscesses.

A particularly interesting case of abnormal localization of the typhoid process, is described by Chiari. The stomach, duodenum, and upper part of the jejunum were the seat of swelling, hyperæmia, hemorrhage, and superficial necrosis, while scarcely any abnormal change could be demonstrated in the ileum. Prof. Chiari states that he has not seldom observed typhoid changes in the stomach, and there can be no doubt that typhoid processes in the stomach and its neighborhood would be frequently found if carefully sought for. But such a search is decidedly exceptional, since there is a general belief that all claims to represent typhoid fever have been long since preëmpted by the ileum.

Diagnostic indications of this process in the stomach are cardialgia, sometimes intense, vomiting, tenderness in the epigastrium, and pain in the same region elicited by pressure over the cervical sympathetic. This last symptom was well marked in the case reported by Weiss. Eichhorst observed in the Zürich epidemic that a rise in temperature preceded the occurrence of intestinal hemorrhage; and in analogy with this Weiss reports that in his case the temperature rose to 105° F. immediately before the vomiting of blood.

The treatment of this form of hæmatemesis is the same as that of gastric hemorrhage from other causes, and includes the administration of ice pills and styptics, of which one of the best is alum whey. It is certainly reasonable to suppose that the efficacy of such remedies administered *per os* will be in

proportion to the vicinity of the bleeding surface, and that, in consequence, greater success will attend their exhibition in gastric than in intestinal hemorrhage. Ergotine hypodermatically and cold compresses to the abdomen are important therapeutic measures, although the latter may be contraindicated, as they were in the case reported by Weiss, by excessive epigastric tenderness.

The communication of Weiss proves that the [illegible] exhausted, although undoubtedly hackneyed from continued reiteration of well-known facts. It should stimulate observers to a more careful study of the upper sections of the digestive tract, not only when the lesions in the ileum are slightly manifest or absent, but as a matter of routine in every case of typhoid fever.

THE INDUCTION OF LABOR BY ELECTRICITY.

The report of seven cases by Brühl in the *Archiv für Gynäkologie*, B. xxx. H. 1, confirms and emphasizes the unfavorable opinion we had occasion to express some time ago in regard to the employment of electricity to induce premature labor. In each case the application of a galvanic current for a number of days successively resulted in uniform failure. Nothing more was accomplished than the dilatation of the os to the size of a dollar; so that, in order to stimulate the uterine muscle to sufficiently energetic action to complete the labor, other means had to be employed.

Not only was the galvanic current insufficient, but it was also decidedly deleterious in its action. In one case, the skin over the fundus uteri was injured by the anode, while in two cases there was a purulent vagitinis as the result of the application of the cathode to the cervix, although careful antiseptic precautions were observed.

The prolonged application of the electricity, moreover, deadened the sensibility of the uterus in a remarkable manner, so that when it became necessary to resort to more powerful stimuli, they met with but a sluggish response. But still more serious was the fœtal mortality, for, of the seven children, five were stillborn, three from prolapse of the umbilical cord, due to the lively movements of the fœtus excited by the electrical current.

Electricity by no means answers the description of the best agent for inducing labor, one that will with certainty cause the expulsion of the fœtus within a reasonable time without danger to the mother or child; but in view of the fact that it will dilate the cervical canal up to a certain point, it might possibly be used, as suggested by Lusk, as a substitute for tents. On the whole, however, we are disposed to echo Dr. Brühl's conclusion that he cannot recommend it.

THE COMPARATIVE ACTION OF ANTIPYRIN AND ANTIFEBRIN.

Although antifebrin has but just come into use as compared with its fellow, antipyrin, little doubt exists that it is preferable to the latter. Aside from the results obtained by comparative tests at the bedside, more particularly by Eisenhart, as reported in *Münchener med. Wochenschrift*, 1886, No. 47, and by Cahn and Hepp in *Berlin. med. Wochenschrift*, 1887, Nos. 1 and 2, the general profession has not reported as many untoward effects from its use as from antipyrin, while its cheapness, small dosage, and reliability have already given it a place of high esteem among clinicians.

Both Eisenhart and the French observers reach the conclusion that five grains of antifebrin are equal to twenty of antipyrin, and although this is somewhat below the estimate made by the profession in America, it so nearly approaches the results obtained here that the matter may be considered as settled.

It will be remembered that the chief objection to antipyrin was that it was capable of causing profound collapse, as well as other minor, but scarcely less alarming, symptoms, and it should not be forgotten that antifebrin may produce the same result, if given in large doses in susceptible cases.

Many observers have noted the appearance of an exanthematous rash under its use, and Heinzelmann, in the *Münchener med. Wochenschrift*, 1887, No. 3, reports cases in which deafness and mydriasis occurred. These instances of untoward effects produced by antifebrin are fortunately sufficiently scattered to permit us to use the drug with great freedom. Indeed, the only manner in which the two drugs act identically, other than as antipyretics, appears to be the profuse sweat which they produce about the time of their absorption into the circulation.

Sudden cardiac failure has been produced by both drugs, and in a single case of pneumonia in which antifebrin was administered, which has come to our knowledge, the patient, apparently convalescing, while sitting up in bed talking to a friend suddenly dropped back dead on the pillow. It is but just, however, to state that the patient had been a sufferer for many years from disease of the mitral valve, and as no post-mortem was allowed, the exact cause of death cannot be stated; although the attending physician, a man of good judgment, ascribed it to the drug, with sufficient reason in his own mind to prevent his using it but carefully a second time.

The experience of the profession in this city has certainly engendered the belief that in a very large proportion of cases the newer antipyretic may be used with advantage in place of antipyrin, and unless some as yet undetected evil influence exerted by it is discovered, it will, without doubt, remain

one of our chief aids in the reduction of abnormally high temperatures.

MORTALITY OF FOUNDLINGS.

From some inquiries recently made at the Philadelphia Hospital we learned that of sixty-six foundlings received during four years into that institution, thirty-five died within the first year. It is true, some of these deaths were caused by measles, but the great majority of these infants perished from what, though commonly known as marasmus, really means starvation. Now the secret of this starvation was not an inadequate supply, or absolutely unsuitable character of food, or failure to give it at proper intervals, but too much was given.

The most frequent mistake in the artificial nourishment of newborn infants is giving them the quantity of food which the infant at six months, for example, requires; disorder of the digestive organs quickly follows this constant overloading the stomach, the child soon loses its plumpness, then becomes rapidly emaciated, gastric catarrh and diarrhœa set in, and the poor creature dies starved to death by over-feeding. The proper remedy, the true way to prevent this evil in public institutions, and often in private practice, is to have nursing-bottles which will hold only the quantity of food needed; for example, instead of using a bottle which holds four to six ounces, as that generally used does, employ one which will hold only two ounces, for an infant during at least the first two months of its life. We believe, if this rule be observed, the mortality of hand-fed infants would be materially lessened.

The relation between managers and the medical staff of hospitals is, as a rule, on a very unsatisfactory basis, and the recent action of the Managers of the Pennsylvania Hospital in dropping suddenly, without a hearing, and without known cause, one of the surgeons to that institution, has aroused considerable and just indignation among the profession in this city.

Managers occasionally appear, as in the present case, to regard the medical staff as their servants, and to be subject to dismissal at their pleasure. It is true that the staff are the appointees of the managers, but as they contribute their professional services without pay, and as these services are the essential object for which the charity exists, the staff have a just right to consider themselves contributors to the institution fully equal in import to those who give money for the support of the patients while under professional care; and they should receive from managers that consideration to which their position as coördinate dispensers of the charity equitably entitles them.

The recent case appears, in all its phases, as a most flagrant act of injustice to a faithful medical officer, and to place a stigma upon his professional reputation which is ineffaceable and unwarrantable. That the vacancy has been filled is greatly to be regretted, as, apart from its ethical aspect, upon which much could be said, it tends to imperil the position and reputation of every hospital physician and surgeon in the land.

The numerous mental scientists, faith healers, and the like, which have recently sprung up in Chicago, are greatly disturbed over a bill now pending in the Illinois Legislature, which, if it becomes a law, will hamper their operations. The bill was prepared by the State Board of Health. Under the regular State law certain qualifications, such as a diploma from a recognized school of medicine, are required from every person who practises medicine within the State, but a person who has not been graduated from a recognized medical school may get a license by passing an examination that will be satisfactory to the Board of Health. The proposed new act contains this clause:

"Any citizen shall be regarded as practising medicine, within the meaning of this Act, who shall treat, operate on, or prescribe for, the sick or afflicted."

It is furthermore provided, that a fee of $25 shall be paid for the examination of non-graduates, and that itinerant vendors of anything intended for the treatment of disease, or who, in any way, profess to heal disease by any drug, nostrum, manipulation, or other expedient, shall pay a license of $100 a month to the Board.

If this bill becomes a law, the large number of irregulars in Chicago, who profess to cure the body by magnetic healing, Christian or mental science, or by any means of a spiritualistic or metaphysical character—whether natural or supernatural—must pass a satisfactory examination before being allowed to practise.

With its issue of May 7th *The Medical and Surgical Reporter* passed under the control of Drs. Randolph and Dulles as editors and publishers. Its new managers, who, however, are not new to medical journalism, are well equipped for the task which they have undertaken, and the interests which have been confided to their hands will be ably maintained and promoted.

Dr. D. G. Brinton states that it is not his intention to retire from the arena of medical journalism, and that he hopes in the early autumn to announce his connection with a journal which will fully meet the legitimate demands of the medical public of the day.

THE second annual meeting of the Association of American Physicians will be held in the Army Medical Museum building at Washington, on Thursday and Friday, June 2d and 3d, under the presidency of Dr. S. Weir Mitchell. The programme, which appears in another column, embraces the titles of a number of interesting papers.

THE American Laryngological Association will hold its Ninth Congress in New York, Thursday, Friday, and Saturday of next week, under the presidency of Dr. E. Fletcher Ingalls, of Chicago. The programme, which appears in another column, gives promise of an unusually attractive and instructive meeting. The profession is cordially invited by the Association to attend its sessions.

THE Annual Commencement of the College of Physicians and Surgeons of New York was held at Steinway Hall on May 12th, and the degree of M.D. was conferred on 106 graduates. The Cartwright Alumni prize of $500 for the best medical essay, open to universal competition was awarded to Dr. B. Farquhar Curtis, of New York, for his monograph on "Injuries to the Abdomen and Rupture of the Intestines."

SOCIETY PROCEEDINGS.

AMERICAN SURGICAL ASSOCIATION.

WEDNESDAY, MAY 11TH, FIRST DAY.

MORNING SESSION.

The Association was called to order by THE PRESIDENT, DR. HUNTER MCGUIRE, of Richmond, at 11 A. M. On motion roll call was dispensed with, and the President delivered the *Annual Address* on

THE NEED AND VALUE OF COÖPERATI[illegible] IN SURGERY.

That "in union there is strength" is a proverb recognized and accepted by all men. Nearly every advance is secured by coöperative effort. Every department of life is full of illustrations of the power of association in the accomplishment of great purposes, while the examples are almost as numerous of the failure of individuals to attain those ends because they work unaided and alone. A number of historical examples were cited to demonstrate what has actually been accomplished by united effort, and such, the speaker added, are the successes and triumphs which await us, if we too appreciate its value, and avail ourselves of its potent influence. If the celebrated aphorism of Pliny be true, that "to live is to observe," it is evident that the more observers there are in the field, all having their investigations directed to one end, the richer must be the discoveries which make professional life, in the largest sense of the word, worth living.

Advance in surgery can be more surely made by Associations such as ours, than by any individual effort. The life of one man is too short, and his field of labor too narrow, for him alone to hope to settle many of the vexed problems in our science. The day has passed when the dictum of one man, however exalted, is received without question. The desire now is to know what the mass of thinking men in our profession believe, preach, and practise. Few discoveries of value have been obtained by the observations of one man, although they may at the first glance thus appear.

The difficulties which beset us are many, and at first sight almost insuperable. Disease presents problems difficult to determine. We cannot apply to the human machine the fixed rules by which inanimate bodies are governed. The result of the work of the surgeon in private houses and in public hospitals must be different. The result obtained by the military surgeon is something different from the work of the surgeon in time of peace. The subtle influence of social and moral condition, of climate, season, individual and race peculiarity, the surroundings of the patient, have all to be considered in settling many questions, and determining the value of many contributions.

But we cannot as surgeons alone hope to determine many of the questions which must arise in our calling. We need and must accept the help of the biologist, the patient disclosures of the pathologist, the work of the chemist, and that of every known science and art. For the developments awaiting us we must be indebted to the contributions which every patient and conscientious laborer may bring to the common stock of ascertained knowledge, and we will accomplish this best by the cultivation of a broad and generous appreciation of each other's work.

In conclusion, the President made a few suggestions for the improvement of the Association.

DR. GROSS asked that a committee be appointed to consider the suggestions contained in the address of the President. Drs. Gross, C. H. Mastin, D. W. Yandell, Moses Gunn, and C. Johnston, were appointed this committee.

The Association then went into executive session.

AFTERNOON SESSION.

DR. F. S. DENNIS, of New York, read a paper on

THE EXPLORATION OF THE BLADDER BY THE SUPRAPUBIC METHOD,

which will appear in full in an early number of THE MEDICAL NEWS.

DR. JOHN H. PACKARD, of Philadelphia, then read a paper entitled

SUPRAPUBIC CYSTOTOMY FOR PURPOSES OTHER THAN THE EXTRACTION OF CALCULUS.

He reviewed the history of the operation. Although introduced in 1560, it has, until very recent times, been regarded with a species of superstition, and in the schools and by private instructors it was either entirely passed over or mentioned with disfavor. When it was first performed in this country by Dr. H. Lenox Hodge, in 1874, the operation was severely criticised by many of the best surgeons, although it was eminently proper.

He did not wish to appear as an advocate of suprapubic cystotomy as against all other methods of access to the bladder; but simply to discuss the question whether or not the objections which have prevailed to place it in the background are shown by reason or by experience to be well founded. This he desired to do without bringing in the matter of hypogastric lithotomy, which has been so ably and so thoroughly handled by Dulles, of Philadelphia, and others; although he recognized, at the same time, the great difficulty encountered in an attempt to leave it wholly aside.

With regard to the proposed surgical procedure, the questions which must arise are: How far is it free from risk in itself? How far does it effect the object in view? What are the difficulties attending its performance? And in comparing any procedure with others having the same end, the same questions must arise, but in the comparative form: Is it more or less safe? Is it better calculated, or not so well, to effect the desired object? Is it easier of performance or more difficult?

He entered into the discussion of the details of the methods of procedure adopted in opening the bladder above the pubes. First, the most thorough antiseptic precautions were advised. In regard to having the bladder distended, he said that most of his cases were of the character in which the organ had been already in danger of bursting from the pressure of the contained urine. With regard to the distention of the rectum, he thought that there is less risk and more advantage. By thus preventing the sinking of the bladder into the pelvis until all the arrangements for drainage have been fully made, one possible source of danger and embarrassment is set aside. With regard to steadying the bladder by the hand of an assistant, when the incision or puncture is to be made, as recommended by some, he thought the procedure not only needless but objectionable. The incision through the skin should be free enough to give ready access to the deep parts. In fat persons it must be about three inches long, but when the abdominal wall is thin two inches in length will suffice. When the incision is made in the median line no vessels of any importance can be encountered. Before opening the bladder it is very necessary to get control of it in some way, lest it should, as the urine flows out, collapse, settle back into the pelvis, and render the orifice made by the surgeon very hard to find. It may become still more difficult to insert a canula. For this purpose he recommended a small double hook, recurved and set at a right angle on a stem. A small tenaculum may be made to answer the same purpose, though its sharp point is objectionable. When a large opening is to be made into the bladder for purposes of exploration, the ligature is perhaps the best method of all for the purpose.

A curious proposition has been made by Duchatelet, and is quoted by Villeneuve, that the opening in the bladder should always be made through the peritoneum, and thus, as he says, that "plasticity should be substituted for friability." Considering the view that the danger of wounding the peritoneum has always been one of the strongest objections to the suprapubic operation, it is only the bolder of the bold who would be thus likely to take the bull by the horns. In regard to the proper point at which to open the bladder, he thought that many authors in avoiding Scylla had steered into Charybdis. In attempting to avoid the peritoneum they had made their incisions so low that the opening must sink below the pubes when the bladder was contracted. In his own opinion the best point is at about the middle of the exposed portion of the viscus.

For drainage he preferred a soft rubber tube of a length to be determined for each case. It should go well into the bladder even when collapsed, and should have lateral openings only near its inner orifice. He did not favor the proposition to have the patient lie on his belly in order to facilitate drainage, because of the discomfort it occasioned. If the opening into the bladder had been large, he recommended the use of two or three catgut sutures. The external wound should be closed also with catgut or silkworm gut, and the drainage tube may be secured by passing through it one of the sutures.

In conclusion, he claimed that it had been his endeavor to examine fairly and without prejudice into the case for and against the suprapubic section of the bladder apart from lithotomy. It would seem, he said, that there has been a mixture of tradition and a sort of superstition in the feeling with which this operation has been regarded. The proportion of absolute successes, so far as he was able to calculate, was eighty per cent., the failures about seven per cent., and the instances in which bad consequences were attributable to the operation about eleven per cent. And in looking at the cases in detail, it seemed to him that on all the counts of the indictment, danger of peritonitis, danger of infiltration of urine and urinary gases, danger of urinary fistula, a verdict of at least "not proven" may fairly be asked for. The suprapubic operation does not by any means in any case preclude the perineal, as was shown by a number of cases cited in the paper. On the contrary, it frequently prepares the way for it.

One question he would ask: If the suprapubic operation had been first tried and generally adopted, is it likely that the perineal operation would have been afterward performed on account of its great ease, simplicity, or efficiency?

DR. A. VANDERVEER, of Albany, then presented a paper entitled

TO WHAT EXTENT CAN WE CLASSIFY VESICAL CALCULI FOR OPERATION, WITH A REPORT OF CASES AND REMARKS ON THE DIFFERENT METHODS EMPLOYED.

In explanation of his presenting a paper on this subject, he remarked that, while he did not come from a stone-bearing section, he had found from conversations with his associates, that he had operated upon rather more than the average number of cases in the vicinity, and it is an operation to which he had devoted considerable study. He then reported briefly his more marked cases, forty-one in number, following the reports with a brief statement of the different methods employed in this and other countries for the treatment of stone. The cases presented represented every variety of stone, as to location in the bladder, prostatic, membranous, and spongy portions of the urethra. The kinds as to formation of hard and soft calculi was singularly complete, while the extremes as to size were remarkable.

After a review of the literature of the subject, he formulated the following conclusions:

In the cases reported, the litholapaxies, where the

stone was small or up to moderate size, did quite as well as the clean lithotomies.

Regarding the operation of rapid lithotrity, there is much that is wanting in the study of the after condition of the patients, and we ought soon to have valuable statistics on the subject. In this regard we must remember the fallacy of all tables, since many cases never return to the first operator.

In male adults if there is severe chronic cystitis, the suprapubic, or some form of perineal section seems best. One condition in the adult has not received proper attention, namely, the contracted bladder with adhesions, and that must in some instances embarrass the doing of the suprapubic operation. On anatomical grounds the suprapubic operation is much simpler in the youth, owing to the fact that the bladder is much higher in the pelvis.

In girls, rapid lithotrity or suprapubic lithotomy will undoubtedly reach all cases. In adult women, vaginal lithotomy may be added.

Can we yet classify our cases with certainty as to what is the best and most certain course to pursue for the safety of our patient's life and future comfort? In attempting to do this with his own cases, he said, there were seven perineal lithotomies with two deaths and five recoveries, the deaths being in old men with very large calculi. Of attempted lithotapaxies there were two cases, both resulting in death, one in his own practice and one in that of the late Dr. Snow. Both were very severe cases of large stone, and the patients presented a history of much suffering through many years. Of dilatation in the female and washing out of fragments or removal of stone entire, there were six cases, all recovering with no complication whatever. Of urethral calculi in the male, there were four cases, all recovering. Of simple lithotrity in the male, there was one case, followed by recovery. Of attempted litholapaxies, which were not completed, there were four cases, three ending in death, and one in which the stone was hidden in a sac and later underwent lithotomy and recovered. One was probably complicated with some form of tumor of the bladder, and had a history of chronic disease of the kidneys. One was a case of chronic alcoholism. One was complicated with sacculated bladder, and the last two were cases of surgical kidney of the very gravest kind. Of the litholapaxies in the male there were eighteen patients having twenty-two operations, four requiring a second operation. Of the number, sixteen recovered and two died; the latter, one after the first and one after the second operation.

He closed with a few remarks on the difficulty of securing a proper examination of the urine, such as would reveal the true condition of the kidneys. Casts are very generally absent; albumen can very often be traced to the presence of pus, and he expressed the conviction that we have yet much to learn from the surgical kidney.

On motion, the discussion of the papers read was postponed until Thursday morning.

The President then announced the following

[illegible]

Drs. J. Collins Warren, John H. Brinton, N. P. Dandridge, T. F. Prewitt, and D. W. Yandell.

THURSDAY, MAY 12TH, SECOND DAY.

MORNING SESSION.

The special order of business was the discussion of the papers read on Wednesday on

OPERATION FOR STONE.

DR. W. T. BRIGGS said that Dr. Dennis's paper gave us the history of the details of performance of suprapubic cystotomy for the removal of stone, and the only point which he desired to notice was the sweeping annunciation that it should be applied, and would be applied hereafter, to all cases, and in all conditions and circumstances, except those in which litholapaxy is resorted to. His own impression is that there is no special operation adapted to all cases, but that each case should be closely scrutinized, and selected for some special operation adapted to that case. He is satisfied that the suprapubic operation is not adapted to all cases. That it is the best for a certain number of cases, there can be no doubt. For a very large stone, too large to be brought through the pelvis without tearing and bruising the soft parts, where there is a deformity of the pelvis, or an injury of the limbs which will not permit of their being brought into the proper position for operation, he has no doubt that it is the better operation to perform.

But there are dangers which attach to this operation, which are greater than any that attach to the perineal section. First, there is the danger of injuring the peritoneum, though that is not great. There is danger from the very manner in which the operation is performed, the distention of the bladder, the distention of the rectum, and then there is a remote danger of hemorrhage. Nor do the statistics bear out the claim that it is the best operation. Further, statistics are always uncertain. If he remembered correctly, the essayist had stated the ratio of deaths as 11 in 120; other statistics give it as much higher. Dr. Gross's statistics state it as 1 in about 4½. He did not think that we can regard the operation as so innocuous as Dr. Dennis did. That we can safely reach the bladder by this method is certain; that we reach it at the best point is another thing. There is no reason that, in cases of stone of moderate size, we should not reach it by passing through the perineum. The lateral operation is so safe as to be attended by almost entire success in children. As a matter of course, when we advance in life the mortality is greater, for, as a rule, the stone is larger in size. The bladder is easily reached; we reach it at a part where it is naturally most easily drained, and at a point where the wound is readily recovered from.

Then again, the operation which he regards as the best, and one in which we can reach the bladder more easily, in a shorter distance, with less hemorrhage, is one where the incision is made directly in the median line, in the raphé, which is merely a seam holding the other parts taut, and which, when divided, permits dilatation of the parts on either side, to almost any extent. There is a considerable danger, however, in the median operation of the neck of the bladder being firm and resisting, but this can be readily overcome by making a little incision on either side into the prostate gland, dividing the gland and the mucous membrane, and when this incision of three lines on either side has been made, the

parts can be opened up to a sufficient extent to remove any stone which can be brought out of the pelvis. It is sometimes said that an incision cannot be made in the median line large enough to bring out a stone of very large size; that if large stones are brought out of the median opening, they bruise and tear the parts so as to cause infiltration of urine and the consequent bad results, but he showed a few stones that he had brought out through the three-line incision with dilatation, and whether the soft parts were lacerated or not, the patients got well. He produced several calculi of remarkably large size, one being as large as a goose's egg. The largest stone, he remarked, would have been better removed by the suprapubic method, as the patient made a tedious recovery. The median operation is certainly simpler and safer than the suprapubic. If the stone is so large that it will tear the perineum, there is no reason why we cannot pass in an instrument through the opening into the bladder, and crush it previous to extracting.

The world owes a debt of gratitude to Dr. Bigelow for litholapaxy. There is no doubt, however, in his mind whether a clean incision with the removal of all the stone at once, would not present a greater amount of relief—*i. e.*, a less mortality—than would litholapaxy. He then narrated the circumstances which led to his adopting the median operation, which is substantially that of Civiale. Previous to this, he had operated on 45 cases; 40 of them were done according to the old method of Dupuytren, with the lithotome. Since he had adopted the method of Civiale, taking all cases, and not confining it to children, some being children, some adults, some old men, he had operated on 74 consecutive cases without a death. Then two deaths followed, in men of twenty-two years. One had a pelvic abscess, which ruptured in the operation, and the other was a scrofulous subject. Since that time, 45 cases have been operated upon, with one death. That patient died of general tuberculosis three months after operation, with the wound ununited, but with no trouble in the bladder whatever. The mortality of the operation is very light.

In conclusion, he expressed the belief that if the cases are suited to the operation, and the operation is skilfully performed, it can be done with no mortality. Six of his cases were old men, over sixty years of age, and all recovered.

Dr. D. Hayes Agnew said that, as Dr. Briggs had remarked, we cannot tie ourselves to any one operation. Every case must be a case that stands by itself. In reference to the suprapubic operation, he had always said that he did not see the advantage of getting on top of a house to get in, when you can get in on the ground floor. The median operation is unquestionably the safest of all operations in the perineum. Nothing of any importance is divided. The only damage likely to be caused in extracting a large stone is to the neck of the bladder, and that can be corrected by a little nick made upon either side which admits of expansion of the wound to almost any extent that is necessary for the extraction of an ordinary stone. Where the stone is found by exploration with the finger to be one of great magnitude, and yet one which should come through the perineum, it is well to divide a little on either side of the neck of the bladder, and convert what would be a lacerated wound into an incised one, which is always less dangerous.

There is still another feature, which is likely to make this operation even less dangerous than heretofore. That is the use of antiseptic solutions, substituting the warm water which used to be employed by a weak solution of the bichloride. The cases in which the suprapubic operation should be used, are those in which the stones are of very great magnitude; so that, when we come to sum up this whole matter in the future, as we will do, the profession will settle down to the old operation. Still he thinks that we should adhere to the old maxim, "Try all things; choose the good."

Dr. J. R. Weist had operated a few times for stone by other methods before, but since he was acquainted with the operation of Dr. Briggs, he had invariably followed it. He felt so well pleased with his successes, all his patients having recovered, that he was indisposed to change for an operation which he was led to believe requires more care and a higher degree of skill. It would be remembered that the essayist was particular to give very specific directions as to making the incision, he also spoke of the danger of going too far up, the danger of going too far down, too near the pubis, all of which conveyed the impression that the operation is one requiring great experience and care. All of his patients, he continued, with one exception, have been old. While he was willing to admit that there are cases in which a resort to the suprapubic operation would be proper, still he believed that the median bilateral operation is preferable, and that it is a safer operation even than crushing the stone. In the report of Dr. Vanderveer yesterday, he had observed that in some instances in which he had very carefully washed out the bladder, the autopsy revealed the fact that he had not succeeded in removing all the fragments.

Dr. William A. Byrd remarked that there was no occasion for tearing the soft parts in extracting a large stone through a perineal opening, providing the stone be crushed. For this purpose he recommended an instrument with short thick blades, capable of exerting great pressure, without risk of including the walls of the bladder in its grasp.

Dr. Mudd remarked that the median lateral operation had been followed by such successes that it seemed to him the last of operations to be displaced; but with the introduction of litholapaxy there came a revival of the suprapubic operation, and to this, he thought, is due, more than to any other circumstance, the attention which has been given to the latter operation. That it is a valuable operation for exploration or for the removal of a very large stone he agreed, but that it is better than the other operations he did not believe.

In the discussion yesterday the proper test of the value of this operation was referred to—that is, its applicability to those cases of chronic cystitis with firmly contracted bladder. He had in his possession a specimen in which the bladder was very small, not capable of containing more than two ounces of fluid, the walls being from a half to three-fourths of an inch thick and so rigid that they would break before they would yield. In this instance he made the lateral operation and consequently lost the patient.

In another case in which he had conducted a post-mortem in an old man who had suffered for years from stricture, he found a very firm, hard bladder. In another case a bullet had passed entirely through the

bladder. The viscus had been operated upon and explored by the perineal method. He found an injury in the floor of the bladder through the base, on the left side. The patient had a severe and purulent cystitis. Another induration was felt in front extending above the pubic bone. It was so rigid and dense that no impression could be made on it through the abdominal wall. Suprapubic cystotomy was made. Upon passing through the abdominal wall in the median line, a firm, dense, fibrous thickening of pyramidal form was found resting upon the pubic bone. Into this he made an incision but found himself unable to separate the edges of the wound so as to get access to the bladder, although the latter viscus was easily distended. The sound in the bladder reached the abdominal wall above the induration. After exposing quite fully, as he thought, the bladder wall, he made an incision and found that he had punctured the peritoneum. Opening up more freely the cavity he pushed his finger on and exposed the bladder, made an incision into it and explored it with the finger. He accomplished nothing by the operation. He found no difficulty in closing the wound and the patient made a good recovery.

DR. J. COLLINS WARREN had seen two cases of suprapubic cystotomy within the past year, one for a stone of large size, the other for a tumor of the bladder. There did not seem to be any difficulty in the operation on anatomical grounds. Both cases recovered. The sound was not required in either case. He had also had a case which illustrated the advantage of this operation. The patient was one who had been operated upon for stone by the father of the speaker, thirty years ago, by the bilateral method, and came under his care suffering again from symptoms of stone. Upon examination he found a calculus lying in a cul-de-sac on the distal side of the cicatrix in the bladder wall. It was removed by perineal section and the man recovered. He had, however, thereafter, ejaculation of semen into the bladder entirely.

He had in one case performed vaginal cystotomy. He found no danger of the production of vesico-vaginal fistula. It is only in cases in which a large amount of the vaginal wall is destroyed that there is danger of a fistulous opening remaining; an incised wound of the wall readily heals. For large stones suprapubic lithotomy may be resorted to, although litholapaxy is a good operation, performed many times in Boston. It is an operation which, however, is not required in females. Operators have never had any difficulty in Boston, he concluded, in getting out the fragments of stone after litholapaxy. A good deal depends upon the method of using the evacuator, it should be used slowly and cautiously.

DR. T. R. VARICK thought that the size of the stone had been made a good deal of a bugbear in regard to the extraction through the perineum. He reported the case of a boy of fourteen who had suffered from symptoms of stone for seven years, and upon whom he operated by the bilateral method and extracted entire a stone weighing seven ounces and four scruples, as large as an ordinary goose's egg. There was no perceptible laceration of the soft parts and the boy made a progressive recovery. That seems to controvert the idea of Sir Henry Thompson that no stone weighing more than three ounces can be removed through the perineum. The operation just reported was made on the 9th of December and the boy left the hospital on the 30th of December, well. The speaker makes a practice of applying hot water to the wound immediately after the operation, both as a styptic and as an antiseptic, using a sponge dipped into water just below the boiling point.

DR. D. W. VANDELL said that, in the main, the ground occupied by Dr. Agnew exactly expressed his views of the subject. His own experience amounted to a total of 106 cases; of lithotomy 92 cases, of lithotrity 8, and of litholapaxy 6. He did not feel inclined to change to the suprapubic operation. It did not strike him as an operation that is any better or any safer, except as to virile powers. Nearly all his cases were in young persons. In the cutting operation his losses had been seven per cent., without any returns of the stone. In the eight lithotrities he had had two returns, and the same number of returns in the six litholapaxies. Up to date he considered the operation of Dr. Briggs the best that can be made, and preferred any perineal section to the suprapubic.

DR. JOHN B. ROBERTS remarked that we yesterday heard only one side of the operation; whereas, to-day, we hear only the other side of it. The truth would probably be found in the median line. For his own part, he could not change the opinion he had expressed three years ago, when he said that the high operation is certain to become an important one. The discussion this morning has been almost entirely with reference to stone, without taking into consideration its applicability for exploratory purposes, for tumors of the bladder, etc. Is not the suprapubic operation in reality the better; is it not the safer operation? In regard to treating stricture of the urethra by the suprapubic operation, he thought it rather a severe operation to attempt. Aspiration will generally, on the second or third day, at least, result in getting an instrument into the bladder.

DR. J. E. MICHAEL thought that we should consider further the remarks of Dr. Packard with reference to the evacuation of retained urine. As to this or the same operation for the relief of stricture he thought the latter speaker had gone too far. Opening the bladder by the "ground floor," as Dr. Agnew expressed it, is always simple, and seems to have many advantages over the suprapubic method. He thought that suprapubic aspiration is all that is necessary for the immediate relief of the retention, and the true indication in prostatic cases is the use of the soft catheter. The use of suprapubic cystotomy in these cases simply exposes the patient to the risk of two operations where only one is necessary. It seems more sensible and more just to the patient to perform the perineal operation at once. With reference to the suprapubic operation for exploratory purposes, and in some cases for foreign bodies, there can be no question as to its being proper, but for prostatic trouble and for most cases of calculus, the perineal section is better. He had performed the operation nine times without a guide and had not lost a case.

DR. VANDERVEER thought the remarks of Drs. Michael and Yandell in reference to the paper of Dr. Packard were correct. He had twice made the perineal operation, once for exploration and once for chronic cystitis, in which cases, if he had it to do over, he would

use the suprapubic method. He recognized the correctness of Dr. Warren's advice to remove the débris slowly, and begged to remind the latter of the fact that he had only once experienced difficulty in the extraction of the fragments. In that case the crushed stone appeared to form a kind of plug which completely clogged the tube. The other case was one in which the instrument broke. If the removal is attempted with too great rapidity, there is danger of drawing in the bladder wall and causing injury. Dr. Yandell struck the keynote, when he said we have no one method of operating in all cases. Dr. Agnew also expressed the truth in an admirable manner. Of his six cases, five were operated upon by the median bilateral method, with the rectangular staff, and he thought that hereafter he would always use this staff.

It is too soon for us to collect statistics on this operation. Dr. Byrd has had admirable success with the crushing instrument, and thinks that he can crush any stone, but crushing through the perineal opening is a difficult matter on account of the possibility, almost certainty, of doing injury to the soft parts. Sir William MacCormac insists upon closing the wound in the bladder if it is possible. This is, however, contrary to the view expressed in Dr. Warren's paper. In conclusion, the speaker expressed his preference for aspiration of the bladder for retention of urine over the suprapubic operation.

DR. CHARLES B. NANCREDE then read a paper entitled

SHOULD LAPAROTOMY BE DONE FOR PENETRATING WOUNDS OF THE ABDOMEN INVOLVING VISCERA?

His chief object in presenting this paper he said, is a medico-legal one. A few years since, the counsel for the defense in a famous murder trial asserted that the examination of the track of a bullet with a probe in a penetrating gunshot wound of the abdomen had turned the scale toward a fatal issue, and cited many eminent authorities, in support of this view, and urged an acquittal of his client of the crime of murder in the first degree. At present the tendency seems toward active interference, toward operations which, in the hands of the most experienced, cannot be denied to have a certain mortality *per se*, and which, done promiscuously, by those inexperienced in abdominal surgery, will undoubtedly tend to render death more certain. Laparotomy for these injuries has been generally endorsed by the American Medical Association; in a most emphatic manner, by the New York State Medical Association, at its last meeting, and by the Philadelphia Academy of Surgery. Nevertheless, protests have appeared in the journals from time to time, and he felt impelled to ask the Association to express an authoritative opinion which may serve as a precedent for appeal.

The questions which must be decided are:

What are the tendencies of an injury; are they toward recovery, or toward death? When death takes place, what are its causes? When recovery occurs, what conservative processes occur? How likely are these conservative processes to take place, and what favors or prevents them? How reliable are unaided natural methods compared with those art affords; and should they be imitated by the surgeon or avoided? Finally, what are the dangers inherent to the operation of laparotomy, and what advantages does it afford?

He then reviewed the experiments of Wegner and Grawitz, since in them he found the explanation of certain otherwise inexplicable clinical facts and a clear indication of the causes of the complications especially dreaded after belly injuries or laparotomy, and how these dangers may be averted. The experiments, he thought, demonstrated that the theory of gynecologists is true, that operations through the peritoneum are safer than most operations in the daily experience of the surgeon, since many of the microörganisms can be introduced with impunity into the peritoneal cavity, and the ordinary germs of decomposition can produce suppuration only in the presence of certain conditions which can be avoided. They also indicate the importance of thorough cleansing of the wound and the removal of all foreign matter.

What are the tendencies of the disease, toward recovery or death? Examination of the only statistics of sufficiently large size shows that a fraction under eight per cent. of recoveries follow penetrating wounds of the abdomen, but of these some doubtless sustained no visceral injuries, as is not uncommon. Others, perhaps, there were, the walls of whose hollow viscera were penetrated obliquely; others again in whom the alimentary tract was wounded in those parts which possess an anatomical arrangement unfavorable to the extravasation of their contents. After penetrating abdominal wounds, as after every other injury, however severe, there are certain conservative processes initiated which occasionally succeed unaided by art; yet from an impartial consideration of the above facts, it appears that when visceral wounds undoubtedly exist, the tendency of these injuries is invariably toward death, recoveries being so rare as to be regarded and reported as surgical curiosities.

What is the cause of death? Hemorrhage in itself is rarely fatal, but may occur to a dangerous extent, especially in the young or the aged, and that, too, from vessels of a size to be readily considered insignificant, were they not situated in a closed cavity. Death is, however, due in nearly every case to septic peritonitis caused by the extravasation of flatus, feces, urine, or bile, possibly also by fragments of soiled clothing. When recovery takes place, what conservative processes occur? The feces, fluids, gases are absorbed without causing either local inflammation or systemic infection, and a limited adhesive inflammation results which is just sufficient to glue the injured organs to the abdominal wall, or to a neighboring viscus. What favors or prevents these conservative processes? The absence or slight extent of flatulent, fecal, urinary, or biliary extravasation; the absence or slight amount of effused blood or serum; a favorable relation of the wounds with reference to neighboring viscera or the abdominal wall, providing for free drainage in the exceptional cases mentioned in this paper; valve wounds, and above all, an antiseptic condition of the peritoneal surfaces of the wounds and the immediate environment, since without these no reliable limited adhesive inflammation can occur; and partial or complete arrest of intestinal peristalsis—*i. e.*, rest—admitting the most perfect permanent coaptation of the wounded peritoneal surfaces which is feasible—all favor the conservative processes, while the reverse prevents them.

What are the dangers of laparotomy? Shock is all that we need dread.

The advantages of the operation are manifold. Thus, we can either forestall septic peritonitis or reduce its dangers to the minimum; we can prevent septicæmia; we can arrest hemorrhage; we can substitute for adhesions of doubtful permanence, certain methods which secure the escape of injured portions of the gut into the lumen of the bowels; we can prevent the fatal result which must follow the casting off of the decomposed slough, of a wounded portion of the omentum or mesentery into the general peritoneal cavity; we can restore the continuity of the gut; we can avoid the risk of fecal fistula; we can remove the hopelessly wounded kidney or spleen and repair the injured pancreas or liver.

With regard to the objection that all of the symptoms of perforation of the bowel are fallacious, except those of fecal or gaseous extravasation, he referred to four cases reported by the President, from which he inferred that even punctured wounds of the abdomen, without penetration of the viscera, are better treated by exploratory incision than by the expectant plan of treatment, provided the operation be done with due care.

He then reviewed briefly the symptoms which are relied upon by most authors as evidence of the perforation of viscera, as the extravasation of bile, urine, feces, gases, repeated vomiting, the passage of blood in quantity per anum, etc. Among the more important contraindications to the operation, he mentioned profound shock as the most important. If, because the patient has been seen too late, a generalized, well-defined peritonitis exists, laparotomy is strongly contraindicated.

With reference to the proper time for the operation, he said that it should be done at the earliest possible moment the condition of the patient will warrant it.

[illegible]

DR. C. H. MASTIN, Chairman of the committee appointed at the last annual meeting of the Association, reported a series of resolutions adopted by the committee in regard to the proposed American Congress.

Resolved, 1. That it is desirable that the following societies, viz., the American Surgical Association, the American Ophthalmological Society, the American Otological Society, the American Neurological Association, the American Laryngological Association, the American Gynecological Association, the American Dermatological Association, the American Climatological Association, and the Association of American Physicians, shall arrange for a conjoint meeting in the city of Washington, in the month of September, 1888, and subsequently at intervals of three years at the same time and place.

2. That this arrangement shall not interfere in any way with the autonomy of each of the special societies, and that each society shall retain the right to withdraw at any time from this joint scheme.

3. That the special features of the meeting shall be the joint assemblage of the special societies on two evenings during the session, on one of which there shall be an address delivered by the President of the conjoint meeting, and on the other there shall be a communication by a referee and a coreferee on some subject of general professional interest.

4. Each special society approving of this report is invited to appoint one representative (with an alternate) and that the representatives so appointed shall constitute an executive committee to serve for one year, and with power to elect such officers for the first conjoint meeting as may be deemed necessary, to prepare a programme for such meeting, to make all the other necessary arrangements and to prepare and submit a plan of organization for future meetings.

5. That all expenses connected with the conjoint meetings shall be apportioned equally by the executive committee among the societies participating.

The report of the committee was received and the resolutions adopted.

Dr. C. H. Mastin was appointed as representative and Dr. J. Ford Thompson as alternate on the proposed Executive Committee.

AFTERNOON SESSION.

DR. R. A. KINLOCH reported

A CASE OF GUNSHOT WOUND TREATED BY LAPAROTOMY,

which will appear in full in an early number of THE MEDICAL NEWS.

DR. W. W. KEEN then presented a paper on

PISTOLSHOT WOUND OF THE ABDOMEN: LAPAROTOMY, NEPHRECTOMY, DEATH.

(See THE MEDICAL NEWS for May 14, page 533.)

DR. P. S. CONNER remarked that we all now agree that, if an operation is to be made it should be made in a certain definite manner, the method which is most tried, most reliable, and most certain in its results. The question is not how to close the wound in the intestine, but when to open the abdominal cavity in order to find the intestinal puncture. We know that in the great majority of cases of perforating wound of the intestinal cavity death results either from shock, from hemorrhage, or from extravasation and peritonitis. We know further than this that a certain, though limited, proportion of cases recover if they are let alone. We know that if the operation is made it by no means necessarily saves the patient, and in the presence of an actual case the point to be determined is whether it is advisable to add to the existing traumatism another one. If extravasation of bile, blood, urine, or feces occur, however, there can be no question of the propriety of opening the abdomen; but if we simply know that a gunshot or stab have penetrated the abdomen, it is very difficult to determine whether extravasation have occurred or not. There is not a single symptom that can be relied upon. On the other hand a bullet may pass through the stomach itself, or still more some portion of the intestinal tract, and no blood or other fluid may have been extravasated. Hemorrhage from the bowel does not mean anything. Shock does not indicate anything. We would naturally suppose that an individual who is struck in the abdomen would have profound shock, but every one of us has seen cases in which the shock is comparatively trivial. He has seen cases of more profound shock from a wound of the hand than from a gunshot wound of the abdomen. The shock, again, may be merely nervous in character, and not that from hemorrhage. Further, the condition of the patient may be good and it may be bad. He thought that con-

siderable reliance may be placed on the observation of a profound depression of the temperature, and he still believes that if the temperature is below normal for five or six hours after the receipt of the injury, perforation may be supposed to be present, but there is still room for doubt.

If the intestine is injured should the abdomen be opened? Theoretically, yes. Practically, we know that many cases are no better off after opening the abdomen than they were before. A great deal of harm may be done by opening the abdomen where no injury is found. It is a very different thing to open the abdominal cavity where the peritoneum is normal and healthy, from opening it where the peritoneum has been pressed upon for a long time by a tumor. Many of these cases involve legal questions, and, as has been intimated, if the patient die after surgical interference, it may be the means of permitting to escape a criminal who should be made to suffer his just punishment. If the operation be delayed eighteen to twenty-four hours the chances for recovery are slight.

He then referred to a case which he had seen in the hands of Dr. Dandridge, in which eleven wounds of the bowel were found and accurately closed, without benefit. He had himself, on two occasions, sewed up knife wounds of the intestine so closely that water could not be forced through the openings at the autopsy, which had to be made within twenty-four hours afterward. From all this he concluded that for the treatment of penetrating wounds of the intestine we are not yet justified in laying down any rigid rule that this operation must be done in all cases. We want light, therefore, if possible, upon the diagnosis of these cases. If we can in any possible way ascertain, without opening the abdomen, that perforation has or has not occurred, we want to know it. At the present time the diagnostic signs are very uncertain. Of these cases, therefore, a great many will be lost because of the delay which is almost inevitable, from the present state of our knowledge.

DR. MOSES GUNN remarked that we are about as much in the dark as ever regarding the important matter of diagnosis. He reviewed the early history of the operation as done for ovariotomy, of which it was at one time said that the operation was a lottery in which the drawing was a blank. Then it was explained that the successes which followed it were due to changes in the structure of the peritoneum. The peritoneum was thought to be particularly susceptible to inflammation, and when the ovariotomists brought forward their successful cases of operation, where there had been extensive adhesions, the doubting members said that the peritoneum had undergone some change. Then antiseptic surgery developed, and it was found that the time for ovariotomy was early. It was found that the peritoneum, with all its pristine individuality, could be handled antiseptically without danger. Finally, Sims came forward with the view that the operation should be made for traumatism. With regard to this application of the operation, although only a few years have elapsed since its introduction, he thinks we are safe in saying that it should be made. Cases occur in which the danger of perforation of the intestine has been great, and laparotomy is a safe method to pursue for its relief. We can all call to mind cases in which there was every possible indication that the intestine was perforated, and yet the patient recovered; but we could not say positively that the intestine had been perforated. He then referred to an insane woman who stabbed herself with a scissors, drew forth eleven inches of intestine, cut it off, and recovered after the wound had been properly closed. He could not answer the question how to make a diagnosis of perforation, but confessed a weakness for diagnostitial laparotomy.

DR. DAVID PRINCE reported a case of laparotomy for gunshot wound in which, after the most careful search, a perforation of the colon was found back of the liver, where it becomes transverse. The patient made a slow but perfect recovery. He expressed preference for making the incision, not in the median line, but directly over the point of entrance of the missile.

DR. T. G. RICHARDSON stated that he desired to make a criticism upon the paper of Nancrede, without casting any slur upon the operation of laparotomy. The essayist is apparently in favor of making laparotomy upon every case of gunshot wound or other injury of the abdomen; he was particular to state, however, that it should be made only by a skilful surgeon. If we restrict the operation to this class of operators, a great part of the benefit of the operation is taken away, for the majority of cases do not fall directly into the hands of those whom we call experienced and skilful surgeons. His own experience demonstrated to him that a large majority of cases of gunshot wound of the abdomen get well without operation. Of 31 cases of penetrating knife wound, 24 recovered, 7 died. On the other hand, however, of 37 cases of gunshot wound only 17 recovered, 20 died. Adding these together, gives us 68 cases of penetrating wound, of which 41 recovered, 27 died.

DR. D. HAYES AGNEW desired to place himself on record, for he had very strong convictions with regard to this operation. Where we have a reasonable degree of evidence that we have a wound penetrating the intestine, especially a shot wound, it is our duty to open the abdomen. We are not to be deterred because of the possibility of some legal technicality if the case comes into court. We are to do our duty without reference to consequences.

DR. N. P. DANDRIDGE reported a case of gastrostomy in which the operation was for stricture of the œsophagus, caused by swallowing washing fluid, about six months after the accident. The patient was emaciated to the last degree, and was at the time of the operation unable to swallow anything. The condition of the child was so desperate at the conclusion of the operation, that it was considered advisable to introduce at once nourishment by means of the aspirator into the stomach. The child was nourished for several days in this manner, the quantity injected being gradually increased, until four or five ounces were thrown in at a time. The child did well until she took measles; then the wound began to ulcerate, and she finally died of erysipelas.

DR. JOSEPH RANSOHOFF reported two cases which had come under his observation in which the question of laparotomy was of great importance. The first case was that of a young man who had suffered from stricture of the rectum for two years. The stricture was high up, so that it could be just reached with the finger. By a process of gradual dilatation he had become able

to pass the largest size of the soft rubber bougie. He then used hard rubber bougies, choosing the largest of the nest of bougies made in England. The ninth time he had passed it, he experienced no difficulty, but the patient complained of a good deal of pain. Two hours later he had severe pain in the iliac region and was vomiting. He decided to make an exploratory incision, and telegraphed to the patient's physician to that effect. A physician and a surgeon were called in consultation. The physician did not think the time for laparotomy had arrived, and the surgeon was opposed to it *in toto*. The physician twenty-four hours later concluded the time had arrived, the surgeon still opposed, and it was abandoned. The patient died six days after the accident. A post-mortem was not allowed. The question in this case is whether the result would have been different had the abdomen been opened. In regard to it, he felt no little regret, inasmuch as he feared that the death of the patient might have been to some extent the result of his efforts, and was permitted to occur without any attempt at prevention.

Only last Sunday he was asked to see a man who had been shot in the back. He had received a number of wounds of large size, entering just above the ilium, and, apparently, taking a forward course. He saw the patient about an hour after the receipt of the injury. He was in good condition, pulse 84 to 90, and full. He had vomited, probably owing to the fact that he had indulged largely in beer. There was considerable pain. Next morning, Dr. Conner was called in consultation. The condition of the patient was such as to render the operation out of the question. Two hours later he was moribund and died soon after. The post-mortem showed that the laparotomy would not have been of any service. In the case of stricture of the rectum he thought laparotomy would have saved the patient, although no autopsy was made. The patient was too young to render the presence of cancer at all probable.

Dr. Nancrede did not consider that a prominent depression of the temperature is a symptom in these cases. A healthy peritoneum does not resent a laparotomy, for it is able to dispose of a large amount of feces, urine, bile, blood, and, to some extent, also of septic microörganisms. But the moment the vitality of the peritoneum is impaired, just that moment the dangers of the operation are increased. In regard to diagnosis, he thought that a penetration could readily be determined by a careful incision of the abdominal wall down to the peritoneum, following the track of the ball, and that in many cases the result, where no perforation was found to exist, would be better than if the patient had been let alone. By the term skill he had meant to imply a knowledge of what was to be done and an attention to detail, both of which were certainly requisite in the performance of this operation. He finally objected to the custom of giving large doses of opium after all operations, as introduced by Alonzo Clarke and practised by many.

Dr. Kinloch stated that there was one thing in the discussion which had gratified him more than anything else. That is, that two distinguished members of the Association have said clearly and authoritatively that laparotomy, under proper circumstances, should be performed. Some who have discussed the question, however, are inclined to think that the great question is that of diagnosis. He was opposed to the practice of waiting too long. It was the uncertainty of diagnosis that for a long time checked the progress of surgery in the operation of ovariotomy, and where is it now? It was this fear that checked the progress of surgery in regard to the treatment of injuries of the brain, and where is it to-day? This is the same reasoning that the surgeons of old advocated. Many of them advised ovariotomy, but none of them performed it, and we should make a difference between the surgery of the past and that of the present. In regard to the question of whose duty it was to perform the operation, he applied the words of Dr. Agnew. We should do our duty, and because a poor negro is shot in a cotton field and the nearest doctor is called, we must not say that he shall not attempt to save a life because he is not a skilful surgeon. He then narrated his first experience with the operation, in a Confederate hospital during the war. When he had finished, he found that his older assistant had left the room in order not to witness his inhumanity. After the patient recovered, however, he numbered that older physician as one of his warmest friends.

To be continued.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, May 4, 1887.

THE PRESIDENT, CHARLES McBURNEY, M.D., IN THE CHAIR.

CASE OF FRACTURE AND DISLOCATION OF THE ASTRAGALUS.

Dr. Stimson showed a portion of an astragalus, and read the following history: Man, about twenty-eight years old, in a fit of drunken delirium jumped from a third-story window, and was brought to Bellevue Hospital, April 27, 1887. I saw him the next morning, about eighteen hours after the accident. There was a large tumor below the right patella and a row of abrasions along the left shin, and a small tumor below the left patella. The left foot and lower half of the leg were swollen and discolored, the foot at right angles to the leg and capable of some flexion and extension, and without deviation. A marked prominence at the inner ankle, over which the skin was tightly drawn and livid, was at first thought to be the internal malleolus, and the foot seemed to be carried bodily to the outer side, but on palpation the prominence was found to be behind and a little below the malleolus, and to have a curved border running backward and outward; below this border could be felt a broad surface, that was curved backward and inward, and flat downward and inward, in front was an abrupt depression. The scaphoid was normally placed in respect to the malleolus, and no depression could be felt behind it in the situation of the head of the astragalus, although the swelling was such that the examination was not deemed very trustworthy. The perineal tendons were displaced forward, lying upon the outer surface of the external malleolus. The relations of the fifth metatarsal, cuboid, and calcaneum appeared to be normal. The dorsalis pedis artery was beating, the posterior tibial could not be felt.

The diagnosis of fracture of the neck of the astragalus with dislocation backward and inward, and inward rota-

tion of the body was made, and an attempt was made to reduce under ether by flexing the knee, making traction downward upon the foot, and pressure outward and forward upon the projection behind the internal malleolus. This failing, an incision three inches long was at once made backward and downward from in front of the malleolus, its centre corresponding to the most prominent part of the projection. The upper articular surface and outer edge of the astragalus presented in the wound, and the body of the bone was found lying below and behind the malleolus; its broken neck directed forward and inward, its upper articular surface looking inward and downward, its posterior border close to the tendo Achillis, and its inferior surface close behind and below the posterior border of the end of the tibia; transverse fracture had taken place at the junction of the body and neck, and the body had been completely dislocated backward and inward, with rotation inward of about 120 degrees about its antero-posterior axis, and about 45 degrees inward about its vertical axis. The tendons of the tibialis posticus and flexor longus digitorum were torn from their sheaths and crossed the inner surface of the malleolus above the astragalus. The posterior tibial artery was pressed backward and separated from the tibia by the interposed posterior portion of the body of the astragalus. Exploration of the joint showed the head of the astragalus in place, and absence of injury to the tibia or fibula. The lower tibio-fibular joint was not injured. The fracture ran from the anterior border of the trochlea downward into the groove occupied by the interosseous ligament.

The body was easily removed, as all its ligaments and connections had been ruptured except a part of those attached to its posterior border. The wound and joint were thoroughly cleaned, a drainage tube inserted, the incision loosely closed by two silkworm gut sutures, the foot and lower part of the leg enveloped in iodoform and bichloride gauze, and a plaster-of-Paris bandage applied over all.

On the following day the patient's alcoholic symptoms were much less marked, and his condition good. On the third day a fenestra was cut, and the tube removed; the wound was dry, the swelling less, and everything looked favorable, but three days later he developed pneumonia, and died on the ninth day after the accident.

To this record of the case he added a brief mention of the few similar cases that have been reported. They are those of Denonvilliers, Lejeune, MacCormac, Legros Clark, Pichoree, and Cheever. In the first two the dislocation was directly backward; in the others, backward and inward, as in the present case. Of Denonvilliers, he had only the brief note given by Malgaigne: the body of the astragalus covered the calcaneum at right angles, and its trochlea appeared through the skin below and behind the internal malleolus; he removed it, but the patient died. Of Lejeune's and Pichoree's, the quotations by Delorme (*Dict. de Med. et Chir. Prat.*, vol. xxvii., p. 643) and Poinsot (translation of Hamilton's *Fractures and Dislocations*) are even briefer; of the first it is said only that the dislocation was compound; of the second only that after two unsuccessful attempts to reduce, including division of the tendo Achillis, suppuration ensued, and the limb was amputated.

MacCormac's[1] patient was injured in the fall of a platform; the character of the injury was not recognized, and after rest for some weeks in bed, he was able to walk well and continue his occupation as bricklayer. Two years later MacCormac removed the leg because of disease at the knee, and made a careful dissection of it. The foot was stiff, at a right angle with the leg, and without deviation. The astragalus had been broken at the neck, and the body had been so displaced and rotated that it lay behind the tibia, and a little to the inner side, its trochlear surface looking inward and backward, its posterior border in contact with the tendo Achillis, and its broken surface looking downward and forward. The internal malleolus had been broken, and had reunited, and the astragalus was connected with it by bony union. The tendons of the tibialis posticus and flexor longus digitorum were displaced inward and forward, lying on the inner surface of the malleolus, that of the flexor longus pollicis was separated from the tibia by the body of the astragalus, and lay upon the trochlear surface of the latter. No mention is made of flexion of the great toe, such as existed in Cheever's case, and in others in which the unbroken astragalus was displaced backward and inward, but one of the accompanying figures shows the terminal phalanx flexed.

MacCormac reports also a case treated in 1863 by Legros Clark, which he himself had an opportunity to examine twelve years later; he found the body of the astragalus in a position identical with that of his own case, and supposed there had also, probably, been fracture of the neck. The patient had full use of the limb, walking without any lameness.

Cheever's[2] patient, a man thirty-two years old, was injured in a fall of about twelve feet. There was a very marked, partly rounded, partly sharp projection of bone between the inner malleolus and the heel, and a depression beneath the outer malleolus. The tendo Achillis was tense and shortened over the unnatural prominence of bone which lay between the inner ankle and the heel. The heel was drawn up; the mobility of the ankle-joint was greatly diminished. The last joint of the great toe was strongly and immovably flexed at a right angle. After failing to reduce by traction under ether, he divided the tendo Achillis, then the tibialis anticus and posticus, then the flexor communis digitorum, and finally the flexor longus pollicis at the toe, but the dislocation still remained irreducible. The skin sloughed over the astragalus, but did not expose it, and the ulcer soon healed; in seven weeks the patient could freely move the foot, and in five months could walk with a cane. The divided tendons appeared to have solidly united.

The histories do not make clear the mode of production of the fracture and dislocation, but it seems probable that they occurred while the foot was in dorsal flexion, and by the agency of extreme violence acting in the direction of the long axis of the leg, along the sloping articular surface of the calcaneum, and bringing the tibia and calcaneum closer together, so that the posterior part of the astragalus is squeezed out from between them.

[1] Trans. Path. Soc. London, 1875, vol. xxvi. p. 174.

[2] Cheever: Boston Med. and Surg. Journ., 1875, vol. 93. p. 237.

Dr. Sands said that he had a specimen similar to the one presented. It was obtained from a patient whom he saw in consultation in Tarrytown, with a fracture and dislocation of the astragalus inward. The fracture was nearly vertical in direction, and was situated just in front of the ankle-joint. The skin over the upper dislocated fragments was greatly stretched. He cut down directly upon the bone and easily removed it. The patient recovered and walked well afterward, but had slight shortening and stiffness of ankle. He thought that there was no advantage in wasting time by trying to effect reduction, because the conditions were so unfavorable; it was better to excise early, especially since the results obtained by modern antiseptic methods were so good. The broken bone acted as a foreign body, and would, if allowed to remain, do injury to the soft parts.

NEWS ITEMS.

The Association of American Physicians announces the following programme for its second annual meeting at Washington.

THURSDAY [illegible] *Morning Session*, 10 A.M.—Remarks by the President, Dr. S. Weir Mitchell. Cirrhosis of the Liver in Children, by Dr. R. Palmer Howard, of Montreal. Obstructive Safety-valve Action in the Heart, and direct Functional Murmurs, by Dr. John Guiteras, of Charleston. Pneumatic Differentiation, by Dr. Hosmer A. Johnson, of Chicago.

Afternoon Session, 2.30 P.M.—Discussion on Antipyretic Treatment, introduced by Drs. H. C. Wood, of Philadelphia, and G. Baumgarten, of St. Louis. Cases of Sewer-gas Poisoning, by Dr. Henry Hun, of Albany. A Case of Aneurism of the Abdominal Aorta, by Dr. James T. Dana, of Portland.

Evening Session.—Discussion on Hemorrhagic Infarction, introduced by Drs. W. H. Welch, of Baltimore, and Wm. Osler, of Philadelphia.

FRIDAY, M[illegible] *Morning Session*, 10 A.M.—Method of Treating Phthisis, by Drs. E. T. Bruen, of Philadelphia, and F. C. Shattuck, of Boston. Atrophy of Gastric Tubules; its Relation to Pernicious Anæmia, by Dr. F. P. Kinnicutt, of New York.

Afternoon Session.—Observations on the Employment of Antipyrin and Thallin in the Treatment of Typhoid Fever, by Dr. Francis Minot, of Boston. An Inquiry into the Frequency with which Lead may be Found in the Urine, and on the Symptomatology of Chronic Lead Poisoning, by Dr. James J. Putnam, of Boston. Forms of Typhoid Fever Simulating Intermittent Malarial Fever, by Dr. I. E. Atkinson, of Baltimore.

The American Laryngological Association will hold its Ninth Annual Congress in the Hall of the Academy of Medicine, in New York, on May 26th, 27th, and 28th. The following papers are announced:

May 26. *Morning Session, 10 o'clock.*—Intubation of the Larynx, by E. Fletcher Ingals, M.D., of Chicago. Description of a Modified Laryngectomy, by J. Solis-Cohen, M.D., of Philadelphia. A New Method of Intubation of the Larynx, by Charles E. Sajous, M.D., of Philadelphia.

Afternoon Session, 3 o'clock.—The Pathological Nasal Reflex: an Historical Study, by John N. Mackenzie, M.D., of Baltimore. Hay Fever, with Results of Treatment, by John O. Roe, M.D., of Rochester. On the Treatment of Atrophic Rhinitis by Applications of the Galvanic Current, by D. Bryson Delavan, M.D., of New York. Myalgia of the Pharynx and Larynx, by S. H. Chapman, M.D., of New Haven. Discussion. Sensory Affections of the Throat, opened by Frederick I. Knight, M.D., of Boston.

May 27. *Morning Session.*—Further Researches upon the Function of the Recurrent Laryngeal Nerve, by Frank Donaldson, Jr., M.D., of Baltimore. The Anatomy and Physiology of the Recurrent Laryngeal Nerve, by Franklin H. Hooper, M.D., of Boston. On Certain Measures for the Relief of Congestive Headaches, by William C. Glasgow, M.D., of St. Louis. A Case of Leucoplakia Buccalis: Recovery, by William C. Glasgow, M.D., of St. Louis.

Afternoon Session.—Discussion. The Treatment of Laryngitis in Professionals who are Unable to Rest, opened by J. Solis-Cohen, M.D., of Philadelphia. Glandular and Connective Tissue Hypertrophies of the Lateral Walls of the Pharynx, by Clarence C. Rice, M.D., of New York. The Galvano-cautery in the Treatment of Hypertrophied Tonsils, by Charles H. Knight, M.D., of New York. Note on a Frequent Cause of Nasal Hemorrhage, by Beverley Robinson, M.D., of New York. The Constitutional Causes of Sore Throat, by S. W. Langmaid, M.D., of Boston.

May 28. *Morning Session.*—Affections of the Crico-Arytenoid Articulation, by George W. Major, M.D., of Montreal. Cancer of the Larynx, by Hosmer A. Johnson, M.D., of Chicago. A Case of Recurring Laryngitis Hemorrhagica, by C. E. Bean, M.D., of St. Paul. A Case of Stenosis of the Larynx, treated by Divulsion and Systematic Dilatation, by Morris J. Asch, M.D., of New York. The Importance of Local Treatment in Diphtheria, by William Porter, M.D., of St. Louis.

Afternoon Session.—A Comparative Study of some of the Methods of Treatment best adapted to the Relief of Occlusion of the Posterior Nares, by Alexander W. MacCoy, M.D., of Philadelphia. Plaster-of-Paris Dressing for Fractures of the Nose, by J. W. Robertson, M.D., of Detroit. On the Etiology of Deflections of the Nasal Septum, by D. Bryson Delavan, M.D., of New York. Congenital Occlusion of the Nasal Passages, and its Successful Treatment by means of a Novel Surgical Procedure, with a practical demonstration of the Operation.

The Officers of the Medical and Chirurgical Faculty of Maryland, elected at the recent annual meeting for the coming year, are as follows:

President.—Dr. I. E. Atkinson.

Vice-Presidents.—Dr. Charles H. Jones, Dr. James Carey Thomas.

Recording Secretary.—Dr. G. Lane Taneyhill.

Treasurer.—Dr. W. F. A. Kemp.

The Thirtieth Annual Meeting of the Missouri State Medical Association was held at Macon City, Mo., on May 10, 11, and 12, 1887. The meeting was highly satisfactory to the members present, a larger number participating, and a larger number of papers were read and discussed than at any previous meeting. The Association passed a resolution appropriating

three hundred dollars to the International Medical Congress. It was decided to hold the thirty-first annual meeting at Kansas City, Mo.

THE MEDICAL SOCIETY OF NORTH CAROLINA held its thirty-fourth annual meeting at Charlotte on April 13th, and the following officers were elected for the ensuing year:

President.—Dr. D. T. Haigh, of Fayetteville.

Vice-Presidents.—Drs. W. T. Ennett, of Burgan; J. B. Dunn, of Raleigh; Thomas E. Anderson, of Statesville.

Secretary.—Dr. Julian M. Baker, of Tarboro.

Treasurer.—Dr. C. M. Poole, of Salisbury.

INTERNATIONAL CONGRESS ON INEBRIETY. — The Council of the English Society for the "Study and Cure of Inebriety," have completed arrangements for an International Medical Congress, to be held at Westminster Hall, London, July 5 and 6, 1887.

The object of this Congress is to present and discuss the problems of inebriety medically, and from a purely *scientific standpoint*, by the best authorities, thus laying the foundation for a broader and more exact study of this subject.

PASTEUR AND HIS INSTITUTE.—The members of the Committee of the Pasteur Institute have decided to refuse the site offered by the municipality, and to purchase a site beyond Montparnasse Station for 430,000 f. They have also agreed on plans for the erection of four buildings, to cost 600,000 f. About 1,000,000 f. will then remain available, representing a revenue of 40,000 f. This is inadequate, for the calculations made, not only for the treatment of rabies, but for fresh experiments and a laboratory, show that an income of 100,000 f. is necessary. The fund will, therefore, be kept open until this income has been secured. With devotion equalled only by the absence of ostentation, M. Pasteur has written a letter to the committee assigning to the institute the proceeds of his splenic fever treatment and industrial processes, which bring in 25,000 f. a year. This sum added to the one mentioned above of 40,000 f. makes a revenue of 65,000 f., leaving 35,000 f. still to be secured. It is sad to have to add that M. Pasteur himself is seriously unwell, and that his condition gives great uneasiness to those who love and admire him.—*Galignani's Messenger.*

DEATH OF LIEBERKÜHN.—Dr. Nathaniel Lieberkühn, Medical Privy Councillor and Professor of Anatomy in Marburg University, died recently at the age of sixty-five. He was the son of the discoverer of Lieberkühn's follicles, and was a disciple of Johannes Müller, and a fellow-student of Dubois Reymond, Helmholtz, Ludwig, and Virchow. His own researches, which were numerous, were mainly connected with development. He was formerly Prosector of Anatomy in Berlin.

RESULTS OF A PHYSICAL EXAMINATION FOR CADETS. —A remarkable showing is made by the result of the physical examination of candidates from the public schools for the appointment of a cadetship at the Naval Academy at Annapolis. The position was offered by Col. L. S. Bryce, member of Congress for the Seventh New York District, to the lads between fourteen and eighteen years of age, in the district, who should pass the best competitive examination; and, on the 29th of April, twelve youths presented themselves at the College of the City of New York for the trial. The physical examination was made by Drs. Stuyvesant F. Morris, of New York, and Shaeffer, of the Navy, and not one of the twelve was found to answer to the qualifications as regards physique required by the Government for admission to the Academy. Of the candidates, three were rejected for defective eyesight, and four for malformation of the chest or heart troubles, while one was under the minimum stature allowed.—*Boston Medical and Surgical Journal*, May 5, 1887.

THE LACTOCRITE.—The lactocrite, a new apparatus for testing milk, particularly with regard to its value for butter, is the invention of de Laval, also the inventor of the well-known centrifugal separator, which bears his name, and is designed to be used with the latter. The milk is first heated with its own bulk of strong acetic acid, to which five per cent. of strong sulphuric acid has been added. This treatment, continued for seven or eight minutes, suffices to set free the fat of the milk from its emulsionized state. A glass tube with a narrow neck, properly graduated, is then filled with the milk, placed in a suitable holder in a disk which is attached to the centrifugal separator, and the latter set in operation. A complete separation of the fat is then effected in the narrow neck of the tube, where the amount is read off. The instrument is designed to enable creameries using the centrifugal to test the quality of each patron's milk; and it appears to be well adapted to this purpose. Several tests of its accuracy have been made of late. Sexhlet, in the *Milch Zeitung* (xvi. 14), reports that he obtained by it results agreeing within 0.1 per cent. with those of his aërometric method. Sebelien (*Landw. Vers. Stat.*, xxxiii. 405) finds that, if all the directions are strictly observed, the results do not vary at most more than 0.1 per cent., and usually not over 0.05 per cent., from those of gravimetric analysis, but notes that these directions must be carefully followed. Faber (*Analyst*, xii. 6) obtained about the same results. Blythe (*Ibid.*, xii. 34) found in eleven trials a maximum error of 0.14 per cent., and an average error of 0.05 per cent.—*Science.*

PRACTICE OF MEDICINE BY AMERICAN PHYSICIANS IN FRANCE.—For some years past the native practitioners at French watering places and elsewhere have displayed a good deal of irritation at the success of the English and American medical men, who practically exclude them from the emoluments derived from attendance on the wealthy and invalid foreign visitors. This feeling has now taken a tangible form in the promulgation of a law which somewhat enhances the difficulty of obtaining the right to practise on French territory unless the doctorate of one or other faculties of medicine in France be first obtained, a proceeding of some time, difficulty, and expense, except to one who has lived for some years in the country. Hitherto, the English or American practitioner who desired to practise in France contented himself with obtaining a provisional license (*permis d'exercer*) which was practically perennial; or, at most, took the certificate of *officier de santé*, an inferior diploma, but one which enabled its holder to

comply with the law. Until within the last few years, one or other of these *permis* were obtainable on fairly easy terms. Under the new law, however, no permits are to be granted other than those conferred by passing one or other of the legal entrances of the profession. Further, in order to prevent undue competition at the hands of men who might take the *officat de santé*, they are forbidden to practise in the chief towns of departments and arrondissements, and in cities of over 10,000 inhabitants. In all important surgical and obstetrical operations they are required to call in the assistance of a [illegible]

IMPORTANCE OF THE TEETH AS A MEANS OF IDENTIFICATION.—The occurrence of the Prince Imperial's death revived a question which has been somewhat neglected by lawyers and physicians, viz., the importance of the teeth as a means of identification of deceased persons. The late Prince Imperial had been so much disfigured that identification would have been extremely difficult but that the prince had had four small cavities in the first molar teeth filled with gold by Dr. Rottenstein, of Paris, and had met with a slight accident in April, 1876, from a blow on the front teeth, which had made it necessary to fill the teeth a little in order to smooth the enamel. These constituted signs which are unalterable even by ages; and, as careful dentists usually keep a record of such operations, they afford a means of identification which is unerring, and which, as in the present instance, was of great value, and might, under certain circumstances, be of the highest importance.—*American Journal of Dental Science*, March, 1[illegible].

OBITUARY RECORD.—Died of pneumonia, on Tuesday, May 3d, in the fifty-seventh year of his age, WILSON FOX, M.D., F.R.C.P., Physician-in-ordinary to the Queen, and Holme Professor of Clinical Medicine at University College, London. Dr. Fox was well known on this side of the Atlantic by his numerous and valuable contributions to medical science, and particularly by his research into the nature of tubercle, to which he devoted the best energies of his life. By his death the London profession loses one of its most distinguished members.

NOTES AND QUERIES.

[illegible]

[illegible]

[illegible] seen the stitch, and all the practitioners on this portion of the earth's surface are as ignorant as myself, on this subject.

Truly,

S. C. GRAVES, M.D.

[illegible], May 13, 1887.

The Czerny-Lembert suture is applied in two rows. The first or inner row includes the mucous membrane only, and is applied in the form of a series of simple suture points. The second or outer row includes the peritoneum only, and is applied in the form of Lembert's Suture (see fig.), in which the needle is first made to pick up a fold of peritoneum about one line in width and about three lines from the edge of the wound; a similar fold is then picked up at a corresponding point on the other side of the wound, and then the thread has to be drawn through the two folds and thus carried across the incision; the knot may be tied in the ordinary way. The stitches should not be more than a line apart, and the whole number required must be introduced before any are tightened. By this suture the serous surfaces are turned in toward the lumen of the viscus and are brought into close contact.

[illegible] per transit [illegible]

Of course, when the outer series of sutures are applied the inner row, including the mucous membrane, is entirely covered in.

This suture is employed in closing intestinal wounds, and is particularly valuable in bringing the two serous surfaces of the wound in close apposition, which is necessary for union. The inner row of sutures, advised by Czerny, affords additional security.

SUPRAPUBIC CYSTOTOMY.

ITS TECHNIQUE ILLUSTRATED BY ANATOMICAL PREPARATIONS.[1]

BY FREDERIC S. DENNIS, M.D.,

PROFESSOR OF SURGERY IN BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK

THE revival of suprapubic cystotomy awakes great interest among surgeons throughout the civilized world. In former years the high operation was reserved for large calculi which could not be removed by any of the perineal operations. The rate of mortality was so high that the operation was considered justifiable only in extreme cases. At the present time, through the influence of the writings and demonstrations of Garson and Petersen, suprapubic cystotomy has become a recognized operation for the removal of calculi of all sizes, and of all descriptions, and under all conditions.

In addition to the removal of stone, the high operation has opened up a new field to the practical surgeon. Vesical tumors and ruptures of the bladder are now operated upon where heretofore no operation was performed. This great change in operative procedure has been brought about by anatomical demonstrations and by experimental work upon the cadaver. The results of these experiments have proved the safety of exploration of the bladder by the sectio alta. It is interesting to observe in this connection the different stages through which the operation has passed, from the earliest recorded dates down to the present time.

In studying the history of the operation in chronological order, one is forcibly impressed with the fact that the present complete and perfect method of performing epicystotomy is not due to the entire work of any individual. The operation as it is now performed, according to the technique recommended by Garson and Petersen, has been the result of a gradual growth and steady development. The work of the anatomist has been supplemented by the surgeon. Practical applications have been made of knowledge obtained by experimental work. Suprapubic cystotomy of the present century differs from the suprapubic cystotomy of the sixteenth century only in the perfection and completion of the details. The same general principles were formerly recognized, as I shall endeavor to point out, and it has been through the improvement of these different methods that the present complete operation has been perfected. In other words, improvements in the technique, rather than the introduction of any new principle, have given us this eminently satisfactory operation. I shall endeavor to prove that the suprapubic operation of to day owes its parentage to the original operation.

In reading the early description of this operation, it is obvious that the great dangers were fully recognized, but the exact way in which to avert these dangers was not understood. The prevention of injury to the peritoneum and the avoidance of urinary infiltration were aimed at in the early operations, but the means to bring about immunity from these special dangers were crude and undeveloped. In the modern high operation the peritoneum is protected and urinary infiltration avoided by forcing the bladder upward by conjoined distention of the rectum and bladder. The additional safeguard to the danger of urinary infiltration is offered by the employment of an antiseptic fluid for distending the bladder, instead of ordinary fluid. The principle of lifting the bladder upward was crudely demonstrated by the surgeon introducing his finger into the rectum and pushing up the bladder. The distention of the bladder was made by injecting fluid into the viscus. Hilanus, in the seventeenth century, recommended the use of the finger in the rectum for the purpose of lifting up the bladder. The accomplishment of this object is now secured by the use of the colpeurynter in the rectum and by the injection of an antiseptic fluid into the bladder. Douglas, Cheselden, and other surgeons practised a certain amount of vesical distention. The principle recognized in the old and the new operation is identical, but the means employed to carry out the principle are widely different. Our forefathers have handed down to us a principle in the high operation which they fully recognized, and which they tried to carry into practice. They were unable to meet practically all the emergencies of the case. Our contemporaries have beautifully perfected and carried into execution the same principle by a method which to-day enables the surgeon to operate with comparative ease and safety.

A brief historical sketch of the suprapubic operation is pertinent, in order to appreciate the important changes through which this operation has passed. There is no authentic description of the suprapubic method until it was performed by Pierre Franco in the year 1561. Franco performed the operation upon a boy, but did not commend it to the profession. Rousset, in 1581, wrote a careful description of the operation, and highly commended it to the profession. Rousset's paper deals with the operation from a theoretical point of view, and King Henry VIII. promised him several criminals for experimental work in order to demonstrate the operation in a practical way. The king died, and Rousset was unable to prove the value of his suggestion by any demonstration upon the live human body. The operation now fell into disuse until 1635, when

[1] Read before the American Surgical Association May 11, 1887.

Mercier advocated it in a thesis before the Faculty of Medicine in Paris. Bonnet performed the operation with success in 1681 at the Hotel Dieu. Proby, in 1694, explored the bladder by the high operation for the removal either of a calculus or a foreign body. Historians do not agree in their accounts as to the object of the operation. Such is the brief historical sketch of this formidable operation until John Douglas, of London, reported four successful cases in 1723. Cheselden, in this same year, published a paper upon the operation, and afterward became its great champion. In 1727 Douglas had performed the operation nine times, with but one death; and Cheselden six times, with but one death. Thornill had twelve cases, and only two of them died. McGill had five cases.

At this epoch, when the results were comparatively brilliant, the introduction of the infrapubic operation caused the suprapubic operation to fall into disrepute; not on account of its failures, but owing to the great *éclat* with which the perineal operations were received. Cheselden improved and developed the perineal method of the monk Frère Jacques, who began his operations in 1695, and of Rau, the Holland surgeon, and Cheselden then became the champion of the perineal operation, as he had been of the high operation. The suprapubic method was but little practised until Frère Comes revived the operation, and in 1779 published a description of his own method of performing suprapubic lithotomy. He made an opening in the membranous portion of the urethra, through the perineum (boutonnière), for the purpose of introducing a sound with a stylet (sonde à dard) in order to pierce the bladder just behind the symphysis pubis.

Since the time of Frère Comes the suprapubic operation has been seldom employed, until the introduction and practical application of Garson's and Petersen's experiments. From its earliest history to 1851 Gunther could only collect 260 cases. From 1850 to 1879 there were but few cases reported. From 1879 to the present time the suprapubic operation has been performed by many surgeons, and with such uniform success as to attract the undivided attention of surgeons throughout the civilized world. Reports of the brilliant success which has attended this modified suprapubic operation come pouring in from every land, and the time has now arrived when the shackles which have hitherto trammelled this operation shall be thrown aside and the results critically examined in an impartial and honest spirit.

The prophetic words of Dr. Roberts, uttered at a former meeting of this distinguished Association, in which he stated "that within ten years the suprapubic operation will be the operation adopted for all cases of stone that are not treated by Bigelow's operation," are now almost realized. I would venture to remark that the time is not far distant when there will be but practically two operations for stone in the bladder, the suprapubic lithotomy and litholapaxy. If future experience demonstrates that a return of calculus occurs in a fair percentage of the cases after lithotrity from débris left behind, and that the mortality of the suprapubic is reduced to a figure equal to or less than perineal lithotomy, then suprapubic lithotomy, with its special advantages, will be the recognized operation of the day. If it can be shown that the mortality in the suprapubic operation is due in great part to causes which may be prevented in these days of antiseptic surgery, there is no doubt as to the future of the operation. It is simple in its technique, safe in its execution, radical in its results, free from injury to the reproductive organs, curative in its application, and finally brilliant in its statistics. With all these advantages time will soon determine the place which this operation is destined to take among the recognized surgical operations. On the other hand, the many and serious accidents which follow the lateral operation are avoided.

The technique of the operation of opening the bladder by the suprapubic method is worthy of consideration. A few days previous to the operation the patient can be put upon a milk diet, and the day previous to the operation the bowels should be freely moved by a dose of castor-oil, and the morning of the operation an enema should be given, so as to empty the rectum for the introduction of the rubber bag. The hair should be shaved from the pubes and the parts should be thoroughly washed and scrubbed and irrigated with a solution of bichloride of mercury or carbolic acid. This ablution should be repeated at the time of the operation. The patient being fully under the influence of ether is prepared for the operation. The surgeon should first introduce the India-rubber bag into the rectum. The bag should be oiled and should be carried well up the rectum so as to be above the internal sphincter. Into the rubber bag are injected, slowly, twelve ounces of warm water; at least I would recommend this quantity as the standard, and from it the amount can be slightly increased or diminished according to individual circumstances. Instead of water, air can be used to inflate the bag, as suggested first by Milliot in 1875, at Lyons; but the water for obvious reasons is preferable. If the patient is a boy, instead of an adult, less than twelve ounces of warm water must be injected. The surgeon should bear in mind the danger of rupture of the rectum, especially in elderly people and young boys, and exercise judgment in regard to the proper quantity of water to be injected in any given case. Serious mischief has followed the careless use of the rubber bag during dilatation of the rectum. In one case, where eighteen ounces were used, the rectum was lacerated.

The next step in the preparation of the pelvic viscera for the suprapubic operation is the distention of the bladder. Here again the surgeon must be very cautious lest he inject too great a quantity of water. A silver catheter should be passed and all the urine drawn, and then into the empty bladder about half the quantity of water should be carefully injected that was used to distend the rectum. The quantity should be about six ounces; at least this amount might be taken as a safe standard and variations made according to individual circumstances. The liquid should be antiseptic, and the best is

Thiersch's solution, which contains boro salicylic acid. The solution should be slowly injected and the surgeon should notice the ascent of the bladder above the pubes. He should also observe the amount of resistance offered to his hand during the distention of the bladder. The same caution here is advised as during the dilatation of the rectum; because any undue force might rupture the bladder, as has happened in several experiments. An India-rubber tubing can be passed around the penis after the catheter has been removed to prevent the escape of the antiseptic fluid which has just been injected for the purpose of distending the bladder. If the assistant's finger is placed over the open mouth of the silver catheter, or, better, a small plug into the end of the catheter, the escape of the fluid will be prevented, and the silver catheter will also serve as a guide to cut upon when the bladder is exposed. This use of the catheter avoids the necessity of withdrawing the instrument and of reintroducing another into the bladder to serve as a guide to cut upon after the viscus is exposed in the wound. The distention of the bladder after dilatation of the rectum increases the distance nearly three inches between the symphysis pubis and the anterior cul-de-sac or pubo-vesical fold of the peritoneum. The membranous and prostatic portions of the urethra are stretched, as has been shown by Sir Henry Thompson.

The patient being placed upon his back with his pelvis elevated so as to cause the abdominal viscera to gravitate toward the diaphragm, is now ready for the operation. The surgeon stands on the left side of the patient and makes an incision three to four inches in length from below, beginning at the pubes and extending upward exactly in the median line of the body. The skin, fasciæ, and cellular tissue having been divided, the linea alba is now exposed. The surgeon cuts along the raphe upon a grooved director between the pyramidales and recti muscles, dividing also the transversalis fasciæ. It sometimes happens that the pyramidalis muscle is exposed by cutting the sheath of the rectus instead of going exactly through the linea alba, and the operator must remember that there is no posterior sheath to the pyramidalis but only the transversalis fascia. The fascia must now be carefully divided and the surgeon next exposes a small space filled with fat and loose connective tissue. Before disturbing this tissue a retractor can be placed in the wound, and this retractor, which is made like an eye-speculum, holds the edges of the wound apart and enables the surgeon to command a good view of the parts and to work with greater facility. The use of the retractor suggested itself to me by its employment in the operation for tracheotomy, where I have found the eye-speculum of great help in holding open the wound while making the deep incisions in order to open the trachea.

The fingers of the surgeon should now be introduced into the wound where he can feel the distended bladder. The loose connective and fatty tissue overlying the bladder should be carefully separated with the handle of the scalpel, then the upper surface of the bladder is brought fully into view with its veins and muscular fasciculi showing on the surface. The surgeon should carefully avoid tearing up the cellulo adipose connective tissue between the pubes and the neck of the bladder, as this might afford an opportunity for urinary infiltration. The point of the silver catheter can be felt within the bladder upon its anterior wall, and this can be relied upon as a guide.

If any uncertainty exists as to whether the peritoneum is out of danger, the surgeon should examine to see if there are two sliding surfaces lying over the beak of the catheter, and if there is a distinct transverse raphe over the summit of the bladder. If only the wall of the bladder is present the surgeon can seize the viscus with two delicate tenacula, and having observed that all hemorrhage and oozing have ceased, open the bladder between the two tenacula and over the point of the catheter.

The walls of the bladder, especially the mucous membrane, are often very much hypertrophied, as a result of the irritation from the stone. The small opening in the bladder is now enlarged by a probe-pointed bistoury in the direction downward toward the symphysis pubis; but never below toward the neck of the bladder and urethra. This last incision would be fraught with great danger. If the object of the operation is the removal of a tumor requiring a free exposure of the interior of the bladder, a stitch is taken in the bladder wall on each side of the incision, and the wound held apart by the suture. The threads also prevent the dipping down of the bladder after the fluid has escaped. The index finger, first dipped into a warm antiseptic solution, is now carried into the bladder and the stone felt, and with the assistance of the other index finger carefully lifted out of the bladder. Instead of the fingers the lithotomy forceps can be employed. If the stone is very large it can be crushed before removal. If there is any difficulty in seizing and removing the calculus, the rubber bag can be emptied and removed and the index finger of the assistant introduced into the rectum and the stone pushed upward so that the surgeon can easily grasp it.

The bladder can now be thoroughly washed out and a soft flexible rubber catheter introduced through the urethra for perineal drainage. The catheter must be removed in forty-eight hours, or its presence will excite a traumatic urethritis. This complication occurred in a case last winter, in which I left the catheter in the bladder too long. An interesting clinical fact in connection with this case was the certainty of the diagnosis as to the traumatic and not specific origin of the discharge. Dr. Seymour Houghton, House Surgeon in Bellevue Hospital, examined very carefully the pus in the Carnegie laboratory, under the microscope for the presence of Neisser's gonococci; but the staining failed after many attempts to show the special germ of this disease. I have seen a boy of ten years and a girl of eight years and also a boy of six years, all affected with gonorrhœa. The first two patients denied any knowledge as to the origin of the trouble; but when the gonococci were found and they were directly charged with it, they confessed. This complication of a traumatic urethritis serves as an important lesson to remind the surgeon not to leave

the catheter in over two days. The catheter in this case was left in four or six days, but was aseptically clean. It was a desire to incur no risks of infiltration on account of the unusual size of the wound in the bladder that induced me to allow the catheter to remain longer than it was necessary.

In this connection might be mentioned the subject of perineal drainage after the suprapubic operation. Some surgeons provide drainage through the perineum by making an opening to the membranous portion of the urethra (the boutonnière) for the purpose of introducing a drainage tube into the bladder by this opening. This seems an unnecessary procedure, for the urethra with a rubber catheter introduced into it, will provide a natural drainage without incurring all the risks incident to wounding the perineum and urethra. Such a procedure exposes the patient to an additional danger of urinary infiltration, and to the danger of the formation of a traumatic stricture and to hemorrhage; and possibly to additional danger of septic infection. The urethra is the natural channel through which to drain, and the opening above can also be used for antiseptic siphon drainage and irrigation, as suggested by Sir Joseph Lister. Hence the perineal incision is unnecessary; besides, it adds the mortality of the median operation to that of the suprapubic. The very object of the high operation is defeated when a perineal wound is made.

The patient should lie with his shoulders elevated, or upon his side, and in this way better drainage is thus secured. Trendelenburg recommends the abdominal position for drainage after the operation. When this is practical it is a most excellent method to establish perfect drainage.

Another question in the technique of the operation is the management of the wound in the bladder. Here an honest diversity of opinion exists among surgeons, and it is an important point for discussion in connection with the high operation. From a careful research into the meagre literature of the suprapubic operation in its modified form, and also from a limited practical experience, I feel convinced that the bladder wound in the majority of cases should be left open. If the bladder in an adult is sewed the wound is most likely to reopen on account of the pathological condition of the bladder wall and the mucous membrane. In chronic cystitis there is thickening of the bladder wall and alteration in the mucous membrane. A failure to secure primary union is quite likely, and if the wound reopens the dangers of infiltration of urine and septicæmia are greatly increased. In twenty-five cases collected by Schmitz with a view to throwing light upon this point six of the patients died, which gives a mortality of twenty four per cent., and in only four cases did primary intention follow. If the wound in the bladder is stitched a natural provision for drainage is sacrificed, and on account of the unhealthy condition of the mucous membrane from a chronic cystitis accompanied by thickening of the entire bladder wall the wound is not likely to heal by primary intention. The wound opens and sloughs occur and the result is extremely unsatisfactory.

While condemning the practice of suturing the bladder wound after removal of a calculus, the same plan is not to be followed in certain other conditions. In rupture of the bladder, for example, the wound should be sewed, but here the conditions of the mucous membrane and the walls of the bladder are altogether different. Primary intention is more likely to be secured in such a case where it would be useless to try under other conditions. If the bladder wound after a high operation for stone is left open to heal by granulation, it will permit the surgeon to treat intelligently a chronic cystitis. The wound in the skin can be partially closed and a large rubber drainage tube introduced into the bladder. After a few days the urine will pass the natural way and any little overflow is cared for by the upper drainage tube.

In young children where suturing the bladder is likely to be followed by primary intention the difficulties of the operation are very great on account of the extreme thinness of the bladder wall and the small abdominal wound. An attempt to close the vesical wound therefore prolongs the operation unnecessarily and should not be attempted unless the bladder is fairly healthy, and the patient is in good bodily condition at the time of the operation. Lembert's sutures in close apposition should be employed and the mucous coat must not be included. The bladder must be carefully manipulated during the sewing so as to prevent a cellulitis. After the wound is stitched an injection of an antiseptic fluid should be carefully made into the bladder to ascertain if there is any leakage. If the bladder is properly sewed no permanent drainage is indicated, but the soft catheter can be passed several times during the first twenty-four hours after the operation, and occasionally after the first day, so as to prevent any distention. The wound heals by primary intention and this occupies only a short time.

The abdominal wound is also closed and a small drainage tube is inserted into the lower angle of the wound. Von Bergmann sutures the bladder and packs the abdominal wound with iodoform gauze for forty-eight hours and thus prevents suppuration. He then closes the abdominal wound in two days after removing the gauze. Schmitz (Langenbeck's *Archiv*, vol. xxxiii., 1886) reports thirty cases of suture of the bladder in children with a mortality of nearly seven per cent. In the thirty cases of suture about half of these cases resulted in primary union of the wound. If children and adult cases are grouped it is estimated that in two-thirds of the cases the bladder wound reopens.

A few days after the operation the patient can sit up in bed and an uninterrupted and speedy recovery should take place. Prof. Annandale recommends the introduction of a lithotrite into the bladder in order to seize the stone and then to cut upon the lithotrite as a guide and remove the stone. A rubber catheter is introduced into the blades of the lithotrite through the abdominal wound and the instrument withdrawn with the rubber catheter. The drainage through the perineum and also in the wound above is the same as in the method already described.

The special indications for exploration of the bladder by the suprapubic method are found:

First. In cases of lithotomy for large hard calculi; also in lithotomy occurring in a patient suffering from paraplegia, a contracted pelvis, perineal tumors, encysted calculi, ankylosis of the hip, hemorrhoids, or great obesity.

Second. For the removal of certain foreign bodies as hairpins, bodkin-needles, etc., for the treatment of chronic cystitis, and for the operation of calculi in the female.

Third. In lithotomy occurring in a patient with greatly enlarged prostate, or with fibroma of the prostate, or in calculi found in diverticula behind the prostate.

Fourth. For the excision of tumors of the bladder.

Fifth. For rupture of the bladder.

The special advantages which the suprapubic operation offers may be enumerated as follows:

First The safe removal of large hard stones which cannot be removed by any of the other methods.

Second. The avoidance of perineal hemorrhage, of urinary infiltration, of perineal fistula, of laceration of the rectum and neck of bladder, the prevention of traumatic stricture and cystic hemorrhage. The avoidance of any interference with the genital apparatus.

Third. The prevention of a vesico-vaginal fistula in young women, or of permanent incontinence of urine in aged women.

Fourth. The safest operation in all forms of renal disease, and the only means of saving life in rupture of bladder.

Fifth. The tendency of recurrence of stone is much less than by lithotrity.

Sixth. Its extreme simplicity, its present reduced rate of mortality, its freedom from danger during its execution, and its safety for the general practitioner in comparison with the perineal operations or lithotrity.

I have collected one hundred and twenty-four cases of the suprapubic operation for the removal of stone since 1879.[1] I have collated all the cases that I could find in medical journals and some cases which have as yet never been published. The influence of antiseptics, and of the rectal rubber-bag together with vesical distention, is apparent when the cases are carefully examined. The death-rate until 1879 was high, since it reached the average of about twenty-five to thirty per cent., but owing to the experiments of Garson and Petersen that mortality has been greatly reduced.

There are one hundred and twenty-four cases. There are, *in toto*, eighteen deaths. This gives a gross mortality of about fourteen per cent. Of these eighteen deaths, the following seven can be, with justice, eliminated from the list in estimating the rate of mortality:

1. Belfield. Corrosive sublimate poisoning.

2. Briggs. Patient was moribund at the time of the operation, and was suffering from suppression of urine before the operation. The operation was performed against the advice of the surgeon, and at the special request of the mother of the child. The conditions were necessarily fatal before any attempt was made to remove the stone.

3. Küster. A median operation was first performed to extract a piece of catheter. He was unable to remove the foreign body, and then performed a suprapubic cystotomy.

4. Martin. Recovery from operation; but patient died three months afterward.

5. Roberts. Recovery from operation. Patient had a gastric ulcer, and died two months after from perforation of the stomach.

6. Rivington. Recovery from operation. Patient died three months after from diarrhœa and a cystitis.

7. Terrillon. Patient died from bronchitis eight days after operation. Autopsy showed that the bladder was healthy—wound aseptic, and nearly healed,

There are eleven deaths, which can be directly ascribed to the operation itself. This gives one death in about eleven cases, or a mortality of about nine per cent., for the removal of stone by suprapubic cystotomy.

The mortality in the lateral operation, according to Sir Henry Thompson, is about one in every eight cases, or, in other words, over twelve per cent.

I am aware of the fact that objection may be raised to taking Sir Henry Thompson's statistics on lateral lithotomy; because other surgeons have published better results. Their experience, however, is not so great, nor is their number so large. In Sir Henry Thompson's cases lateral lithotomy was reserved for cases unsuitable for crushing. I will quote the statistics of other surgeons before any comparison is made.

Freyer reports one hundred and forty-three cases, without a death. Zelt reports one hundred and six cases, with three deaths, or a rate of mortality less than three per cent. Werewkin reports one hundred and forty-seven cases, with a mortality of six per cent. Hensinger reports two hundred and twenty-two cases, with a mortality of nearly seven per cent. Ebermann reports a mortality of fourteen per cent. Skinnisen reports one hundred and fifty-four cases, with seven deaths, or a rate of mortality of about four and a half per cent.

This great difference in the mortality of the lateral operation affords room for much conjecture as to its cause.

In lithotrity Sir Henry Thompson's last statistics show a death-rate of about six per cent. The Norwich Hospital records show a death-rate of over ten per cent.

In litholapaxy Dr. Freyer reports one hundred and eight cases, with a death-rate of nearly four per cent.; Keegan fifty-eight cases, with two deaths, or a rate of mortality of about three and a half per cent. Gross collected one hundred and eighty cases, with four deaths, or a rate of mortality of about three per cent.

The rate of mortality for the suprapubic operation performed with its recent modifications compares favorably with perineal lithotomy, and also with litholapaxy, when the stone is over an ounce. In addition to a favorable comparison, in regard to the rate of mortality in litholapaxy in large stones, the

[1] [The author has collected all the cases and placed them in an alphabetical table in which all the facts in connection with each case are given. Space will not permit the publication of the table in full, though it is one of great value, and will appear in full in the Transactions of the American Surgical Association.—EDITOR.]

important question of recurrence of calculi must not be forgotten. After crushing the recurrence is estimated at one in seven cases, while after lithotomy, one in twenty-five cases. This fact is one of very great importance in estimating the relative value of the two operations in any given case.

Still another very important point to consider, as to the superiority of the suprapubic operation, is the question of emasculation. Langenbeck, as a result of his vast experience, believes that often the seminal ducts are cut and sterility follows. Halberstadt reports eighteen lateral lithotomies in which the patients, after having grown up, married, and only one out of these eighteen cases had issue.

If reliable statistics could be obtained on this point there is no doubt this one fact alone would weigh very strongly against the perineal operation. The successful run of a series of lateral operations is brilliant, and shows wonderful skill on the part of the operator. The history of a patient should be examined years afterward in order to estimate the value of the operation from other points than its mere mortality. Dr. Charles Leale, whose experience has been very great in collecting evidence upon this point, related to me several cases under his own observation when emasculation has been the result of the lateral operation. These patients had little or no hair upon the face, their voices were shrill, their testicles were atrophied, and they were, in fact, eunuchs. I doubt not but many medical men can narrate similar cases. I do not wish to exaggerate the importance of this subject, but simply to call attention to the point as a subject for further examination in the way of collective investigation.

The most important proof of the value of the high operation lies in the fact that heretofore the suprapubic method has been reserved for the removal of calculi above the average size where all other operations were inadmissible. If now the suprapubic operation with its recent modification is resorted to in those cases where the perineal operation only is employed the results will be far more brilliant. These facts demonstrate that the suprapubic operation, as now performed, is a far more successful operation than has been supposed from a reference to its early statistics. It will not, however, supplant litholapaxy in cases of small and soft calculi; but in large stones its results already are far more favorable than perineal lithotomy. The limitations of lateral lithotomy are narrowed by the introduction of the high operation, and future experience will, in all probability, limit the cutting operation for stone through the perineum to those cases where a tight stricture of the urethra exists, and where the operation of external perineal urethrotomy is indicated for the purpose of relieving the urethral stricture.

In conclusion, it may be said that suprapubic cystotomy, in its present form, presents to the practical surgeon a safe, reliable, and radical operation. It should be remembered, however, that the newly modified suprapubic operation has not been sufficiently submitted to the crucial test of time and experience to enable surgeons to estimate accurately its value under all conditions. Hence the great danger of generalization at present. Enough has been done already to convince the most incredulous that in the removal of large stones, and in tumors of the bladder, there is no question as to the superiority of the suprapubic operation.

The revival of this high operation, and its application in cases of traumatism of the bladder, have shown that surgical intervention can save human life where, but a few years ago, these cases were considered fatal. No one can dispute that the two recent cases of Sir William MacCormac bear brilliant testimony to this statement.

Finally, the rate of mortality by the suprapubic operation of about nine per cent. is high for a surgical operation; but a low rate of mortality for an operation performed under the conditions in which this method has been employed. In considering this mortality two facts must be remembered:

First. The causes of death in the majority of the cases are due to septic infection, and not to the immediate effects of the operation itself. The employment of more rigid antisepsis for the bladder should improve this rate of mortality. At the present time there is no ideal antiseptic especially and peculiarly adapted to vesical surgery. The attention of the Association should be directed to this important point.

Second. The largest and hardest stones have been reserved for the high operation. The patients have been, as a rule, in poor physical condition. Improvements in the details of bladder antisepsis and extension of the limits of the high operation to include stones of smaller size, but not to embrace those suitable for litholapaxy, and an earlier period of operation before patients are exhausted from chronic vesical irritation will reduce the rate of mortality so as to compare favorably with any other cutting operation for stone.

NOTES ON THE CAUSE AND TREATMENT OF FUNCTIONAL INSOMNIA.[1]

BY B. SACHS, M.D.,

DURING the past years I have felt a deep interest in that large number of cases of morbid sleeplessness occurring in persons of the neurasthenic habit. I am not concerned with cases of sleeplessness due to other causes, to gross lesions of the brain, incipient insanity, the many acute febrile conditions, nor with wakefulness due to pain.

Allowing for the intentional or unintentional deception in such matters, we still meet with a very large number of persons who may complain of this or that symptom of cerebral or of spinal neurasthenia, but whose chief trouble is insomnia pure and simple. This insomnia may imply mere restless sleep, a sleep of only two or three hours a night, or absolute sleeplessness. And I speak of neurasthenic rather than hysterical insomnia, because I find that really hysterical persons are not so apt to be sufferers from true insomnia, and by far the greatest majority of my cases occurred in men and women

[1] Read before the New York Neurological Society, May 3, 1886.

who could not be accused of the hysterical taint. First, a few typical cases.

Mr. L., aged thirty-four. Educated as engineer, now designer in a large house-decorating firm, consulted me for the first time, nearly eighteen months ago, on account of protracted spells of insomnia. In answer to my questions, he stated that he would sleep tolerably well for a few nights in succession and would then lie awake night after night for weeks. He claimed not to sleep at all during these times, to feel languid and tired in the morning, and as his mind was very actively engaged during the day, he felt completely exhausted. This his looks showed, and, indeed, the marvel was that the man accomplished as much as in reality he did. When asked what kept him awake, whether he thought of his business affairs and so on, he stated that he had no reason to worry about them, and if he did think these matters over, it was simply that he had to busy his mind in some way while lying awake. Headaches were not frequent, but he complained of characteristic pressure on the top of the head. Knee-jerks normal, no tremors of the fingers, no cardiac trouble, but feeble heart beat and weak pulse. Up to this time the patient had been leading a very irregular life, working till late at night, taking his meals whenever it suited his conveniences, and enjoying but little out-door exercise. His entire mode of life was regulated in a way that we shall discuss later on; he was given some hypnotics at the start, these were soon withdrawn, and every thing went well for a period of three months, when he lapsed back into some of his old habits, and again began to suffer from insomnia. From this time on until about six months ago, periods of sound sleep alternated with periods of insomnia. By consent of the patient every form of hypnotic medication was abandoned; massage, electricity, and active exercise were chiefly relied upon.

About six months ago the patient became engaged, and two months later he married. Both engagement and marriage were taken in a matter-of-fact way and seemed to exercise very little influence for good or bad. A few weeks after his marriage were spent in Florida, where the enervating climate and the absolute lack of regular employment exercised a very deleterious influence. "As long as I was in Florida," the patient told me, "I did not close an eye," and this statement his wife corroborated. Since his return to this city, to his regular occupation, and to absolute regularity in his mode of life, including various forms of active exercise, riding, bowling, and the like, he has been sleeping soundly and feels better than ever before. The case illustrates the worthlessness of hypnotic medication and the importance of attending to matters of general regime.

Another case is that of Mr. J. H., æt. twenty-nine, a man of very nervous disposition, easily excitable, and easily depressed in spirits. For the past year he has been greatly distressed by sleeplessness; sleeping but a few hours each night and then very restlessly. He is a man of rather slim physique, but no demonstrable organic changes of any sort. Pulse small and heart beat weak, has occasional asthmatic attacks at night. No headaches. Habits good at present, somewhat doubtful as to past. Knee-jerks exaggerated. As he consulted me during the summer months, I did not waste time with hypnotics and spinal tonics, but sent him to the Adirondacks at once, giving him full directions (in accordance with the maxims of Oertel) as to quality and quantity of exercise he was to take. Since that time he has not been troubled with insomnia.

Mr. W. J. K., æt. thirty, was also a sufferer from insomnia, which was brought on by over-work and worry over his father's illness and death some months previously. All neurasthenic symptoms, including exaggeration of knee-jerks. Insomnia relieved by amorphous hyoscyamia given first four nights, and by change to country air with same directions as other patient.

If we are to gain an insight into the causes of this form of functional insomnia, it will be well for us to note how and what little is known regarding the conditions of normal sleep. I am aware that little or nothing is known of the organic basis of neurasthenia, and it may seem useless, therefore, to attempt to reason about the causation of one of its symptoms. Let us see, however, what physiologists have done to aid us in arguing this question.

The physiological theories regarding sleep are legion in number, a few facts only are undeniable. The first that the abolition of peripheral sensations makes for sleep. We need not depend upon the once famous example, communicated by Strümpell,[1] that has gone the round of all the monographs and text-books, of the boy who could receive impressions from the outer world through his right eye and left ear only, and who fell asleep as soon as both these media were occluded. All of us know that when we are once in bed, the absolute quiet of night, and utter darkness of the room, are most conducive to sleep, and that if there be no noise or light in the room we can fall asleep, provided that other mighty factor in the case, fatigue—be in the ascendant. We know, too, that in the absence of actual peripheral stimuli we can project cortical activity to the periphery, and thus actually engender a state of wakefulness. Before the suspension or withdrawal of actual peripheral sensations it is of the very greatest importance that the cortex should be at rest.

Reasoning by analogy from muscular fatigue, Obersteiner,[2] Preyer,[3] and others have supposed that during mental activity, acid products are formed in the cerebral tissues, and that as soon as a sufficient quantity of this is on hand sleep supervenes. Preyer has even gone so far as to suppose that lactic acid is the product of nerve fatigue as it is of muscular fatigue. There are, to my knowledge, no facts in corroboration of this view. A more ingenious suggestion has been advanced by Pflüger in his *Archives* for 1875, p. 468. He argues that cortical activity can only be maintained by the proper oxygenation of cortical tissue. When this supply of intramolecular oxygen is exhausted, or if the supply cannot be promptly renewed, sleep supervenes. The supply of oxygen is, of course, effected through the blood. On this theory, too, sleep might be the result of an insufficient supply of blood-oxygen, or there might be some peculiarity in the nerve tissue itself which inhibited nerve action. Lyman[4] has carried the argument one step farther, and has attempted to show that *artificial* sleep is the result of impregnating the brain with anæsthetic substances that interfere with sensibility, and, finally, produce stupefaction by hindering the normal processes of intramo-

lecular oxidation in the protoplasm of nervous tissues. These are his words, but such speculations will be of little use to us in explaining morbid wakefulness, and whether or not the direct cause of sleep resides in a peculiarity of the nerve tissue itself, or in the changes of blood supply, it will be more important for us to cling to the indisputable facts observed and advanced by Mosso,[1] Burkhardt,[2] Meynert,[3] and others. Mosso proved, by direct observation, beyond the shadow of a doubt, that emotional or intellectual activity increased the activity of cerebral circulation, and, which is an important fact for us, that there was a correspondingly deficient supply in other parts of the body, particularly in the extremities.[4] I shall have occasion to show that in several cases of very troublesome insomnia the peripheral circulation was seriously at fault.

Putting it broadly, sleep is a vasomotor affair; insomnia a vasomotor disturbance. But the rub comes in when we attempt to decide whether the vasomotor innervation of the cerebral bloodvessels is an extra-cerebral function, or whether there be not in the brain itself at least one, perhaps not the *only*, vasomotor regulator. If so, the trouble is worse confounded, and this inter-relation and interdependence of vasomotor and cerebral function seriously complicate matters. Many of us are, I think, hampered by the idea that the supply of blood is relatively and absolutely so plentiful in any one part or organ, that a change in the blood supply of that part or organ cannot seriously interfere with the blood supply of a distant organ. If the quantity of blood alone were to be considered, such changes would not be of serious import, but we must not forget that anæmia or hyperæmia of an organ has, or, I will say, may have an important influence upon pressure of circulation in other distant parts. At all events, I am not willing to believe that the conditions I have observed in several patients were entirely accidental, although the observations were made and noted at a time when I was not concerned with any theory on this head.

The case which I now relate will show what a fickle thing sleep is, and how it may be seriously influenced by apparently trivial causes.

A lady, aged forty, the mother of four children; married at a very early age, and has always had irregular menstruation, which very often is extremely scanty. The patient is a stout person with feeble pulse and cold extremities, who suffers by turns from sudden flushing of the face, light asthmatic attacks,[5] and occasional severe headaches. The patient is a lady of leisure, very much averse to severe physical exercise, and altogether too fond of a carriage. Heart sounds are weak, probably from deposit of fat about the heart; heart beat not intermittent; no audible murmurs. All abdominal and thoracic viscera healthy. Urine free from albumen and sugar. For the past ten years patient has had but the one serious trouble—insomnia. According to the account which was first given me, over two years ago, she had protracted spells of sleeplessness, during which time she would have great difficulty in falling asleep, and if she fell asleep, would at best sleep but one or two hours. This account is substantiated by the statements of her husband and of her maid. She had been thoroughly soaked with bromides, chloral, etc., with the result of procuring a few nights' good sleep, to be followed by many more of distressing insomnia. The time of menstruation was the most critical period. If the menstrual flow was free, sleep would be tolerably good; if the flow was scanty, insomnia would be certain to set in during the time of menstruation, and for at least eight or fourteen days to follow. In the course of the time that the patient has been under my treatment, I have had ample opportunity to verify this exact succession of events. During these periods of insomnia galvanism to head, lukewarm ablutions of the entire body before retiring, application of mustard to nape of neck and upper spine, the exhibition of urethan or paraldehyde: each agent would be followed by temporary relief, but no permanent cure was to be effected in this way. During the past few summers drinking the waters of Marienbad or Carlsbad, brought the greatest relief; and here sleep was induced, I am certain not so much by the effects of the water upon a mild form of chronic constipation, and the reduction of her superfluous adipose, as by the regular exercise she was compelled to take, and the bland diet she adhered to while under treatment at these places. As she returned to this city and again fell into her old habits, sleeplessness would return with unerring certainty. Like so many patients, this one cannot be impressed with the importance of obeying strict rules as to exercise and diet, and is much more deeply impressed by the exhibition of narcotic drugs.

No case that I have had has been so rebellious to treatment, and none has so deeply impressed me with the intimate relation existing between disturbances in peripheral circulation and the condition of insomnia. The irregularities of peripheral circulation are evidenced by the cold, clammy hands, the cold feet, and the scanty uterine flow at time of menstruation. It is not a difficult matter to produce a single or a few nights' sleep in patients even of this description, chloral, urethan, paraldehyde, hypnone each might bring this about; and, indeed, it is to be regretted that this is the case, for upon the withdrawal of these agents, the patient is, as a rule, much worse. You can in this way avoid an otherwise sleepless night, but you cannot and do not cure insomnia. To do this, you must strike at the root of the trouble, and endeavor to better the condition of the circulation.

If anæmia of the brain is conducive to sleep,[1] general anæmia is, on the other hand, a fruitful source of insomnia. These cases are so common that it appears quite superfluous to cite examples in support of this view. A short account of two will answer our purpose.

Mrs. R., æt. thirty-one; married twelve years; no children; has always been nervous, and is easily excitable, but there is no history of hysterical attacks of any sort. Considerable anæmia and very distressing palpitation, with occasional attacks of precordial fear at

[1] A fact not wholly proved.

[illegible]

increase of the blood pressure, causing a larger flow of blood to the brain

bed-time. Menstruation has always been irregular, occurring, as a rule, every five or six weeks. Constipation the rule. Is a great sufferer from headaches of the paralytic migraine type, and from insomnia. The two conditions are sometimes coincident, but not necessarily so. On tonic treatment with iron, gentian, and strychnia, the use of caffeine and ergot for the migraine, and, above all, by closely following out a prescribed regime as regards exercise and diet, the patient has been greatly relieved in the course of two months' treatment, and has been sleeping well for the last two months.

Another, and similar case, is that of Mrs. S. G., æt. forty, mother of four children, who, according to her own and husband's statement, has been a severe sufferer from insomnia and headaches for years. Every form of excitement, of which she has had not a little, would be followed by insomnia and headaches; during such periods she would sleep but an hour each night. Headaches, if present, would keep her awake, but when entirely free from these she spends many sleepless nights. The patient has been very much reduced in strength by chronic gastro-intestinal trouble, with alternate diarrhœa and constipation. Marked anæmia, no cardiac mischief, pulse weak but regular. Urine free from albumen, no sugar; but heavy deposits of urates. In this case, which is still under treatment, marked amelioration has been effected, first and foremost, I think, by the checking of the intestinal catarrh through the use of naphthalin, the pursuit of a non-irritating, nutritious diet, with alkaline waters, and the taking of regular active exercise.

I do not wish to convey the impression that to my thinking all cases of insomnia have the same causation, and how mysterious the cause sometimes is, is frequently brought home to me by a patient whom I see every now and then, a man, æt. fifty-five, very thin, and slightly anæmic, a hard worker in his day, and now a man of leisure, who goes to bed regularly at eleven, to wake up again at two or two-thirty in the night, who then walks the floor until morning, or sits at the window in an arm-chair. For at least six years the man has passed every single night in this way. He does not sleep during the day, the functions of all his organs are perfect; his appetite fair, and his spirits surprisingly good. He was benefited for a time by nocturnal applications of galvanism to the head and by general faradization, but these soon lost their effect; every hypnotic is exciting, and one could scarcely prescribe a stricter diet, more exercise, and a more regular mode of life than he now observes.

From some of these cases I have just mentioned and a number of others, I have been led to recognize the intimate relationship between certain forms of headache and insomnia. In some headache and sleeplessness were coincident, in others there was an alternating relationship between the two conditions.

On looking over my cases of migraine associated with insomnia, I find that the migraine has been of the paralytic type, and that if sleep could by some means be secured the headache would disappear from that time onward. In cases of spastic migraine I have had patients complain of insomnia, but my notes do not show that this insomnia occurred at or about the time of an attack of migraine. Here is a case in point.

F. M., æt. thirty-three, merchant, unmarried; fond of the good things in this world, but not given to troubling himself or exerting himself in any way, has been a sufferer from severe migraine ever since he was five years old. Attacks come on at irregular periods. My first acquaintance with the patient was during one of his attacks which was of a distinctly paralytic type—face flushed, pupils small, etc. These attacks are accompanied, as a rule, by sleeplessness, which the patient does not think is to be attributed to the severity of the headache. He had a rather bloated look at first, and was somewhat gluttonous in appearance.

I insisted on an entire change in his mode of life, compelled him to take active exercise, ride, swing dumb-bells, etc.; reduced his diet, and treated him with galvanization to the head. Patient has been free from migraine and insomnia for three months. Galvanism had a very pronounced influence for good upon his headaches, and his was one of those cases which do well under antipyrin. (I may say, incidentally, that, after two fifteen grain doses of antipyrin, his headache disappeared, and he fell into a sleep lasting ten hours. I am not ready to pronounce antipyrin a hypnotic, but in insomnia associated with migraine I am inclined to think, from my experience in this and two other cases of paralytic migraine, that it kills two birds with one stone.)

I have had proof in still another way of this same relation: without any preconceived notions, except such as were suggested by the general condition of the individual patient, I find, on referring to my notes, that the same form of treatment which has been successful in a number of cases of insomnia has been successful in most of the cases of migraine with which I have had to cope. Until I have good reason to think otherwise, I shall for therapeutic reasons look upon migraine and insomnia as vaso-motor disturbances.[1]

As for the treatment of cases of functional insomnia, I would suggest, as the result of my experience with twenty-four recently treated cases[2] of functional insomnia, that if it be due to mental overwork, or other exhausting causes, these be first removed. Pronounced anæmia and general neurasthenic symptoms should be treated at once by the ordinary

[1] But is there any possibility or probability of determining the state of the cerebral circulation in these morbid states? While the appearance of pale or flushed face may permit a guarded inference respecting the state of the cerebral bloodvessels, it is by no means certain that flushed face means flushed brain. Careful examination of retinal bloodvessels might throw some light upon this point; but while writing this paper, I have received a reprint of an article by Eulenburg, of Berlin, in which another possible method of determining this question is suggested. Eulenburg has made accurate measurements of the resistance offered to the galvanic current by passing the same in a sagittal direction through the head. He determined the minimum of resistance in each case, and at each sitting, and was surprised to find that this minimum resistance varied but little, not only in the same individual, but in different individuals of the same age and condition of life. The average minimum of resistance in healthy persons was between 1200 and 1600 ohms. Marked departures from this average were noted in gross brain lesions, but still more distinctly in cases of severe functional disturbances—in hemicrania, anæmia, chorea, Basedow's disease, hystero-epilepsy, and the like. The increase or diminution of the minimum of resistance Eulenburg attributes to the variability of the quantity of blood within the skull. But the question is not settled yet; for although Eulenburg was able to state that the resistance of a given column of blood was twice as great as an equal volume of cerebro-spinal fluid, he found the resistance increased in those conditions of the brain in which there was presumably a reduction in the total quantity of blood present within the cranial cavity.

[2] Dispensary patients seem to be relatively free from insomnia. While the number of neurasthenics is great enough, they do not often complain of sleeplessness.

blood and spinal tonics; but, above all, every precaution should be taken to increase the force of the heart and of the whole circulatory apparatus; and that this cannot be done better in any way than by the use of cool douches to the head, chest, and spine; by prescribing a bland diet, together with some alkaline water, and by compelling the patient to take considerable outdoor exercise, either in the form of walking several hours each day, or of riding, rowing, bowling, and the like. During the summer months, mountain climbing, if not carried to excess, would be an admirable substitute for such exercise as we city people are at other times compelled to take.

The adoption of the rules laid down by Oertel would surely be followed by good results.

The substitution of passive for active exercise is, in my opinion, not sufficient, and incidentally I may remark that a patient who was otherwise doing well under a modified Weir Mitchell treatment was, during the greater part of the time, a great sufferer from insomnia.

After a few weeks of such treatment, I believe there will be marked improvement in many, if not in most cases of insomnia. But patients have an annoying way of wishing to obtain *prompt* relief, and obtaining this they become more tractable, and more amenable to every other form of treatment. It is on this account chiefly that we cannot dispense altogether with hypnotics, and must administer them occasionally in spite of ourselves.

Summarizing the experience I have had in the above cases of functional insomnia seen during the last year or more, I find that I have used for treatment chloral and bromide, the bromides separately, the amorphous hyoscyamine, paraldehyde, urethan, and, in a single instance, hypnone. Morphine I have never used in these cases, as I object to it in all cases in which there is not severe pain, and certainly object to it in cases such as these when the patient would be quite prepared to contract the habit. The bromides alone have been of occasional service to me if given in one-half to one drachm doses, in cases of extreme restlessness, but even in these I have learnt to substitute the amorphous hyoscyamine in doses of about one-twentieth of a grain, repeated every three hours.

I object most strenuously to the plan advocated by Dr. W. A. Hammond and others, of keeping these patients for a long time under the influence of the bromides. These neurasthenic patients require all the will power they can possibly command, and are in much greater need of tonics than bromides. It is easy enough to bring about a condition of semi-stupor in such patients, but that is not equivalent to bringing about healthful sleep.

Paraldehyde I used freely about nine months ago, and for several months later. I gave it in doses of one to one and a half drachms in claret. This dose was always sufficient to bring about sleep the first few nights, but if required beyond this time, the drug proved unsatisfactory, as the hypnotic dose had to be increased, and, while I noticed no deleterious action upon the heart or other organs, the odor it imparted to the breath was excessively disagreeable. One female patient, whom I had not had occasion to see for some months, sent for me one morning after she had had a sleepless night. She had been using paraldehyde steadily in spite of my remonstrances, and I found, on entering, that the room was actually filled with the exhalation of paraldehyde.

Urethan has been satisfactory in a number of cases. It has no disagreeable after-effects, and does not irritate either the stomach or bowels. It has been my experience that the dose should be between two and three grammes, and that greater quantities of Merck's preparation induce wakefulness rather than sleep.

The mixture of fifteen grains of bromide and twenty grains of chloral has often come to the rescue when every other hypnotic refused to act. I have seen no ill-effects follow the exhibition of this mixture, even in cases of weak heart.

A word as regards electrical treatment. In several cases in which no other remedy could secure relief, I have been able to induce sleep by galvanism applied to the head after the patient had retired for the night. I have given galvanism in the form of subaural, supposed sympathetic galvanization, and by passing currents directly through the head, with one pole on the nape of the neck, and the other on the forehead; changing cautiously the nature of the poles, and allowing the current to flow in an opposite direction, and never using a current of more than two milliampères. Occasionally I placed one pole over each temple. I have not been successful in the endeavor to bring on sleep by general faradization. Faradism to the head I would not apply under any circumstances. Moreover, so far as our present knowledge goes, galvanism is more effective than faradism in bringing about vasomotor changes.[1]

If I have accomplished nothing else, I trust I have convinced some of you that in the treatment of these cases of neurasthenic insomnia, we are in need not so much of additional hypnotics, as of more effective means of regulating and influencing cerebral circulation.

THE POLAR METHOD OF ELECTROTHERAPY IN GYNECOLOGY.[2]

APPLICATION, DOSAGE, AND MEDICATION.

By GEORGE J. ENGELMANN, M.D.,

[redacted]

IV. Electro-medication.

We cannot doubt the value of electricity to man; that it is an agent of infinite power, and one adapted to all possible purposes, the discoveries of the last decade have shown, and this subtile fluid, which has

[redacted]

the subject has been published by Massey in this journal for May 7, 1887. It will be observed that my opinions differ in some respects from his. It is worth noting that in the discussion following the reading of my paper, the soporific effects of Franklinization were referred to by several speakers, thus corroborating by antici[redacted]

[2] Read before the St. Louis Medico-Chirurgical Society.

added to so great an extent to the comfort and convenience of the human race, which is so well serving the outer wants of man, must now be made to contribute to the welfare of his inner being. The medicinal virtues of electricity are still to be developed; many attributes which are of value to us you know—the contracting power of faradism, the chemical properties of galvanism, as you see by the affinity of acids for the positive pole, and of alkali for the negative, and the electrolytic action of galvanism, as shown by the rapid disintegration of water, hydrogen seeking the negative pole, oxygen the positive.

I have told you that I have instantaneously checked hemorrhage in the uterus post partum, by the contractile action of faradism in desperate cases, and by two applications brought about the menses which had ceased for a twelvemonth; that I have destroyed intrauterine tumors as large as a hen's egg in three sittings of five minutes each; completely relieved the distressing symptoms of congestion, gastritis, dysuria, and constipation, in a patient suffering from a large abdominal tumor, and reduced the circumference by five inches, by five consecutive daily treatments of eight or ten minutes each. I have dispersed the painful swelling due to a contusion of a joint, which had for three weeks resisted treatment, by a single mild application of faradism, and relieved the pain of articular rheumatism which opiates could no longer control. I have relieved aneurisms and destroyed angioma by the coagulating action of the positive pole, and increased the flow of blood from indurated hyperplastic uteri by the fluidifying action of the negative pole; a prolapse with œdema of the leg was relieved by faradism, and the patient, who had not walked for twenty years, was enabled to move about as freely as any one of her age, after a two months' treatment; a stenosis of the uterine canal, which caused agonizing menstrual suffering, was relieved in three sittings of five minutes each, and permanently overcome by six or seven more; the most obstinate pruritus, which had long resisted treatment, was cured by one application; constipation and dysuria have been rapidly relieved after resisting the usual remedies. We have just discharged a poor girl who came to the clinic two months ago, partially disabled by a solid pelvic effusion, which had the appearance of a fibroid rather than of an inflammatory product, filling the pelvic cavity, displacing the uterus, and wedging the cervix in between the effusion and the symphysis; in twelve treatments, electro-cauterization, of five minutes each, with from 60 to 100 milliampères, the *complete absorption* of this mass was brought about, it has disappeared, leaving only the somewhat thickened normal tissues. How rapidly it was destroyed I cannot say, since no examination was made until the twelfth treatment, and then it was gone. Is not this a triumph?

An effusion, as hard as fibroid tissue can be, which had for five years been undermining the health of this poor girl, and at last almost disabled her by hemorrhage and pain, is dispersed by twelve painless treatments, which not only do not interfere with her work, but aid her in it by the immediate relief afforded; each application was marked by improvement and increased well-being; first hemorrhage, then pain subsided, whilst her strength steadily increased.

This rapid result has induced me to observe other patients more carefully, and I find similar effects in similar conditions, with an opportunity of observing the final disappearance, the steady decrease, of such effusions called fibroids by some.

Such are the results which may be obtained by the proper use of the "polar method," by the application of strong and effective currents, and their localization, as taught by Apostoli in the treatment of fibroid tumors. More still can be accomplished.

In an early paper I treated of electricity as a nerve sedative, and a stimulant, a muscle contractor, and antispasmodic, an antiphlogistic and counter-irritant, a vesicant, a tonic and promoter of development, an absorbent, chemical cautery and escharotic, electrolytic, hemostatic and decongester, and a promoter of hemorrhage and congestion. It has other properties still. Since then I have utilized it as a *medicator*, and although I have not as yet obtained such striking results, this property of the electric current is one so peculiar that it deserves recognition; I have termed *electro-medication* this method of treatment by the *nascent ions* of an *electrolyte*.

By the electrolytic, or electro-chemical, action of galvanism water is resolved into its components H and O. Bromide of potash, iodide of potash, muriate of ammonium, and chloride of sodium respond in a precisely similar manner, while the bases are set free at the negative pole, the metalloids, Br, I, and Cl, are found at the positive pole.

In order to limit the extent of this paper, I shall confine myself to the above combinations or types. Br, I, and Cl are powerful gases, especially active in the nascent state in which they are brought in contact with the tissues in electro-medication. I shall not here treat of the possibilities of conducting the electrolyte *into* and *through* the tissues, but merely of its effects *upon* the tissues in contact with the pole at which it is set free.

If we place positive and negative poles of a galvanic battery, armed each with a platinum needle, into a glass filled with a solution of iodide of potash and starch, we will at once see the bubbles of hydrogen rising at the negative needle, and the fluid about the positive pole turning blue from the action of the developing iodine on the starch; in like manner is the iodine set free at the positive pole when in contact with the tissues.

Saturated solutions must be used and prepared at the time, as solutions which have been standing are no longer serviceable on account of chemical changes which take place.

Platinum should be used as a carrier, as most of the nascent metalloid is taken up by other metals and lost to the tissues, if the electrode be of susceptible metal.

The stronger the current the more rapid the development.

The positive pole must be the active pole, and must carry the solution in contact with the tissues to be acted upon.

The negative must be the dispersing pole.

These applications are admissible only in cases in which galvanism is not contraindicated.

They can be made most effective in locations in which greater quantities of the fluid can be applied, as in the vagina, in the uterus, and on the abdomen, where large electrodes can be placed.

These applications may be made directly for the purpose of medicating the diseased surface, or as an addition to the proper application of the electric current, as indicated in the case—*e.g.*, in making a vagino-abdominal application of galvanism for purposes of absorption in chronic perimetritis, we obtain precisely the same effect from the electric current, whether we use the abdominal plate saturated with water or with iodide of potash; but in the latter case we assist its action by the developing iodine.

Iodine may be applied in cases of cellulitis by the usual vagino-abdominal application.

a. With the positive dispersing electrode, saturated with iodide of potash over the diseased side, and the negative cotton-covered ball electrode in the vagina, using currents of 40–80 milliampères.

b. With the vaginal ball electrode covered with absorbent cotton saturated with iodide of potash in the vagina, and the negative dispersing plate on the abdomen, using currents 40 to 80 milliampères, or over; in this case the vagina can be filled with the fluid, and a more effective action be produced.

c. In cases of hyperplasia and metritis a saturated solution of iodide of potash is applied to the cavity, and after the tissues are moistened with this, a delicate applicator, best of platinum, is armed (as for medicinal application) with absorbent cotton, saturated with the solution, placed in the cavity, and connected with the positive pole; the abdominal dispersing plate being the negative pole. The current should be of such strength as it would be if used merely for its proper effect; but if this is less than 30 or 40 milliampères, the application should be prolonged to six, eight, or ten minutes, in order to allow of sufficient development of iodine; 100 and 150 milliampères may be used

Bromine. A powerful cautery and antiseptic; is useful—

a. In endometritis with profuse secretion, or with offensive discharge, as an intrauterine application, bromide of potash being used in precisely the same manner as the iodide in the last-mentioned case.

b. To the cervix the application may be made by saturating the cotton covering of the positive electrode with the solution and pressing it against the tissues.

Chlorine is developed from common salt or from chlorate of potash, and will prove less serviceable than either of the preceding agents. Chlorine may be used in the uterine cavity after the removal of offensive tissue by the curette or the douche.

These elements in their nascent state are indicated when a gentle, diffuse, and general action is desired, and the necessary accompaniment of this method of application, the galvanic current, will further the treatment; they are most effective if sufficient quantities of the fluid can be utilized.

Many other remedies may be so applied, and I have merely mentioned the above as examples of this method of electro-medication by which certain advantages may be attained, which will, I hope, be more fully developed by continued experiment. Possibly we may be enabled to carry remedies into the tissues, as was at one time hoped by that enthusiastic electrician and eminent surgeon, my honored teacher, Victor von Bruns, more than twenty years ago.

Recent operators have again claimed to have carried iodine into pelvic effusions by this means. I have myself only attained negative results in my attempts to develop this method of interstitial medication which would prove the turning-point of local applications, and a most progressive step, if it could be accomplished. As I have no results, I will not discuss the subject, and have confined myself to what I have found feasible, superficial electro-medication by gaseous elements in their most effective state, when nascent.

I have been gratified by the general interest which is taken in the development of gynecological electrotherapy, and more than pleased by the results of my efforts to establish the galvanometer, the use of effective currents, and the large dispersing plate for the indifferent pole; hence I have not waited to develop fully this method of electro-medication, but now present to you the outlines and the fundamental principles of the method which I believe to be susceptible of development, and this I hope it will receive at the hands of one of our active workers who is interested in the success of electrotherapy.

MEDICAL PROGRESS.

COCAINE IN THE TREATMENT OF WHOOPING-COUGH.—BIANCHÉ has given cocaine internally for whooping-cough, with good results. His dosage was from 1½ to 2 centigrammes [0.225 to 0.3 grains] in 24 hours. Given in solution in small, frequently repeated doses.—*Lo Sperimentale*, 1886.

TREPHINING THE HYMENOCHTIS.—The following case is reported from the Royal Infirmary, Dublin, from the clinic of GRAINGER STEWART:

After consultation on the morning of March 1st, as the symptoms had become during the night even more pronounced, it was decided to trephine without delay. The point selected was that corresponding to the posterior part of the third left frontal convolution. Chloroform having been administered, a curved incision, three inches long, was made along the lower edge of the part to be trephined. A trephine, with diameter of one inch, was applied, and a circular piece of bone removed. The dura mater being partially adherent to the bone, was torn at one point in elevating the circle, and through this opening there immediately welled out with a pulsatile movement a quantity of serous fluid, at first brownish-red, afterward dark red in color. The opening in the dura mater was enlarged, and about six ounces of this fluid escaped. On inserting the finger, it was found that the fluid lay between the dura mater and the [illegible] a space extending backwards about three

inches, and forward two inches, and it at once became clear that the pressure of a hemorrhage had led to the increase of the symptoms. We concluded that this hemorrhage was the result of a pachymeningitic process, and recognized that while the immediate danger had probably been obviated, the ultimate prospects of the patient were less favorable than they might have been had an abscess within the hemisphere been the cause.

On recovering from the chloroform the patient showed marked improvement in respect of intelligence, sensibility to touch, and motor power, and he soon began to speak sensibly, and to express the great relief he had experienced from the operation. The exaggeration of reflexes which had appeared on the right side had now passed off.

On March 6th nineteen convulsive fits occurred in the course of six hours, the patient often screaming loudly during the attacks. The condition gradually became worse; during the last hours of life the convulsions had for the most part disappeared; the patient lay comatose, breathing stertorously, and with much puffing of the cheeks, especially the right. The skin and conjunctival reflexes were abolished, the deep reflexes were masked by clonus in the right arm, were exaggerated in the left arm, and were completely absent in both legs. Respiration became peculiar; the tracing taken with Marey's polygraph showed 26 full respirations, 19 shallow, 20 full, 18 shallow, with sudden alternation. The urine was drawn off; it was dark in color, very acid, and contained a considerable amount of albumen, but no peptone, bile, or sugar. There was an occasional jerk of the muscles of the fingers or of the pectorals. The character of the breathing changed suddenly, expiration becoming much longer and sighing in character, and the patient died shortly after 11 P.M. Just before death the temperature in the left axilla was 98.8° F., and in the right axilla 102.4° F., the pulse 150, and the respiration 50 per minute. After death the temperature rose in both axillæ, but more in the left than in the right. —*British Medical Journal*, April 23, 1887.

Convenient Formulæ for the Use of Balsam of Copaiba.—For internal use:

℞.—Balsam copaivæ . . . . . 2 parts.
Spirit. juniperi . . . . . 3 "
Spirit. ætheris nitrosi . . . . 1 " —M.
Sig. 30 drops 4 times daily.—Schœmann.

An emulsion, for topical use, by injection:

℞.—Balsam copaivæ . . . . . 4 parts.
Sodii carb. cryst. . . . . 2 "
Aquæ . . . . . q. s. ad. 100 " —M.
Sig. For injection.

This emulsion was originally a French prescription, but being a convenient and permanent emulsion has been widely used. It is commonly diluted with three parts water, when an intravesical injection is made; when excessive pain is present, a few drops of tincture of opium may be added.—Jeannel.

℞.—Balsam copaivæ,
Extr. cubebæ . . . . . aa ʒ 2½.
Cubebæ pulv.,
Myrrh. pulv. . . . . aā q. s.
Ft. pil. 50 in num. Coat with gelatine.
Sig. Two or three pills several times daily.

Treatment of Malignant Stricture of the Œsophagus by Tubage.—Symonds, of London, reports his methods as follows:

1. So long as solids can be swallowed, let the patency be maintained by the passage of bougies, for neither by tubage nor through the opening formed by gastrostomy can solid food be introduced. Well-stewed tripe, rabbit, and pigs' and calves' feet are swallowed readily.

2. When solids can no longer be taken, a short tube should be introduced. This, when considerable dilatation has been effected, may be removed altogether from time to time, and the patient allowed to take solids. This form can be worn till the case terminates, unless pulmonary symptoms supervene, especially cough on swallowing.

3. When the passage of fluids can no longer be borne, then they must be withdrawn altogether from the gullet. This can be accomplished in two ways: (*a*) by the use of Krishaber's long tube; (*b*) by gastrostomy.

The duration of life after this stage has been reached will in no case be long, and it becomes a question of giving the patient the greatest amount of comfort. The experience of others as well as my own shows that long tubes may be worn till the termination of a case; and, as I believe, the ulceration will be avoided by using rubber tubes, and passing them by the nose. To this method I give my adhesion, rather than to gastrostomy. Those who have seen many cases know the difficulty that often arises from escape of the gastric juice, and that not a few have been fed into the peritoneum, while the operation, if done when the patient is in a depressed condition, is very likely to be unsuccessful, either from want of union or exhaustion. Other means are sufficient in the earlier stages.—*British Medical Journal*, April 23, 1887.

Sparteine, in Comparison with Digitalis.—Stalssel has made extensive experiments in Vienna, and concludes as follows:

Sparteine, in doses of $\frac{1}{6}$, $\frac{1}{3}$, and $\frac{1}{2}$ grains, produces the same results as digitalis, in somewhat less degree. It is not a pure diuretic. No ill after-effects were observed.

Digitalis is superior to sparteine in every respect. It is only when digitalis is not well borne, or when the newer drug can be used as an adjuvant to digitalis that it should be employed.—*Centralblatt für die Gesammte Therapie*, April, 1887.

Transverse Septa in the Cervix Uteri.—M. Budin has recently published in the *Progrès Médical* an original article on incomplete transverse septa in the cervix uteri. In 1875 he discovered a diaphragm of this kind in a patient at the Maternité, Paris, during labor. She had already borne one child. M. Budin found the cervix completely effaced. On passing the finger over the fœtal head, the edge of the septum could be plainly detected. The septum was well marked on the right side, and existed in front and behind, but appeared to be absent on the left side. Labor was normal. In 1879 Professor Depaul induced premature labor in a primipara, aged thirty, with a deformed pelvis. M. Budin detected, when the os was well dilated, a septum equally marked in all directions; it had a wide orifice, and appeared to be attached to the walls of the cervix

below the os internum. Labor was long, but the waters pushed the septum well downward, so that it did not appear to be the cause of the prolonged process of parturition. When the patient was convalescent the septum could be detected, but it was less marked than before. Müller detected a similar septum below the os internum in a single girl, aged twenty, subject to retroversion and menorrhagia. Breisky, in his notes, recorded a case of cervical septum in a woman, aged forty, also subject to menorrhagia. Bidder detected a septum in a primipara, aged twenty-six, during labor, as in Budin's cases; here, again, the septum was most developed on the right side. The pains were feeble, and the septum certainly obstructed labor. Its edge was incised, and the margin of the os externum was also incised; the os was then dilated, and a male child delivered with the aid of forceps. The septum seems to have disappeared after labor. Perhaps, Budin suggests, the left side of the septum had been destroyed in his case during the first labor. From notes supplied to him by the head widwife at the Maternité, there appear to have been seen in 1884 and 1886, in Professor Tarnier's wards, two cases of uterine septa. The first occurred in an instrumental labor, the termination of the patient's seventh pregnancy. The septum seemed to lie at the level of the os internum; it was very rigid, its orifice was minute, and its tissue contracted simultaneously with the uterine contractions. In the second case, a primipara, a septum with a very narrow orifice was detected nearly an inch above the os internum. The shoulder presented, and tore the septum. Turning was performed, and the child was delivered alive. The torn septum could be detected afterward. The true relation of the menorrhagia in some of the above cases of cervical septum is doubtful.—*Brit. Med. Journ.*, April 23, 1887.

R.—Acid. tannic. . . . . gr. 23.
Plumbi subacetat. (liquid) . . m145.
Tinct. catechu . . . . . 5jss.
Tinct. opii . . . . . m23.
[illegible] . . . . . 5 12!.
Aquæ destillat. . . . . 5ij½.—M.

Sig.—Inject morning and evening, and allow to remain in the urethra two or three minutes.—*L'Union Médicale*, April 11, 1887.

Dosage with Children.—Buttin gives the following table:

For children from

1 to 2 years, $\frac{1}{10}$ the dose for adults.
[illegible]

For aged persons, between 65 and 80, $\frac{4}{5}$ the ordinary adult dose.—*Journal de Médecine*, April 10, 1887.

A Postural Theory of Phthisis.—A theory advanced by G. W. Hambleton, of King's and Queen's College of Physicians, Ireland, is as follows:

Man, in a state of civilization, does not hold himself erect: he stoops more or less. The weight of his shoulders is thrown on the thorax, and, consequently, the latter is impeded in its movement, and his chest is narrow. Man, in the uncivilized state, holds himself erect; the weight of his arms is borne by the spine; his chest is broad, well developed, and freely movable; and he passes the whole of his existence in active exercise in the open air. The trades and occupations that supply the greatest number of cases are those in which small particles of various substances are constantly inhaled, those that necessitate little movement or even a cramped position of the chest, and those where a considerable time is spent in small and badly ventilated rooms. In the army those who become phthisical are those who have a chest capacity below the average. In short, the conditions that produce consumption are those that reduce the capacity of the lungs below a certain point.

In support of this theory, Mr. Hambleton gives the results of some experimental investigations which he has made, in the form of the following propositions: 1. That artificially induced reduction of the breathing surface of the lungs below a certain point, together with the prevention of compensatory action of other organs, is followed by a local and general state not to be distinguished from consumption; 2. That arrest of this artificially induced reduction of the breathing surface of the lungs, together with induced compensatory action of other organs, is followed by relief of the prominent symptoms, and improvement of the general state; 3. That artificially induced full development of the breathing surface of the lungs is followed by an entire absence of all symptoms of disease, and by general good health. *Lancet*, April 30, 1887.

The Causes of Suppuration.—A. Zuckermann [illegible] relates his experiments upon suppuration, which have led him to these conclusions:

That no chemical, mechanical, or thermic influences can excite suppuration if they are wholly free from microbes; and in cases where these causes apparently act it is probably through some pyogenic microbe. For substances chemically pure may be mycotically impure; thus some disinfectants are not always free from microbes. The varieties of microbe known to cause suppuration are Staphylococcus pyogenes aureus, albus, and citreus; Streptococcus pyogenes; and in fetid abscesses, Bacillus pyogenes fœtidus. Inoculations with staphylococcus and streptococcus produce fatal results if injected in large amount into animals, or lead to suppuration if death do not occur. The pyogenic microbes must have a very general distribution in nature; they may enter the body through the air-passages, the intestinal canal, and especially the skin, and by means of small wounds or the orifices of the cutaneous glands. Staphylococcus is more frequent than the streptococcus pyogenes.—*Lancet*, April 30, 1887.

Prognostic Value of Sudamina in Typhoid Fever.—Baradat and Lacase give the following conclusions in an article in the *Revue de Médecine* for April 10, 1887:

Sudamina appearing at the commencement of the second week of typhoid fever have no value in prognosis. Sudamina appearing after the second week announce the approach of convalescence.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

COLD IN THE TREATMENT OF LOCALIZED NEURALGIAS.

THE many and various methods which have been introduced for the relief of this most painful and annoying affection, particularly when occurring in nerves situated in superficial regions, have none of them, unfortunately, brought the widespread and permanent relief for which their originators hoped. Although the discovery of a cure for all neuralgias is probably an impossibility, owing to their many causes, it is perhaps fortunate that the physician has so large a number of therapeutical resources, since he can always tell the sufferer of the cures which still another remedy has effected.

Almost all the remedies which have been used locally for this affection have belonged to one of two classes, namely, counter-irritants and sensory nerve paralyzants. Lately, however, extreme cold has been tried with no small degree of success, and although its use is by no means novel, it may be of interest to call attention to the results obtained.

Early in April of the present year M. DEBOVE reported to the Société Médicale des Hôpitaux no less than one hundred and sixty-eight cases treated in this manner, of which one hundred and fifty were cases of neuralgia of the sciatic nerve. His results are even startling in their success, and if further experiments show that they are to be relied upon, a remedial measure of great value in such cases is given to the profession, for in only ten cases did relief fail to appear, while in the treatment of eighteen cases of facial neuralgia, but two were unsuccessful, notwithstanding the fact that several of them had heretofore proved most intractable. Thus he mentions the case of a woman who had suffered for years with neuralgia of the face, and who had submitted to section of the nerve no less than three times, in whom these cold applications effected a cure in two months.

M. Debove, after stating that he had used the chloride of methyl in the form of a spray for the purpose of lowering the temperature of the area involved, proceeds to warn us against the discoloration of the skin which sometimes follows its use, and insists that the surface and not the deep parts should be treated. It seems probable that the cold must act in quite a different manner in the case of neuralgia of the sciatic and of any of the facial nerves, since in the one case the nerve fibre is much more deeply buried than in the other, so that while the facial nerves are directly acted on by the cold, the sciatic is only affected by the increase or decrease of blood and warmth in its immediate neighborhood.

CHOLERA IN PREGNANCY.

A VERY interesting memoir upon this subject by QUEIREL, of Marseilles, was recently presented to the Paris Academy of Medicine by Charpentier, and an abstract of it is found in the *Archives de Tocologie* of March 30th. It is founded upon sixty-seven cases, of cholera occurring in pregnant women in the last epidemic of the disease, thirty-nine of which were observed by the author, and our readers will be interested in some of the important facts he notes.

Of the sixty-seven cases, thirty-nine died, and twenty-eight recovered; twenty-nine of the sixty-seven aborted or had premature labor. Previous statistics have shown that interruption of pregnancy is rather more favorable for recovery than its continuance; but the figures of Queirel indicate the reverse, the mortality of women who did not abort or have premature labor, being only forty-three per cent., while that of those in which one or the other of these accidents occurred was seventy per cent. The cases of premature labor gave the number of twenty children born alive, but most of these died soon after birth.

Queirel, in considering the causes of the arrest of pregnancy, discusses the following hypotheses: reflex action, uterine cramps corresponding to those of the limbs, toxæmia, and disturbances in the fœto-placental circulation. He regards it as probable that each is efficient in arresting the pregnancy. In some cases the uterine action appears to occur without the consciousness of the patient; the tissues seem to present no resistance, the neck and the perineum yielding at once, and the ovum is expelled entire. A remarkable fact is observed in these cases, and that is the striking diminution of the amniotic liquor, the loss of fluid corresponding with that in the mother's tissues. The depressing influences of the diarrhœa, and especially of the vomiting, facilitate the occurrence of abortion. Cramps of the

uterine muscular tissues are assisted by those of the muscles of the abdomen in expelling the ovum.

A hemorrhagic endometritis has been regarded in cholera, as well as in some other diseases, as a cause of abortion. But Queirel has never found, either in abortions or in premature labors occurring in cholera, any proof of this; on the contrary, there have been no hemorrhages, even in cases where there was uterine inertia. He does, however, attribute very great importance to the condition of the blood; it is less fluid and it is loaded with carbonic acid, and, hence, premature uterine contractions occur. Further, not only does the maternal blood, under such circumstances, fail to furnish oxygen, but it subtracts it from the fœtal blood, and, hence, the fœtus dies before the mother.

The question of pyrexia as a cause of the death of the fœtus and consequent abortion is considered. Until quite recently it has been held that, as the fœtus has a slightly higher temperature than the mother, should her temperature be for some time greatly increased, the child perishes. But in 1883, Charpentier, assisted by Doléris and Doré arrived at very different results from those obtained by German observers, whose experiments were regarded as establishing this statement; it was proved that a hyperthermia gradually produced had no such injurious effect upon the fœtus, and this conclusion has been confirmed by experiments made by Runge and Preyer. Nevertheless, we observe that in the most recent German work upon obstetrics, that of Zweifel, the author gives as the causes of death hyperthermia and asphyxia. Queirel finds the cause of death, as observed by Charpentier, the same as that in syphilis, variola, scarlatina, rubeola, erysipelas, typhoid fever, and toxæmia. "This has the chief *rôle*; hyperthermia, when present, acts only an accessory part."

Such is a brief presentation of the results of Queirel's observations of cholera affecting pregnant women.

THE USE OF ANTIPYRIN FOR THE PURPOSE OF RELIEVING PAIN.

WITHIN the last few years the so-called coal-tar group has been worked over so thoroughly that we have already at our disposal no small number of drugs which we constantly use at the bedside for the purpose of reducing temperature, and notwithstanding the fact that these substances have become well-nigh absolute necessities as antipyretics, recent observations point to their use in many other directions. Quite recently GERMAIN SÉE, in *L'Union Médicale*, for April 26, 1887, has recommended antipyrin as an analgesic, and has obtained results from its use in such a number of cases of severe pain that his experience deserves notice.

After discussing the use of antipyrin in the pain associated with gouty and rheumatic lesions in the joints, he proceeds to record observations of alleviation of severe suffering in headache, facial neuralgia, obstinate migraine, and even in neuritis, including in the list not only those symptoms dependent on gouty and rheumatic tendencies, but also almost every painful affection, be its cause what it may, such as lumbago in all its forms, neuritis occurring in diabetes and from injuries, and muscular rheumatism; the greater number of cases consisting, however, in disorder of the peripheral nervous apparatus rather than the centric. While Sée is perhaps the first observer who has used antipyrin on such an extended scale for this purpose, it should not be forgotten that others have preceded him in more limited lines of clinical experiment, among whom may be noted Ungar and Martin, who have reported very favorable results from its use in sciatica.

As is often the case, clinical experience leads one to direct experiment, and under the direction of Sée, his chief laboratory assistant GLEY confirmed the analgesic action of the drug by experiment on the dog, in which they found that doses of about thirty grains produced lessened reflex activity, benumbing of the receptive and perceptive centres, and sensory nerves, without influencing either the cardiac rhythm or the respiration. The general circulatory system remained unaffected, and, if the temperature of the animal was normal, no change took place in its bodily heat.

Some of the experiments of Sée and of Gley, have been confirmed in this country, and there exists no doubt that antipyrin can be used as an analgesic without any fear of untoward effects on organs which we are accustomed to regard as vital. While conservatism tends to make us doubtful as to the power of the drug to produce the results which are claimed, the eminence of the authorities named is sufficient guarantee to induce the practitioner to give it trial, since the physician who possesses a large number of "pain-killers" is sure of professional success.

GAVAGE OF THE NEWBORN.

GAVAGE was first employed by Tarnier in the case of infants born prematurely; and it is recommended, also, for those who, though born at term, suffer from coryza, or who have just been operated upon for harelip, the former not being able to nurse, while in the latter the movements made in sucking interfere with primary union. In the *Archives de Tocologie* for March 30th, we find a description of the method of gavage advised by BAR.

Human milk is, of course, preferable, and next that of the ass. But instead of these cow's milk may be used, prepared according to the following method advised by Tarnier. One part of sugar is added to

twenty parts of water, and this is added to cow's milk in the proportion of three to one. The mixture is kept in boiling water for half an hour; then the sterilized liquid is decanted, and placed in a suitable vessel of glass or of porcelain.

The simplest form of apparatus, advised by Bar, for administering this food to the infant is composed of a glass funnel to which a sound (No. 14), or a rubber-tube of the same diameter, but twice as long, is attached. The funnel and tube being filled, pressure is made upon the tube just below its attachment to the funnel, in order to prevent the escape through the lower end. The infant is placed in the lap of a nurse, the head moderately extended, and the physician holding the apparatus in his left hand, takes the free end of the tube in his right hand and, after moistening it, passes it into the back part of the throat, and thence by gentle pressure into the œsophagus; when about six inches of the tube have passed the lips the end is in the stomach, and the compression of the tube is stopped, and the liquid passes simply by gravitation into the stomach. The tube should be removed immediately after the funnel is emptied, in order to prevent regurgitation; the quantity of nourishment used should be, if the infant is very small, only two or three drachms, and in that case the gavage should be repeated every hour. Fermentation of the nutritious mixture should be prevented by the proper preparation of the latter, by washing out the apparatus with a one per cent. solution of boric acid, and by keeping the apparatus in the intervals between its employment in a similar solution.

The results of this treatment have been so satisfactory in Paris—many infants having been saved by it that would otherwise have perished—that it is worthy of a more extensive trial.

PRACTICAL RESULTS IN RESTRICTING DIPHTHERIA.

Bearing on the communicability of diphtheria and the practicability of its restriction, Dr. H. B. Baker presented at the recent meeting of the Michigan State Medical Society, at Lansing, a table and a diagram based on a compilation of reports by local health officers in Michigan for the year 1886, exhibiting the results of isolation and disinfection in outbreaks of diphtheria.

In the 102 outbreaks where isolation or disinfection or both were neglected, the average *cases* per outbreak were a little over 16, and the average *deaths* were 3.23; while in the 116 outbreaks in which isolation and disinfection were both enforced, the average *cases* per outbreak were 2.86 and the average *deaths* were 0.66; indicating a saving of over 13 cases, and 2.57 deaths per outbreak, or 1545 cases and 298 deaths during the year, by isolation and disinfection in the 116 outbreaks, compared with those in which little or nothing was done.

Dr. F. P. Henry, of Philadelphia, has been elected a Corresponding Member of the Royal Academy of Medicine of Rome.

The profession will learn with regret of the death of Thomas F. Rochester, M.D., Professor of Medicine in the University of Buffalo, which sad event occurred on Tuesday, the result of Bright's disease. Dr. Rochester was born in Rochester, N. Y., in 1823, received a liberal education and graduated in medicine at the University of Pennsylvania in 1848. After study in Europe he began practice in New York, in 1851, but two years later removed to Buffalo and accepted a professorship in the University of Buffalo. He was held in the highest esteem by all who knew him, and he occupied many positions of honor and trust. In 1875 he was elected President of the New York State Medical Society.

Dr. Edmond Felix Alfred Vulpian, Dean of the Faculty of the French Academy of Medicine, died in Paris on May 18th, in the sixty-first year of his age. He was born in 1826, and received his degree in 1854. He was attached to the Museum of Natural History, and made nervous diseases a study. In 1867 he was appointed Professor of Pathological Anatomy at the Faculté de Médecine, and his lectures from this chair created something of a sensation, bringing on him the charge of teaching materialism and atheism. Dr. Vulpian was elected a member of the Academy of Sciences in 1876. He published a number of medical works, the two best known being *The Physiology of the Nervous System* and *Diseases of the Nervous System*.

SOCIETY PROCEEDINGS.

ASSOCIATION OF GENITO-URINARY SURGEONS.

First Annual Meeting, held at the Laurel House, Lakewood House, Lakewood, N. J., May 17 and 18, 1887.

TUESDAY, MAY 17TH—MORNING SESSION.

The meeting was called to order at 11.30 A.M., by the Temporary Chairman, Dr. E. L. Keyes. In his

ADDRESS OF WELCOME,

he first alluded to the circumstances which had led to the formation of the Association. Then, speaking of its objects, he said, he need not enter into the question of specialism as distinguished from general medicine and surgery. That distinction was being made for us by the circumstances of the times. The concentration of labor certainly yielded more perfect results than its general distribution. There was a field ready and those who wished might enter in and work. Because a man be-

longed to this Association it did not imply that he at all confined his ability to its peculiar line of study; but it furnished to him an arena in which he might develop his ideas and display the work he had done under the keen criticism of minds familiar with the subject matter treated, and capable of still further refining, by their discussion, the quality of his work and enhancing its value.

DR. F. B. GREENOUGH, of Boston, then presented

A FEW STATISTICS ON THE COMPARATIVE FREQUENCY OF THE CHANCROID.

He referred to the marked individuality that was given to the chancroid by the text-books, in spite of which the great difference in the statistics by different observers would show that they must have used a different system of classification. Throughout this divergence of statistics, however, two facts appeared: First, that this lesion had diminished in its relative frequency to the true chancre, with the exception of two periods in Paris, that is, during the war and siege (1870–1871), and during the exposition (1875), and that it occurred more frequently in hospital than in private practice. Dr. Greenough's records at the Boston Dispensary, from July 1, 1873, to March 31, 1887, gave a total of 1593 cases, of which 391 were chancroids, 219 true chancres, 931 doubtful, and 52 cases of herpes progenitalis; making the chancroid stand in proportion to other lesions in the ratio of one to three. These records were not satisfactory, as they showed only the diagnosis made at the time of the first visit. In private practice, out of 100 cases seen, 10 were chancroids, 63 were true chancres, 13 were doubtful, and 14 were herpes progenitalis, being a ratio of one to ten. The diagnosis in these cases was much more reliable. Both sets of cases showed diminution in the frequency of chancroid. The author thought this was due in part to a change in the type of the disease, and a change in the severity of the cutaneous manifestations in syphilis. Herpes progenitalis not having been recognized by earlier writers, was undoubtedly often mistaken for chancroid, and probably, also, a not uncommon inflammation of a sebaceous follicle on the shaft of the penis, and the treatment of either of these lesions by cauterization, universally practised at that time, would make a very good imitation of a chancroid. The fact that the chancroid had just been recognized and described as a local venereal sore, distinct from the chancre, would make it largely sought for at that time.

Dr. Greenough thought that at the present day a virulent bubo was not more frequently seen in connection with a chancroid than with a true chancre, which he considered was due partly to the fact that this lesion was not so frequently irritated by caustics, and he also ascribed the greater variety of the chancroid to the fact that they were no longer manufactured by cauterizing every venereal sore that was not a typical true chancre.

DR. F. R. STURGIS said that according to his observation in the Charity Hospital and Dispensary (New York) practice, the number of cases of chancroid compared with those of chancre, were diminishing.

DR. R. W. TAYLOR, DR. HYDE, DR. MORROW, and DR. ROCKWELL, had observed a diminution in the relative frequency of chancroid to chancre.

DR. HYDE thought the need of time in which to form an opinion, whether a given lesion would or would not be followed by the manifestations of syphilis, should be more generally recognized.

DR. OTIS did not agree in so general a condemnation of the cautery; when used early it was of benefit, used late it might do harm.

THE CHAIRMAN agreed in the remarks made regarding statistics. But he expressed his belief in the virulence of chancroidal pus as compared with ordinary pus. He agreed with Dr. Otis that cauterization of virulent sores within the first ten days is good practice.

THE PRESIDENT read a paper entitled

SUPRAPUBIC CYSTOTOMY FOR VESICAL TUMORS AND LARGE CALCULUS; A RECORD OF THREE CONSECUTIVE SUCCESSFUL CASES, WITH COMMENTS UPON VESICAL SUTURE AND A SUGGESTION FOR DRAINAGE.

He advocated suprapubic cystotomy for vesical tumors, for certain foreign bodies, in cases of very large stone, and in certain exceptional instances for exploration. The method should not be adopted as the usual one in stone. He gave statistics showing that it was especially objectionable in children. He had operated for the relief of large fibro-papilloma, for flat villous growth, and for a large calculus. He described his way of dealing with hemorrhage and of applying the vesical suture. A double curved retractor was exhibited, and a description given of his method of effecting perineal drainage by puncture, probe, and catheter, making only a small perineal incision. The drainage is considered by Dr. Keyes, a most essential step in the operation, and the one feature which makes vesical suture safe and likely to be generally effective; while drainage in the perineum avoids one of the discomforts of suprapubic section, namely, obstinate fistule. He prepares a No. 30 French red rubber catheter by passing a string through it, the string being knotted inside the tip. This he passes by means of a long probe inserted through a puncture made upon a broadly grooved staff, and by aid of a finger in the rectum, thus entering the draining catheter through a hole only just as large as itself.

DR. A. T. CABOT, of Boston, reported

A CASE OF HYSTERECTOMY FOR THE RELIEF OF PYELITIS FROM OBSTRUCTION,

and referred first to a case in which an operation was not performed. The patient died, and the autopsy revealed the fact that the symptoms of obstruction of the ureters which came on late in the history of the fibroid were probably due to settling of the fibroid in the pelvis and contraction of former adhesions while it was in that position. In the case which was made the basis of the paper the pyelitis occurred as an early symptom while removal of the pelvic tumor was possible. A second tumor the size of an orange was felt near the umbilicus, thought to be probably attached by pedicle to the one, the size of a child's head, projecting deeply into Douglas's pouch. Later the condition of the urine and the character of micturition, pain, etc., pointed to cystitis from pressure. Two weeks later the symptoms were those of probable suppuration in one or both tumors. The smaller abdominal tumor was removed, after which micturition was less frequent, but the appearance of pus in the urine and other symptoms pointed to pyelitis, the condition of the kidney being considered due to

pressure of the pelvic tumor. At an operation for its removal it was with difficulty that it could be pushed up into the abdominal cavity, so tightly was it wedged in the pelvis. The adhesions were not important. The uterus was removed with the tumor, only a part of the cervix being left. The patient rapidly regained strength, and wished to return to work. The urine had become almost clear.

DR. GEORGE CHISMORE, of San Francisco, forwarded a paper entitled

SOME CASES OF PYELITIS IN WHICH FREQUENT AND PAINFUL MICTURITION WAS THE CHIEF SYMPTOM.

Two cases in particular were cited to call attention to the fact noted in the books but not sufficiently emphasized, namely, that frequent and painful micturition might be so pronounced a symptom in pyelitis as to mislead the experienced observer as to the nature of the case, and cause him to address treatment to the bladder alone while the real malady was in the kidneys. In one of his cases in which frequent and painful micturition was the chief symptom the man had sustained a violent muscular strain in the region of the kidney, and for some years afterward suffered in the extreme, and was treated for cystitis by some of the most distinguished specialists; but finally the abscess of the kidney discharged and the patient recovered.

In the second case treatment was directed to presumable cystitis, and at the autopsy the kidney was found riddled with abscesses. He asked, how many times has the healthy bladder been subjected to every variety of persistent treatment while disease of the kidneys has gone on, only shown to be present by post mortem examination? He believed that in many cases the diagnosis of pyelitis could be made only by exclusion.

EVENING SESSION.

DR. J. H. BRINTON, of Philadelphia, read a paper on

HORNY GROWTH OF THE PENIS,

which will appear in full in an early number of THE MEDICAL NEWS.

DR. CABOT had seen a horn perhaps the size of the thumb nail occupying the dorsum of the glans penis in a patient of Dr. Bigelow's about twelve years ago. He could not say whether it had been reported.

DR. J. P. BRYSON, of St. Louis, then read a paper on

THE CHOICE OF OPERATION FOR THE REMOVAL OF VESICAL CALCULUS IN CASES COMPLICATED BY PROSTATIC OBSTRUCTION.

It seemed strange, he thought, how little influence prostatic enlargement has upon the cutting or crushing operation for stone in the bladder. He believed that very rarely is section made purely for prostatic reasons, that is, with the intention not only of removing the stone, but for reducing the size of the prostate as well, and thus reducing in intensity at least, the causes which are most active in the production of stone as well as lessening the sufferings of the patient in after years. Since 1884 he had operated for stone by prerectal section in four cases, all complicated by a large hypertrophied prostate gland, and had had opportunity to observe one other similar case in the practice of a friend. The age of the patients varied from sixty-five to seventy-four years. The operation in each case was successful. In one of his cases he had occasion again to make an incision and enter the tip of his finger, having failed at the first operation to evacuate entirely all the fragments; in two others opportunity to remeasure the size of the prostate was offered during an operation for return of the stone. In one case he estimated the reduction in size of the prostate after the first operation to have been about one-third in its length, and in the other about one-fourth; in none was there now any residual urine of importance. He did not believe that any other operation for removal of the stone would have been attended by so marked reduction in the size of the enlarged prostate.

THE PRESIDENT remarked that while the success of the cutting operation in the case reported by Dr. Bryson as occurring in old people, had been all that one could ask, yet this operation was shown by statistics to have a much larger mortality in the aged than litholapaxy. Whatever the effect of the cutting operation upon the size of the prostate, he thought we should do the crushing operation first if it were practicable, as it was much less dangerous, and if it failed to relieve the symptoms to consider afterward the propriety of any other procedure.

DR. BRYSON said that in none of his cases was the cutting operation the operation of choice. The effect upon the prostate having been noticed, he thought it was worthy of consideration. The discussion was participated in by Drs. Otis and Cabot.

DR. P. A. MORROW read a paper on

IDIOSYNCRASY AS AFFECTING THE SPECIFIC TREATMENT OF SYPHILIS.

He first referred to the ample justification of the claims of mercury and iodide of potassium to be ranked as "specifics" in the treatment of syphilis. These agents when introduced into the organism, directly attack and cause to disappear the organic lesions as well as the functional disorders created by the syphilitic virus. Experience shows, however, that the action of these drugs is by no means constant and infallible—all syphilitics are not equally susceptible to this curative action. The definite peculiarities of constitution which are generally included in the term idiosyncrasy exert a dominant influence in modifying drug action. The therapeutic action of specific remedies is especially subordinated to conditions of aptitude inherent in the individual.

Idiosyncrasy in relation to the action of mercury and iodide of potassium may be manifest in various modes and degrees of intensity:

1. In an abnormal susceptibility to their physiological or toxic effects.

2. In the production of incidental ill effects which may be associated with the drug's physiological action, or may take the place of it, constituting an aberration of the drug's typical mode of action.

3. In an insensibility or failure on the part of the system to respond to the curative action of these drugs.

Various clinical examples were given illustrating the foregoing propositions, particularly cases of idiosyncrasy against the iodide so marked that the local and constitutional disorders caused by the drug surpassed

in severity the symptoms of the disease itself. In one case under recent observation, ordinary medicinal doses of the iodide repeatedly caused a multiform eruption consisting of pustular, bullous, nodular, and keloidal lesions, attended with the most pronounced symptoms of constitutional "iodism." The specific lesions were much aggravated under its use.

The various expedients which have been recommended to secure tolerance of these drugs by counteracting their ill effects were enumerated in detail, and their comparative value considered.

In conclusion he suggested that the practical significance of idiosyncrasy and its bearing upon treatment had not received from specialists the consideration its importance demands. The rules of treatment had been rigorously and mathematically formulated—so many months of mercury, and after a certain date recourse to the iodide of potassium without reference to the immense variance in the constitution and idiosyncrasies of patients, not only in the toleration of those drugs, but in susceptibility to their curative action.

Dr. R. W. Taylor, of New York, presented some

OBSERVATIONS ON THE USE OF OIL OF WINTERGREEN IN TREATMENT OF GONORRHŒAL RHEUMATISM,

and detailed the histories of about twenty cases of gonorrhœal rheumatism occurring in the Charity Hospital the past year, in which he had given the oil of wintergreen a thorough trial. In about nine of the cases the disease was of that chronic kind, in old or neglected subjects, in whom no treatment could prove of much benefit. In the others the benefit was marked, and most of them after some weeks recovered entirely. The drug was administered in capsules in pretty large doses, varying according to the circumstances. The urethral secretion also became bland under the action of the drug, and disappeared. Other remedies had in most cases been tried with little or no effect.

Dr. Algernon S. Garnet then made

A FEW PRACTICAL OBSERVATIONS ON THE TREATMENT OF LATE NEOPLASMS OF SYPHILIS.

He thought it an error to give fixed doses, especially in the later stages of syphilis, without due regard to the nature of the case. He believed in removing neoplasms, slight or grave, and considered no patient safe as long as there was the slightest evidence of the disease. The iodide of potassium or mercury should be pushed in every stage of syphilis as far as it could be borne. If cachexia in the later stage prevented the free use of mercury, tolerance of the drug must be cultivated until the patient could be put under its full influence. Syphilis, he thought, is not a benign disease at all.

Wednesday, May 18th—Morning Session.

The Society went into an election for

OFFICERS FOR THE ENSUING YEAR,

resulting in the choice of Dr. E. L. Keyes as *President*, and Dr. R. W. Taylor, *Secretary and Treasurer*.

Dr. F. N. Otis read a paper on

TEMPORARY OVERSTRAIN OF THE BLADDER PRODUCING CHRONIC RETENTION OF URINE.

He introduced his subject by defining the usual causes and varieties of atony of the bladder. He called especial attention to that form recognized as occasionally resulting from sudden overstrain through even a single attack of retention, particularly when it occurred independent of any organic obstruction, but probably as a result of reflex irritation caused by a contracted meatus urinarius, or urethral stricture of large calibre. Such reflex trouble might, however, arise from the irritation of hemorrhoids, or it might be caused through temporary loss of consciousness, or any nervous shock, or from sexual excess. However caused, he claimed that a single retention of urine from any cause might, within a few hours, produce such an overstrain of the muscular structures of the bladder as to necessitate in some cases the use of the catheter during the remainder of the patient's life. Several cases were cited in proof of the occurrence of acute retention from reflex causes, which were promptly and permanently relieved by division of a urethral contraction. Illustrative cases were given; in none of these was there any prostatic enlargement or close stricture, nor general atrophy of the bladder. From this fact Dr. Otis assumed that the overstrain had been local, chiefly in that portion concerned in opening the vesical orifice. The portion thus weakened was unable to overcome the resistance of the muscular structure of the so-called vesical sphincter.

Dr. J. N. Hyde, of Chicago, read a paper on

EARLY SYPHILITIC EPIDIDYMITIS.

He cited cases which had come under his observation with a view of presenting the negative side of the subject. The following propositions, he thought, rested on fairly sound clinical grounds: 1. A male patient may suffer from blennorrhagic epididymitis on one side, subsequently contract syphilis, yet escape syphilitic involvement of the epididymis. 2. A male patient may suffer from blennorrhagic epididymitis involving first one organ, then the other, finally acquire syphilis and escape syphilitic epididymitis. 3. A male patient may suffer from blennorrhagic epididymitis of one or both organs, become so irritable as to exhibit by inflammatory accidents sympathy with successive blennorrhagic attacks, yet throughout a final syphilis betray no sensitiveness to the last-named disease. 4. A male patient affected at the same time with syphilis and blennorrhœa may suffer from an epididymitis, evidently a complication of the last-mentioned disease, namely, blennorrhœa, and yet escape syphilitic involvement of the organ. 5. A male patient may suffer from tuberculosis, subsequently incur syphilis, yet the epididymis escape involvement. 6. A male patient who has suffered from repeated attacks of blennorrhœa, and that lately, may exhibit the typical form of early syphilitic epididymitis.

Dr. A. T. Cabot, of Boston, reported two cases of

PROSTATOTOMY FOR OBSTRUCTION.

In one the operation was followed by almost complete recovery of the function of the bladder. In this case litholapaxy was done on the stone before the operation of prostatotomy. In the other case, although the first result of the operation was satisfactory, a certain amount of incontinence appeared some months later. Dr. Cabot ascribed this to the hypertrophied condition of the bladder, which was sufficient to overcome the constrictor muscle, weakened as a result of the incision into the membranous urethra. He queried whether in a case

like this, with good evidence of a hypertrophied bladder, and in which the obstruction was a narrow bar, the internal prostatotomy of Mercier might not prove the better operation.

Dr. Keyes then read

A PLEA FOR THE MORE GENERAL USE OF THE NITRATE OF SILVER IN THE DEEP URETHRA,

and presented an instrument for injecting the deep urethra, which he believed was more suitable and more serviceable than other syringes in general use. His method is to deposit three to five minims of a watery solution of the nitrate of silver of a strength varying from one to forty-eight grains in the ounce very accurately in the centre of the membranous urethra, placing it there by the use of an instrument open at its tip. He thinks the method is not suitable in cancer, tubercle, or when the deep urethral symptoms are due to considerable periurethral inflammation, but most beneficial for inflammatory and neurotic surface disturbances of the deep urethra and neck of the bladder. He gave illustrative cases of cure of gonorrhœal cystitis, relapsing epididymitis, vesical irritability, prostatorrhœa, etc.

In the full discussion of the paper which followed, most of the members expressed hopes of better results from the deep urethral injections of nitrate of silver than had hitherto been generally attained.

Dr. J. H. Brinton was one of the strongest advocates of this method, which he had practised extensively. To relieve the discomfort or pain which the patient experienced after treatment by this or other methods, he had the patient stand by the basin and allow a small stream of water run over the corona of the penis; the relief was almost immediate.

Dr. Mastin referred to the practice of Prof. Richardson, consisting in injecting a drachm of almost a saturated solution of nitrate of silver into the bladder in gonorrhœa and chronic cystitis.

Dr. R. W. Taylor, of New York, read a paper on

A RARE FORM OF SEPTICÆMIA FOLLOWING INTERNAL URETHROTOMY.

The operation was performed in 1878 by a colleague, and the case was seen by Dr. Taylor in consultation. The occurrence of the accident, complicating urethrotomy, is unique in medical literature, and this consideration, together with the fact that the form of septicæmia is little known and only indifferently described by English and American writers, prompted the preparation of the paper. The patient was a perfectly healthy man, aged twenty-eight, who had a tight stricture of the bulbomembranous junction, which was incised by means of Maisonneuve's instrument. The operation was performed with all care. Within twenty-four hours severe pain attacked the perineal region, and soon a reddish, boggy appearance was observed. Then the inflammatory action extended, and presented marked features. The integument became œdematous, and a distinct emphysematous crackling was felt when pressure was made on the parts. As this rapidly extended, large brown patches of skin developed, which felt as hard as the rind of ham. Beside these there were large ecchymotic spots and deep blue-black lines which were caused by congestion and destruction of the veins. This condition extended over the whole body, which during life was much enlarged by the œdema and gas in the subcutaneous tissue, and after death the body became rapidly swollen beyond recognition and to fully twice its normal size, and was a deep purple, gangrenous mass, covered with large bullæ, and emitting a horrible stench. Death took place eighty-seven hours after the operation. The subjective symptoms were rapid pulse, tremulous action of the heart, progressive and distressing dyspnœa, intense restlessness, utter agony and despair. The temperature at first rose, then fell below normal.

The disease was not accurately known until 1870, although many cases of it had been reported, particularly as occurring in the army, navy, and crowded hospitals. The cases were mostly epidemic. It started on the limbs generally, most frequently on the legs. It had been called many names, but Dr. Taylor referred the one proposed by Mollière, *septicémie gazeuse foudroyante*.

Reasons were given in support of the view that the disease caused by a specific septic microbe. The only treatment is thorough amputation of the part in which the septicæmia begins, if that is practicable.

Dr. R. W. Taylor, of New York, then exhibited

SECTIONS OF TUBERCULAR TESTES WITH BACILLI, AND THE COEXISTENT BACILLI IN THE SPUTA.

The Association then adjourned to meet next year, time and place to be announced hereafter.

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting, Washington, D. C., May 11, 12, and 13, 1887.

(Specially reported for THE MEDICAL NEWS.)

THURSDAY, MAY 11TH.—AFTERNOON SESSION.

(Continued from page 584.)

Dr. J. Collins Warren read a paper on *A Study of the Process of Repair after Resection of the Intestine, and Some of the Complications which may Occur.*

Dr. J. E. Michael then reported

A CASE OF VENTRAL HERNIA SUCCESSFULLY TREATED BY OPERATION, WITH A SUGGESTION AS TO THE METHOD OF OPERATING.

Mrs. F., a stout, robust woman, æt. fifty-five, fell several years ago while engaged in some domestic duties, in such a way that she was struck in the median line about half way between the umbilicus and pubes by the handle of a wash tub. The wound caused a break in the linea alba without breaking the skin, and soon afterward the intestine protruded. No peritonitis followed the injury. Her physician directed her to wear a bandage and pad to keep the intestine within the abdominal cavity, but the arrangement proved unsatisfactory, in that, upon the slightest exertion, even that of walking, the intestines protruded and, getting between the pad and belly-wall, occasioned a great deal of discomfort. Various other appliances were tried by other physicians, but none of them proved efficient. When she came under his care, the return of the protrusion was easy enough, inasmuch as, upon assuming the recumbent posture, the intestine returned almost entirely into the abdominal cavity. The belly was full and fat, but the opening in the abdominal wall was easily recog-

nized. It was elliptical in shape, with the long axis parallel to that of the abdomen, and, apparently, about two and one-half inches in length, and presenting a firm, hard, apparently cicatricial margin.

He was forced to operate, as the patient would hear of no other plan of treatment. This he did on March 15, 1886, with the aid of ether. The room and all articles to come into contact with the patient were thoroughly fumigated with chlorine gas and sulphur, and the antiseptic plan was employed. A long, free incision was made through the skin and subcutaneous fat, exposing the ring. Stout silver wires were passed through the ring a little less than a half inch from each other, and having a hold of about three-fourths of an inch. The wires were twisted over shot and the abdominal opening was closed. No shock occurred; no fever of consequence, and the patient made a good recovery. A bandage was worn for a few months after the operation, when the patient laid it aside.

In conclusion he said that he based his operation upon the fact that a firm cicatricial band of fibrous tissue is formed around foreign bodies which are lodged in the tissues of the body, and that, although so far as he was aware he was without precedent or authority in the operation, he had assumed that if he placed silver wires in the tissues in this manner, the fibrous tissue which would enclose them would be sufficient to close the hernial ring.

DR. T. F. PREWITT thought the operation had been admirably done. The cure was doubtless as supposed, owing to the large amount of new tissue which was thrown out, causing a thickening and strengthening of the ring. This is in fact the method by which charlatans profess to cure hernias in general. The result may be satisfactory, but there is danger that, sometime in the future, it may give away again.

DR. S. W. GROSS then presented a paper on *The Prognosis of Sarcomata of the Breast*, which will appear in full in *The American Journal of the Medical Sciences* for July.

DR. D. HAYES AGNEW read a paper entitled

THE MEDICO-LEGAL ASPECT OF CRANIAL AND HEART WOUNDS.

(See THE MEDICAL NEWS, May 21, page 561).

DR. L. MCLANE TIFFANY thought there could be no doubt of the ability of an individual to shoot himself, either through the head and afterward through the heart, as asserted, or through the heart first and afterward through the head. He had seen cases both where the head was severely wounded without producing death, and where large wounds of the heart were present without destroying life. There are, however, many things besides anatomical conditions to be considered in the case of a suicide. First of these is the presence of powder marks. Nothing was said in the paper about the individual having these marks about his person. Next, could a man point a pistol in the direction that it would go from apex to base, as described here, assuming that he were right-handed? The simple description of the anatomical points of the post-mortem is but a small part to be considered. It is extremely rare that a right-handed man shoots himself in the left side of the body. In conclusion, he recalled the case narrated in *Taylor's Jurisprudence*, in which a double-barrelled shotgun was accidentally discharged, the first load striking the individual in the chest, the recoil causing the remaining load to be discharged into his back.

DR. JOHN B. ROBERTS reported the case of a man who had shot two bullets into his head and afterward shot himself in the left side. In regard to the possibility of a man's shooting himself in the heart first and the head afterward, he agreed with Dr. Tiffany. He referred also to a paper read by himself before the College of Physicians of Philadelphia, in 1883, in which he called attention to the experiments of Dr. Block, tending to show that the heart may be sutured in cases of penetrating wounds.

DR. E. M. MOORE thought that none of the members would be seduced into very readily permitting a man to be buried as a suicide under such circumstances, for although possible, such shooting is exceedingly unlikely to occur. He had seen a number of cases in which suicide had been attempted by passing a very small bullet into the brain; all were attended by immediate or almost immediate unconsciousness. The general condition, the shock, the hemorrhage, or the attendent conditions of mind are usually sufficient to produce unconsciousness, so that while it certainly is possible for a man to inflict the second injury referred to, it is certainly very improbable.

DR. M. H. RICHARDSON, of Boston, stated by invitation, that he had been one of the "experts" referred to by Dr. Agnew. He desired to testify more fully than the author of the paper had been able to do, what had occurred at the trial. Of the physicians who testified, two local physicians asserted most positively that the supposition was not possible. There was no cross-examination at the trial, and no opportunity of bringing out more fully what was desired. He thought that Dr. Agnew if he had had an opportunity, would have testified exactly as he and Dr. Draper had done. The question was not whether these two wounds could both have been inflicted during the life of the individual, or the witnesses would have testified just as has been done here to-day. The question was rather whether this individual could have inflicted both wounds himself. The bullet entered the skull about two inches above the external auditory meatus on the right side and passed out near the occiput. A ball passing through this part of the brain, if it could have been self-inflicted, would almost certainly have produced immediate unconsciousness; and another fact upon which the opinion was based was that there were no marks of powder on the head. Although the witnesses had had an opportunity of testifying that this was a case of murder and not suicide, they had had no opportunity of saying that such injuries could be inflicted during life.

DR. P. S. CONNER stated that bullet wounds of the heart are by no means necessarily fatal, since he had put on record ten years ago, a case in which a bullet had passed through three cavities of the heart, and the subject, a boy, had lived three years and some months afterward. In order further to demonstrate the possibility of such an occurrence, he had, with the aid of the late Professor Longworth, made a number of experiments, and had found that it is not at all difficult to pass a needle through all four cavities of the heart. The specimen in question was for a long time in the museum of the Medical College of Ohio, but careful search re-

cently had failed to find it. The reality of the case, he said in conclusion, had been called into question, but it was a fact and had been presented, with the specimen, to the Academy of Medicine, and published in the *Lancet and Observer*.

Dr. A. R. Kinloch reported a case in which the question was whether it was accidental or suicidal shooting of the head. Upon examination he found the heavy beard of the individual presented no evidences of powder upon superficial examination, but that when examined more closely, a deep furrow was found involving not only the base of the beard, but extending into the skin. This proved that the pistol had been intentionally placed well into the beard before it was fired.

Dr. D. W. Yandell reported several cases of a very similar nature.

Dr. T. F. Prewitt narrated two cases. One was that of a man who, after shooting his wife, shot himself through the frontal bone. He never became unconscious, and apparently recovered. He was sent to the penitentiary, and a year later died of abscess of the brain. A few months ago a boy of eight or nine years of age, found a pistol, put it to his head and fired. The bullet passed through the left parietal bone into the skull. A probe demonstrated that it had passed beyond the skull, and a little piece of brain was found in the wound. The boy never lost consciousness, but recovered and is now, apparently, perfectly well.

Dr. T. R. Varick stated that he had a few years ago testified in a case in which a young man was indicted for killing his schoolmate. A young lady, an eye-witness, swore that the two young men grappled and fell, and that the defendant laid his hand on the shoulder of the one killed and with the pistol in his right hand shot and killed him. On the other hand, the defense claimed that the pistol was discharged accidentally in the fall. The question was then raised as to the position in which the parties were at the time the pistol was discharged, and the question of powder marks was an important one. He made some experiments in this regard with sheets of paper. He found that up to a distance of two and a half feet there were marks of powder, increasing in intensity as the distance was shortened. The ball in this case entered the squamous portion of the temporal bone just above the zygoma and lodged in the hemisphere of the brain, having passed from before backward. The ball was so flattened that it could not be made to enter the barrel of the pistol from which it was alleged to have been shot. No powder-marks were discovered on the person of the killed, and the defendant was acquitted.

Dr. Agnew arose to explain that he had had no desire to criticise any person in his reference to the expert testimony, and that he had drawn his conclusions entirely from the evidence as furnished him by the prosecuting attorney.

To be continued.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, May 3, 1887.

The President, C. L. Dana, M.D., in the Chair.

THE ELECTION OF OFFICERS

for the ensuing year resulted as follows:

President.—C. L. Dana, M.D.

Vice-Presidents.—W. R. Birdsall, M.D., and M. A. Starr, M.D.

Recording Secretary.—G. W. Jacoby, M.D.

Corresponding Secretary.—N. H. Leszinsky, M.D.

Treasurer.—G. M. Hammond, M.D.

Councillors.—E. D. Fisher, M.D., B. Sachs, M.D., L. Weber, M.D., E. C. Seguin, M.D., and G. M. Hammond, M.D.

CEREBRAL TUMOR; PARTIAL REMOVAL.

Dr. S. N. Leo read the history of a case of cerebral tumor occurring in a heavy German woman who had, before its appearance, sustained an injury of the skull where the tumor afterward developed. During the growth of the tumor the patient had consulted several well-known physicians, all of whom were of the opinion that an operation should be performed. Some thought it was a wen of the scalp. The symptoms becoming more serious, she finally asked Dr. Leo to perform the operation. Strict antisepsis was observed. As the operation proceeded it was found that the tumor extended within the cranium, involving the dura mater at the longitudinal sinus, and apparently dipping deeply into the brain substance. These facts, in addition to the patient's bad condition from loss of blood, led him to desist from further procedure after cutting off that portion of the tumor external to the cranial vault. He thought the patient would not have lived so long—over a month—had not the operation been performed. Unfortunately an autopsy was not allowed. The tumor was a sarcoma. He added that the patient's condition had been rendered more serious by cardiac disease.

Dr. B. Sachs then read a paper entitled

NOTES ON THE CAUSE AND TREATMENT OF FUNCTIONAL INSOMNIA.

(See page 594.)

Dr. Fisher thought a very common cause of insomnia is anæmia, and he had seen considerable success in its treatment by cod-liver oil, cream, and articles intended to improve nutrition. In some of the cases ordinary hypnotics had been administered without avail. The patients may have the appearance of being well nourished, while they are really anæmic. The mineral tonics are, as a rule, indicated.

Dr. George B. Jacoby agreed with the author that the cases must be individualized, and thus the cause of the wakefulness might be discovered. He thought that in the majority of cases the cause would be found to lie in the circulation—not always in anæmia, but frequently hyperæmia. Cure the cause and we would cure the sleeplessness. But that which will cure anæmia in one case will not cure it in another. Active and passive exercises, particularly active exercise, are of benefit. For patients who could not go out the muscle-beater is very useful. While he had not much faith in static electricity in the treatment of insomnia, he cited one case in particular in which the physician who applied it for another purpose to one of his patients, himself became sleepy under its influence. Perhaps the production of ozone by the instrument was the cause of this sleepiness, for it is well known that when one goes into an atmosphere of ozone he is likely to become sleepy.

Dr. V. P. Gibney had noticed that static electricity tends to produce the sleepy state. It was one of the

few things they had found static electricity good for at the hospital with which he was formerly connected.

DR. W. R. BIRDSALL thought, as did Dr. Sachs, that we must adopt hygienic rather than purely medicinal measures for the cure of insomnia. But we are occasionally forced, as the author had said, to resort to some drug for temporary relief. For this purpose he had obtained benefit without injurious effects, such as sometimes come from bromine, hydrate of chloral, etc., from a drug first recommended to him by Dr. Seguin, namely conium. This given in large doses, fifteen or twenty drops, or more, of the fluid extract, had in his hands been beneficial. He had continued its use two or three months without deleterious results.

DR. G. M. HAMMOND thought fully eighty per cent. of all his patients were similar to those described in the paper by Dr. Sachs. In the large majority of persons suffering from insomnia, mental anxiety, etc., he thought it due to hyperæmia of more or less limited areas of the brain. When the patients do sleep they have unpleasant dreams. They are also frequently sufferers from dyspepsia, constipation, spots before the eyes, noises in the ears, sometimes hallucinations connected with various senses, and coldness of the extremities. It is rare for such patients to go away without being cured, but if they subject themselves to the same causes the condition returns. He used bromides, and stuck to them right through the disease. He gave only ten or fifteen grains three times a day, and also gave fluid extract of ergot. He applied static electricity and dry cups to the back of the neck, and regulated the sleeping hours.

DR. LESZINSKY was rather surprised, in view of a recent discussion before the Society, to hear Dr. Sachs speak of the use of hyoscyamin as a hypnotic. It is a mistake to rely upon large doses of bromides given at night. There is an objection to their use in ladies because of the bad odor which they give the breath. He had not been able to discover any peculiarity in the circulation of the retina in these cases.

DR. L. WEBER said that since he had adopted the treatment recommended by Dr. W. A. Hammond, and just described by Dr. G. M. Hammond, he had obtained the best results in suitable cases for this mode of treatment; but in other cases the bromides may cause excitement instead of aiding sleep. When there is gastro-intestinal disorder he adds to the treatment calomel with benefit.

DR. LESZINSKY referred to a remark by Dr. Birdsall concerning the use of a mustard sinapism, or other cutaneous irritant, and said that Dr. W. H. Thomson had called attention to the beneficial effects of cayenne pepper, etc., to the surface of the body some years ago.

The PRESIDENT had found the warm bath a very valuable measure in many cases; in mild cases of insomnia the cold douche down the back and massage had proven useful. Hence had discovered that ozone has a hypnotic influence. Lupulin had been of benefit in the insomnia of old people; and lavender in some cases in which the stimulus of alcohol or warm food had failed.

DR. SACHS objected to the use of the bromides, particularly in small doses, more than to anything else in the treatment of the class of cases under discussion, namely, those of insomnia in neurasthenic subjects. It is likely to do more harm than good. The testimony at the discussion referred to by Dr. Leszinsky was not against amorphous hyoscyamin, but against the crystalline form.

The PRESIDENT exhibited

AN APPARATUS FOR THE RELIEF OF WRITER'S CRAMP,

called the "Kaligraph" by its inventor, the late Mr. Charles Thurber. It consists of an iron framework to which is attached a series of levers so arranged that by making large characters at one angle the characters are reproduced in ordinary size at the opposite angle. It is, in fact, a kind of reversed pantagraph. Dr. Dana said that all writer's cramp instruments are based on the principle of resting the groups of muscles most used and throwing the work upon other groups. The kaligraph fulfils these indications better than any other instrument with which he is familiar. The objections to it are that it is cumbersome and expensive. The speaker showed cuts of all the various forms of instruments for writer's cramp (ten in all) which he had been able to collect. The kaligraph has been in practical use for thirty years, but it is very little known. It enabled its inventor, who suffered extremely from the cramp, to write with comfort. He was informed that Mr. Charles Dickens had possessed and used one.

DR. G. W. JACOBY thought this instrument was only palliative, while Nussbaum's was also curative, and could be carried with one. It compelled the writer to use the adductors.

The PRESIDENT replied that an instrument calling into play any other group of muscles of the hand would cause those to be affected after a time.

DR. BIRDSALL thought that writer's cramp is due to cerebral fatigue rather than muscular fatigue, and that instruments for overcoming it could be of only limited benefit.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, May 11, 1887.

THE VICE-PRESIDENT, E. T. BRUEN, M.D., IN THE CHAIR.

DR. S. SOLIS-COHEN reported a case of

ASTHMA TREATED BY BERGEON'S METHOD,

in which immediate relief followed the injection into the intestine of the mixture of carbon dioxide and hydrogen sulphide, as recommended by Bergeon. Having noticed in Morel's paper reports of two cases in which success attended the experiment in one of the Parisian hospitals, and a case presenting itself which offered a fair test, he determined to make the trial.

The patient is a stout married woman, about fifty years of age, of somewhat neurotic temperament, who has for some years been subject to attacks of spasmodic asthma, ordinarily manifesting recurrent paroxysms, lasting ten or twelve days. In the intervals there is neither bronchitis nor dyspnœa. There is no heart lesion. He had seen her in previous attacks, which were relieved by methods with which all are familiar. In one particularly obstinate seizure, the patient was sent to the gas works, and was benefited by inhaling the carburetted vapors there produced. He saw her on the second or third day of the attack, and proposed the injections, but could not obtain consent. Not wishing to complicate the therapeutics too much, in case she

should later accede to the proposal, he simply prescribed, as a palliative for the dyspnœa under which she labored between the paroxysms, quebracho, in twenty drop doses of the fluid extract, repeated hourly or half hourly, according to indications. This, of course, gave great relief, but a paroxysm recurring in the evening, the patient consented to try the injection. Almost immediate relief was experienced. Some dyspnœa persisted, but there was no further paroxysm, and the dyspnœa gradually lessened, finally disappearing within thirty-six hours. After six injections, the latter ones being prophylactic rather than therapeutic, the patient professed herself feeling better than for years, and auscultation revealed only normal breath sounds.

This is, of course, but a single case; yet having a standard of comparison in previous attacks in the same individual, he could, so far as one case is worth anything, confirm Morel's claim that the rectal injection of carbon dioxide and hydrogen sulphide is beneficial in asthma. Which of the two is the active agent, and whether it would be equally efficacious by inhalation are questions which he did not then desire to discuss.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, May 11, 1887.

THE PRESIDENT, CHARLES MCBURNEY, M.D., IN THE CHAIR.

HERNIA OF THE RIGHT OVARY; SUCCESSFUL REMOVAL OF THE GLAND.

THE PRESIDENT exhibited the specimen, and related the following history:

The patient, aged twenty-eight, stated that she had suffered with a right inguinal hernia since the age of twelve, for which she had worn a truss. The tumor had always been reducible, although at times with difficulty. The reporter examined her for the first time on May 5th, when he found a tumor occupying the right labium; it was semi-fluctuating, painful on pressure, and gave no impulse on coughing. From its upper portion a rounded cord, resembling the spermatic cord in the male, could be traced upward to the internal ring. An attempt to reduce the tumor caused severe pain in the head and nausea. The diagnosis of hernia of the right ovary was made, and two days later the speaker cut down upon the mass and found a hernial sac, which was dissected out and laid open. The appearances presented were those of ordinary congenital hernia; there was a persistent pouch of peritoneum, but no intestine could be found. On its posterior wall at the lower end was a mass one-half inch thick, covered anteriorly with thickened peritoneum. At the lowest portion of the tumor there was a quantity of fluid, in which floated a collapsed sac; at its upper portion there was a distinct constriction, which admitted a fine probe, while above this point there was an ordinary hernial tract.

The mass in the posterior wall of the sac was submitted to Dr. Frank Ferguson, the Curator of St. Luke's Hospital, for microscopical examination, who found in it ovarian stroma. The sac was ligated with strong catgut at the level of the internal ring, and was excised, the patient making a good recovery. The speaker added that he had never before had an opportunity to examine a case of hernia of the ovary. The anatomical relations of the gland were the same as those of the testis in a case of congenital hernia.

RIGHT INGUINAL HERNIA WITH NON-DESCENT OF THE TESTIS; CASTRATION.

THE PRESIDENT also showed a specimen which he had removed from a patient, whose history was as follows: A boy, aged seventeen, had never seen his right testicle until three months before, when it appeared in the inguinal canal, and gave rise to severe pain. Shortly after a mass of intestine suddenly came down, and was reduced with some difficulty. This accident occurred on several subsequent occasions, the gut escaping beneath the truss which he wore. The last time it was supposed to be strangulated, and an operation was advised. On May 9th he cut down upon the testicle, which was very small, and removed it with the sac in the usual way The intestine was not seen.

DR. BRIDDON remarked that he had seen but one case of hernia of the ovary, the patient being a prostitute, whose vagina measured only one and a half or two inches in depth, while no uterus could be felt. The external genitals and mammæ were well developed. On either side the canal of Nuck contained a small insensitive body, which could be reduced into the abdominal cavity. The woman subsequently married, and her husband probably never knew that she was not perfectly formed.

DR. YALE asked if this case might not have been one of hypospadias.

DR. BRIDDON replied that the breasts were large and the external genitals normal, although not prominent, while the woman presented decided feminine characteristics.

THE PRESIDENT said, in reply to a question by Dr. Briddon, that there was in the first case the same condition as existed in congenital hernia, the peritoneal pouch remaining open, while the ovary had prolapsed behind the pouch. It was impossible to say how long the ovary had been displaced; the hernia had existed for over fourteen years.

OBSTINATE HEMORRHAGE AFTER TONSILLOTOMY; RECOVERY AFTER LIGATION OF THE COMMON CAROTID ARTERY AND TRANSFUSION OF SALT SOLUTION.

DR. SANDS narrated a case of secondary hemorrhage after removal of the tonsils: Thirteen days ago he was called in consultation by Dr. Speir, of Brooklyn, who requested him to bring his apparatus for transfusion. He arrived at the patient's residence at three o'clock in the afternoon, and found a young man, twenty-four years of age, who had, on the previous day, visited Dr. Fuller's office at 4 P.M., and had both tonsils excised with a tonsil-guillotine. The hemorrhage following the operation was insignificant. The patient returned home, dined, and in the evening went to a wedding, at which he was to act as an usher. While there he began to bleed, and was obliged to return home. The hemorrhage continued all night in spite of the efforts made to control it, by pressure with the fingers, large dressing forceps, and styptic cotton. The bleeding was confined to the right side.

The following morning Dr. Speir was called. He found the patient greatly prostrated and still bleeding.

He tied the right common carotid artery, but the hemorrhage continued, and transfusion was thought of as a last resort. When the speaker saw the patient the latter was extremely weak, could scarcely speak, and his pulse was small and rapid, at times almost imperceptible. Blood was slowly oozing from his mouth. On examining his throat no bleeding point could be detected, but only oozing from the right tonsil, which ceased after the clots had been scraped away with the finger, perhaps because a better surface was thus afforded for the deposit of coagulum.

The speaker opened a vein in the arm and introduced a pint of saline solution in the course of four or five minutes, using a Colin's apparatus, with which any entrance of air is prevented. During the operation the volume and tension of the pulse improved considerably. Dr. Sands had been informed that the patient's subsequent progress was favorable, and that he was now convalescent. How far the transfusion contributed to this fortunate result he was unable to say, but it may have assisted the recovery by increasing the amount of fluid in the bloodvessels.

It had been learned after the removal of the tonsils that the patient belonged to a family of bleeders, and that he had once before bled profusely after the removal of a tooth. Dr. Sands did not believe that this explanation was satisfactory in the present instance; for if the theory of the hemorrhagic diathesis had been correct, there should have been bleeding from both tonsils, and also from the wound made during ligature of the carotid. The hemorrhage was probably due to the division of a large tonsillar artery. He added that this was the only case of the kind he had seen. He had seen very few "bleeders," among whom was an orderly in Roosevelt Hospital, who bled for several days after removal of a tooth, but eventually recovered. A lady, whom he had seen in consultation several years before, had lost a large quantity of blood after having a tooth extracted; pressure was of no avail in this instance.

Dr. Briddon said that he had observed a fatal case of hemorrhage in an infant under one year of age, after lancing of the gums, the child not being a bleeder. He had seen two bleeders in whom hemorrhage continued for five or six days, but was not fatal; one patient had purpura rheumatica.

He was once called to attend a young man whose inflamed tonsil had been incised three days before. The patient was much prostrated. On examination a small stream of blood was seen spurting from the incision. He inserted into the cavity the bulbous end of a silver tube, in which were a number of small perforations, and injected through it a solution of persulphate of iron, when the bleeding ceased at once. In the case of the bleeders he had tried every remedy in vain; in one instance the patient had a wound in the lip, and on passing a couple of stitches through the latter, the hemorrhage from the needle punctures was equally troublesome. He believed that Dr. Sands was correct in denying the influence of the hemorrhagic diathesis in his case, because if this had been the cause of the bleeding, the patient would also have bled from the wound made in ligating the artery.

The President thought that the anatomical relations of the divided vessels often exercise a more important influence in cases of persistent hemorrhage than heredity; arteries are sometimes so situated that they can not retract, and hence coagulation is prevented. As an illustration of this he cited the case of a gentleman who had suffered for twelve years with "hæmoptysis," and had been all over Europe, frequently having his chest examined under the impression that he had phthisis. No evidence of pulmonary trouble could be discovered, and, as none of his physicians had ever chanced to see him when he was bleeding, the cause of the hemorrhage could not be discovered. He happened to examine him while he was spitting blood, and found that it came from the bottom of a tooth cavity. It was cured by removing the tooth. The patient was not a bleeder.

The President said that he had seen a case of hemorrhage after tonsillotomy in a medical student whose tonsils were removed with a scalpel at Demilt Dispensary. The operation was performed at 1 P.M. At 4 P.M., when the speaker saw him, he was lying on the floor and was very weak. Persulphate of iron and other remedies had been tried in vain. His throat was examined under a good light, and a small spouting vessel was seen on the right side; the hemorrhage was readily controlled by pressure with a sponge on a long handle. In many cases of epistaxis, the speaker added, we could, on careful examination, find a single bleeding point in one nostril, generally on the septum and near the external orifice, where the mucous membrane is very thin, and could stop the hemorrhage by direct pressure.

Dr. Rushmore cited the case of a patient in South Brooklyn who belong to a family of bleeders. He bled for three days from a prick of the thumb; he checked the hemorrhage by elevating the hand on a splint.

NEWS ITEMS.

The American Climatological Association will hold its fourth annual meeting at Baltimore, on Tuesday and Wednesday, May 31st and June 1st, in the hall of the New Physical Laboratory of Johns Hopkins University, Monument Street, near Eutaw. Dr. Frank Donaldson, Jr., of Baltimore, is the President for the year. The following programme is announced:

Tuesday, 2 P.M.—Prophylactic Treatment of those who inherit a Predisposition to Phthisis, by Dr. Frank F. Donaldson, Sr., of Baltimore. The Philosophy of Climatic Treatment of Diseases of the Chest, by Dr. James R. Leaming, of New York. An Analysis of Sixty Cases of Asthma, with the Result of Treatment, by Dr. F. H. Bosworth, of New York. The Influence of Sea Air on Syphilitic Phthisis, by Dr. R. G. Curtin, of Philadelphia. Diseased Conditions for which Sea Air is of Doubtful Benefit, by Dr. Boardman Reed, of Atlantic City. An Invalid's Day in Colorado Springs, by Dr. S. E. Solly, of Colorado Springs.

Evening Session, 8 P.M.—The Causes of Cardiac Failure at High Altitudes, by Dr. Frank Donaldson, Jr., of Baltimore. Some Hospital Cases of Phthisis: Marked Improvement under General Treatment, with special reference to Alimentation, by Dr. Frederick C. Shattuck, of Boston. Discussion of Dr. Shattuck's Paper; introducing the subject of Gaseous Injections in connection with Diet, by Dr. E. T. Bruen, of Philadelphia. The Local Treatment of Diseases of the Res-

piratory Organs, by Dr. B. F. Westbrook, of Brooklyn. The Treatment of the Final Stage of Phthisis, by Dr. John B. Musser, of Philadelphia.

Wednesday, *Morning Session*, 10 A.M.—Observations upon the Sanitary Advantages of Tide-Water, Va., including Virginia Beach, as a Winter Health Resort, by Dr. A. Y. P. Garnett, of Washington. Evergreen Forests as a Therapeutic Agent in Pulmonary Phthisis, by Dr. A. L. Loomis, of New York. Environment in its Relation to the Progress of Bacterial Invasion of Tuberculosis, by Dr. E. L. Trudeau, of Saranac Lake. The Climate of the Sub-Peninsular Pinellas, Florida, by Dr. W. C. Van Bibber, of Baltimore. The Climate of St. Moritz, Upper Engadine, Switzerland, by Dr. Walter Platt, of Baltimore. The Climate of Southern California, by Dr. H. S. Orme, of Los Angeles.

Afternoon Session, 3.30 P.M.—Report of Committee on Mineral Springs, by Dr. Clarence C. Rice, of New York. Classification of American Mineral Waters, by Dr. A. C. Peale, of U. S. Geological Survey. St. Augustine as a Winter Health Resort, by Dr. F. F. Smith, of St. Augustine. Pass Christian, Mississippi, as a Health Resort, by Dr. Charles Le Roux, of Pass Christian.

The Michigan State Medical Society held its twenty-second annual meeting on May 12th and 13th inst., at Lansing. Thirty papers were read and discussed. The following were elected officers for the ensuing year:

President.—Dr. T. A. McGraw, of Detroit.

Vice-Presidents.—Drs. G. V. Tyler, of Bay City; W. J. Herdman, of Ann Arbor; G. L. Rose, of Decatur; F. J. Gronn, of Big Rapids.

Secretary.—Dr. George Duffield, of Detroit.

Treasurer.—Dr. A. B. Hemenway, of Kalamazoo.

A Strict Quarantine at New Orleans Against Yellow Fever and Smallpox.—The quarantine system in the Lower Mississippi, initiated by Dr. Joseph Holt, President of the Board of Health of the State of Louisiana, is regarded as eminently fitted to secure all the ends in view, viz., absolute protection against the introduction of yellow fever or smallpox from Cuba and the many West Indian, Central, and South American ports doing business with New Orleans.

Last winter the quarantine wharf, buildings, etc., were destroyed by fire. At once an adjoining wharf was prepared. Improvements were made in securing a fire-proof brick building for the boiler and steam-chest for disinfecting all the effects brought by inward passengers. When a vessel arrives the passengers are sent to the building with all their luggage; the latter is opened, the effects hung upon sliding frames that run into the immense steam-chest, the latter some sixty feet long. They are exposed first to dry heat at a temperature of over 230°. Next live steam direct from the boiler is introduced. They are kept at a temperature of 244° for fully fifteen minutes, a length of time absolutely fatal to all forms of germ life, spores, etc. The goods when taken out are so hot and moist that they cannot be handled. They dry immediately on exposure to the atmosphere. After the luggage has been fumigated, the passengers receive suits of clothing that have been through the disinfecting, germ-killing process, and send the clothing worn on the vessel to be done in its turn.

While the above is going on, the vessel receives the care of a special squad of the quarantine staff. The hatches are put on and ports are closed, and the hold is pumped full of concentrated sulphurous acid vapor, forced in under great pressure. So thorough is its action that, when the hatches are removed, cockroaches, rats, etc., are found dead. The decks, staterooms, etc., are drenched with a solution of mercuric chloride. In short, germs are effectually disposed of and given no opportunity of getting into New Orleans by way of the Mississippi.

All the ports of the Southern States are constantly threatened by yellow fever from Havana and Colon. In both cities it is so common that it excites no remark. Its introduction into the South in 1878, cost 22,000 lives.

The Queen's Physicians.—Sir William Gull, being the senior Physician Extraordinary to the Queen, succeeds the late lamented Dr. Wilson Fox as one of the physicians in ordinary. Dr. Reid, who has been for some years her Majesty's resident medical attendant, has been appointed one of the physicians extraordinary. A contemporary society journal states that Sir William Jenner only attends the Queen when "Her Majesty is really unwell." As a matter of fact, Sir William sleeps at the Castle almost every Saturday night when the court is at Windsor.

Dr. Morell Mackenzie has been summoned to Berlin to attend the Crown Prince of Germany, who has been suffering from an inflamed growth the size of a lentil, on the vocal cord. The growth has been removed, and Prof. Virchow pronounces it innocent in character. The Crown Prince's general health is reported to be good, nevertheless his condition causes considerable anxiety in the absence of more definite information.

Comparison of the Eyes of Whites, Negroes, and Indians.—At various times and in various places the well-known figures compiled by Cohn, Loring, and Derby concerning defective vision have been published. It has remained for Dr. Flavel B. Tiffany, of Kansas City, to compare the eyes of whites, negroes, and Indians. Of these the largest percentage of defective eyes was found at the Indian school at Lawrence, Kansas, due, in the doctor's opinion, to the prevalence of scrofulous diseases among them. The next largest percentage was among the Irish and Germans in the schools in Kansas City; while he found the negroes to have the most perfect eyes of all those examined.—*The Sanitary News*, April 23, 1887.

Antique Japanese Obstetric Instruments.—Dr. Whitney describes in the *Sei-I-Kwai Journal* of March 1887, the following instruments for use in obstetrics, which are described in the earliest Japanese books: A rather curious instrument called the whalebone sling, was the invention of Kagawa Mitsusada, the grandson of Kagawa Genyetsu. By means of this instrument a cord could be passed over any portion of the fœtus, and in some instances, an easy delivery effected. As the results were not infrequently disastrous both to the child and its mother, and, as such instruments were not allowed to be used at all at the court, the son of Mitsusada, Kagawa Mitsustaka, invented a kind of cloth

forceps, which consisted of a wide band of strong linen or silk, attached to two long slender rods, and rolled upon them (as ancient scrolls were rolled). These were introduced within the uterus and unrolled about the head of the fœtus, after which the sticks were withdrawn, and a flat vectus-like stick of whalebone, having a small hole for the passage of the ends of the cloth, was passed over them, and into the vagina. The cloth then enveloping the head and passing out through the hole in the vectus afforded a strong hold, and made altogether a powerful instrument.

ASPHYXIA FROM SEWER GAS.—A striking instance of the toxic effects of undiluted sewer gas was furnished last week in Paris, where the *concierge* of a house in the Rue de Temple and his wife, together with their son, narrowly escaped death. In consequence of their non-appearance one morning, their room was broken into by the neighbors, when all three persons were found insensible in their beds. The son was the first to recover consciousness, and the two others ultimately rallied, but remained seriously ill. A search was instituted, which resulted in the discovery of a fissure in the soil-pipe, which passed down behind the wall of their room, the gas from which had, in all probability, given rise to these severe symptoms. A persistent bad odor had been remarked for some time previously, but as this is rather the rule than the exception in houses in Paris other than those inhabited by the very well-to-do, no particular attention had been paid to it. This case shows very clearly the danger incurred by allowing a soil-pipe to pass down within a building—a fact which, notwithstanding its simplicity, does not as yet seem to have dawned upon foreign architects, who, whatever their theoretical knowledge may be, so largely ignore the elementary principles of hygiene in their plans for dwelling-houses.—*British Medical Journal*, April 23, 1887.

REFORM IN ENGLISH SPELLING.—PROFESSOR SKEAT, in a recent number of *Notes and Queries*, says: "Those who know the whole history of our spelling from the eighth century to the present time best understand the harm done by the pernicious system of trying to transplant Latin and Greek symbols into the English language. The symbols *æ* and *œ* are not English, and are best avoided. Indeed, this is done in practice when once a word becomes common. *Æther* and *æthereal* have been sensibly replaced by *ether* and *ethereal*. No one now writes *æternal*. *Solecism* is now *solecism*, and I trust that *primæval* and *mediæval* will soon prevail over *primæval* and *mediæval*. Pedantic spellings are most objectionable, because they are useless and unphonetic." We heartily agree with Professor Skeat, and trust that *diarrhœa*, *leucorrhœa*, *dysmenorrhœa*, etc., will soon give place to *diarrhea*, *leucorrhea*, *dysmenorrhea*, etc.

DEATH OF LEON GOSSELIN.—This eminent French surgeon died on April 29th, after a long and painful illness. He succeeded Velpeau as Professor of Clinical Surgery in 1867, and succeeded Nélaton in the Academy of Sciences in 1874; he was made President a few months before his death. His writings are numerous and valuable.

NOTES AND QUERIES.

TO DISGUISE THE ODOR OF IODOFORM.

In THE MEDICAL NEWS of April 30th, there was a note on means to disguise the odor of iodoform. After a large experience [illegible] I have found the following formula to be very satisfactory and to [illegible]

℞.—Balsam. Canadensis,
Iodoformi . . . . . ʒiss
Vaselini . . . . . ʒvi
M.—Solve.

If you will kindly print this, others will find it valuable.

ANDREW GRAYDON

PHILADELPHIA, May [illegible]

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 17 TO MAY 23, 1887.

[illegible], Major and Surgeon.—Retired from active service May 14, 1887.—*S. O. 111, A. G. O.*, May 14, 1887.

WHITE, R. H.—Promoted to be surgeon with the rank of major, to take effect from May 14, 1887.

[illegible], F. M., *Captain and Assistant Surgeon*.—Found incapacitated for active service by an Army Retiring Board—sick leave still further extended until further orders on account of disability.—*S. O. 116, A. G. O.*, May 20, 1887.

HALL, JOHN D., *Captain and Assistant Surgeon*.—Granted leave of absence for one month with permission to apply for one [illegible]

SUTER, WILLIAM N., appointed assistant surgeon U. S. Army, with the rank of first lieutenant—to rank as such from May 16, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MAY 21, 1887.

CURTIS, L. W., *Passed Assistant Surgeon*.—Ordered to the [illegible]

BAKER, J. W., *Passed Assistant Surgeon*.—Ordered to the Hospital, Chelsea, Mass.

PRICE, H. F., *Surgeon*.—Ordered to Board duty, Annapolis, Md.

GRAVAT, C. M., *Surgeon*.—Detachment from "Michigan" revoked.

LIDMSDEN, G. P., *Passed Assistant Surgeon*.—Orders to the "Michigan" revoked.

SIEGFRIED, C. A., *Surgeon*.—Ordered to the "Quinnebang."

PERSONS, R. C., *Surgeon*.—Detached from the "Saratoga."

FARWELL, W. G., *Surgeon*.—Ordered to the "Saratoga."

DIXON, W. S., *Surgeon*.—Ordered to special duty, Baltimore.

ROGERS, B. F., *Surgeon*.—Ordered to Marine Rendezvous, [illegible]

WELLS, HOWARD, *Passed Assistant Surgeon*.—Ordered to the [illegible]

WISE, J. C., *Surgeon*.—Detached from the "Jamestown."

HARVEY, H. P., *Surgeon*.—Ordered to the "Iroquois."

WAGGENER, J. K., *Surgeon*.—Detached from the "Iroquois."

WHITE, DR. S. STUART, of Frederick, Md., commissioned Assistant Surgeon in the Navy, May 19th.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING MAY 21, 1887.

GOLDSBOROUGH, C. B., *Surgeon*.—Leave of absence extended to June first, on account of sickness, May 18, 1887.

GUITERAS, JOHN, *Passed Assistant Surgeon*.—Granted leave of absence for four days, May 21, 1887.

ARMSTRONG, S. F., *Passed Assistant Surgeon*.—To remain in charge of service at Memphis, Tenn., until further orders, May [illegible]

LEVANT, S. G., *Passed Assistant Surgeon*.—Leave of absence extended thirty days, May 19, 1887.

CARRINGTON, P. M., *Assistant Surgeon*.—Ordered to U. S. Revenue Steamer "Rush," May 18, 1887.

[illegible], *Assistant Surgeon*.—Ordered to Marine Hospital, Baltimore, Md., for temporary duty, May 20, 1887.

HEATH, F. C., *Assistant Surgeon*.—Granted leave of absence for thirty days, May 18, 1887.

WOODWARD, R. M., *Assistant Surgeon*.—Appointed an Assistant Surgeon May 20, 1887. Assigned to temporary duty at the Marine Hospital, Baltimore, Md., May 21, 1887.

A CONTRIBUTION TO HEPATO-PHLEBOTOMY.

BY HOWARD A. KELLY, M.D.,
OF PHILADELPHIA

My experience in abdominal surgery has occasionally brought to my notice cases in which the existence of a tumor was suspected because of the general enlargement of the abdomen, which, however, upon examination has proved to be due to tympany, or ascites, depending frequently for its cause upon diseases of liver or mesentery.

The ascitic cases have always proved more or less disappointing and unsatisfactory subjects for treatment, and it is with a desire to make some small contribution to an exacter knowledge and possibly better therapy of this difficult subject that I have written the following, describing two of my cases which are most valuable suggestively.

The first stands as a type of many others, in which the sole effective treatment consists in a series of tappings more or less frequent. In the second I have detailed my effort to deal more directly with the disease by a short incision—abdominal section—rapid and thorough evacuation, careful inspection, with the end in view of abstracting blood directly from a diseased liver.

CASE I.—J. N., ropemaker, aged thirty-nine, of good habits, with the exception of inordinate tobacco-chewing. He has long been a chronic dyspeptic, but otherwise in good health, until his abdomen began to enlarge. The swelling continued until his girth was fifty-two inches, and he weighed two hundred and twenty pounds in August, 1884, when he came to me for treatment. He then complained most of frequent belching, constipation, discomfort from the extreme distention, and orthopnœa. The skin was muddy, and the conjunctivæ slightly yellow. I drew four bucketfuls of fluid from his abdomen, when a violent cough set in and stopped the tapping. He was tapped a second time in nine weeks, and once more after several months; the last time through a capillary tube, which emptied the peritoneal sac completely, drop by drop, in thirty hours, without any discomfort to the patient. He weighed after tapping one hundred and sixty pounds.

Medical treatment did not at any time affect his condition. He took large doses of ammonium chloride, iodide of potash in large and small doses, arsenic, diuretics, diaphoretics, and purgatives, and mineral waters.

After tapping, a greatly enlarged liver could be felt almost filling the right side of the abdomen. The free border and smooth convexity were readily palpable following a greater curve concentric with the smaller normal curve.

The diagnosis made was enlargement of the liver due to interstitial hepatitis. He still lives, but is no longer under my care. The futility of my efforts here led me to adopt a bolder plan in the next case, cited below.

I had long since convinced myself that the simple exploratory incision into the peritoneum was absolutely free from danger, when surrounded by those precautions which every prudent surgeon now understands. Observation had also shown me that when supposed abscesses were hunted for by plunging a large size aspirating trocar into the liver no bad results ever followed the injury. The largest trocar I had seen thus used was two and a half millimetres in diameter.

Combining these two factors of experience the suggestion was a natural one, that it would be safe to open the abdomen in a case of disease of the liver due to chronic congestion or an acute enlargement, and draw off a considerable amount of blood, and in cases of coexisting ascites to secure at the same time a thorough evacuation of the fluid, even to dryness. Indeed, the dangers of such a procedure, properly performed, are, I am sure, less than those of tapping in the hands of many, to whom it is merely a matter of plunging an unprepared trocar into the abdomen at any seemingly convenient point, and after an evacuation, covering the hole with a bit of sticking plaster. My determination was, in the next case similar to the one detailed, to make a short but fair trial of the usual resources, and then, in event of failure, to open the peritoneum promptly, thoroughly evacuate the fluid, examine the liver by touch and inspection, and in case of congestion, or any acute enlargement, to plunge a suitable trocar into its substance, and draw off a sufficient amount of blood.

In the meantime Dr. George Harley delivered an admirable address upon this subject before the British Medical Association at Brighton last summer. I had the satisfaction of hearing this paper read, and thus felt more assured in my first attempt in having with me the weight of so eminent an authority. Dr. Harley's method was different from my own, but the result aimed at was the same. This will be discussed later.

CASE II.—J. D,, aged forty-three, had been a gin-drinker, although he stoutly denied it, all his life. He stated that he had always been well until a recent fall from a dummy-car, when the abdomen began to swell, and it had continued to enlarge until he measured thirty-nine inches in the girth, when I saw him. His frame was much emaciated, the eyes slightly jaundiced, and his belly greatly distended. He had had a fair trial of appropriate medical treatment at the Episcopal Hospital, without benefit; I also tried the usual remedies without helping him. On

the twenty-ninth of October, 1886, Dr. T. B. Bradford etherized him, and, assisted by Dr. W. J. Freeman, Dr. R. P. Harris being present, I made a small incision through the thin abdominal walls in the linea alba. The fluid welled out, and by elevating the shoulders and hips, and at the same time rolling him on his side, a perfect evacuation of the fluid contents was secured.

I was then able to catch the liver between two fingers, and with the assistance of a little pressure from without, it was brought fully into view at the incision.

It was pale, hob-nailed, and contracted, and as no possible benefit could reasonably have been expected from puncture and an attempt at bloodletting—if, indeed, any blood would flow from such a gristly structure—the incision was closed. It healed quickly, the patient died forty-seven days after the exploration, in the natural course of his disease.

Thus by a simple operation which may be described, so long as it is confined to a small incision quickly closed, as a modification of the puncture method, I secured a quick, complete evacuation of fluid, and had the liver in my fingers and under my eyes, determining the exact nature, and the exact extent of the morbid process.

The nature of the disease in this particular instance could have been as readily determined after an ordinary tapping, but I was acting under the conviction that the safety of my incision was equally great, and I determined at once the *extent* of the disease, although my *expectation* had been of finding the liver enlarged.

The further procedure would then have been to plunge a trocar three millimetres in diameter into the liver substance, guided by eyes and fingers to the elected point, avoiding gall-bladder, intestines, greater bloodvessels, or the possible simple transfixion of a lobe, and through this draw off a sufficient quantity of blood.

It is for this procedure, which Dr. Harley calls hepato-phlebotomy, that I ask a fair trial, insisting that a diagnostic incision of this sort, with the attendant advantages of inspection and immediate palpation, is far preferable to weeks and even months of protracted treatment in obscure cases. I would especially urge it in ascitic cases where some operation is necessary to remove the fluid.

Dr. Harley's method is different from my own, as he taps the liver (from without) through skin, fasciæ, muscles, and peritoneal reflections; he also extends the indication to include puncture of the tense capsule in chronic hepatitis, mostly malarial. He has found in these latter cases that, just as puncture of the tunica of a swelled testis, or of the sheath of an inflamed sciatic nerve gives relief, so multiple punctures of the painful liver in these cases are valuable. He has made as many as six punctures in one case, using a trocar eight inches long, which enters from right to left up to its hilt; it is then a little withdrawn allowing a channel for the accumulation of the blood, which now flows readily into the aspirator. He justified his procedure by the statement that cupping, leeching, or any abstraction of blood from the hypochondrium has no more effect than so much general depletion; he has also observed for thirty years past that, owing to the elasticity of the liver, no extravasation of blood follows simple puncture of the liver. Thus he was led to adopt the plan he so ably advocated at the Congress.

Out of several cases reported all were relieved, and the first was cured. A lady who had an enlarged liver and anasarca following an attack of acute hepatitis a month before, was tapped in the manner described, and twenty ounces of blood withdrawn. Remedies before inefficient now acted, and after two and a half months the patient was out walking, and at a later date the dulness in the nipple line measured but four and a half inches.

My own method possesses the following distinct advantages over that advocated by Dr. Harley:

In the first place, where ascites coexists, a simultaneous complete evacuation of the fluid is made through the incision. This cannot be secured by tapping high up in the hypochondrium.

Again, diagnosis, often uncertain as to the exact nature of the disease, and always conjectural as to its extent, is made precise by touch and inspection. Implication of neighboring organs is also detected at the same time.

Thirdly, in those cases in which there is a prospect of relief from tapping the liver for blood, the procedure is conducted with a degree of safety and certainty otherwise unattainable. Under full direction of eyes, and fingers grasping the organ, the trocar is guided to the elected spot and the blood withdrawn.

Fourthly, any tendency to ooze after withdrawal of the catheter is at once noticed and checked, either by catching up the lips of the puncture in a suture, or plugging the opening with strands of gut. The amount of blood drawn will vary with the plethoric condition of either patient or liver, and where sufficient is withdrawn to make a decided impression, persistent oozing will hardly occur.

Lastly, all those cases which Dr. Harley has shown may be best treated by multiple puncture to relieve a compressed organ, will, without doubt, be better treated by free *incisions* through the capsule. In puncturing from without it is impossible to say that the trocar has pierced the capsule and gone no deeper, while under control of eyes and fingers free slits may be safely made, extending several inches on the surface, and numerous enough to be *seen* to produce the desired effect.

The points of election for the incision in the abdominal wall are the right hypochondrium, parallel to the lower border of the liver, or the median line above the umbilicus. Thin walls are readily closed by one set of sutures including everything from skin to peritoneum. Fat walls are best closed by including the peritoneum and subperitoneal fat in a separate series of buried gut sutures.

I am aware, in closing, that there is much obscurity in the diagnosis and pathology of diseases of this class, that while we might rationally hope for relief by free depletion in cases of chronic congestion, in enlargement due to cirrhotic process the chances are against the possibility of arrest even by free depletion. Clinically, however, distinctions are not so

clearly made, and even in hypertrophic cirrhosis, in the absence of an exacter knowledge of the true essence of the disease, its primary cause and *modus operandi*, we cannot predict what result might follow a method calculated to produce a local impression so powerful as this. Dr. Harley's successful case, with the favorable results reported in the other instances, gives us good ground for hope and warrants a further trial.

2134 HANCOCK STREET, PHILADELPHIA.

AN EXPERIMENTAL STUDY OF THE EFFECTS OF PUNCTURE OF THE HEART IN CASES OF CHLOROFORM NARCOSIS.[1]

BY B. A. WATSON, A.M., M.D.,
SURGEON TO CHARITY, ST. FRANCIS, AND CHRIST HOSPITALS, JERSEY CITY, N. J.

THERE has been, already, considerable written on cardicentesis, although the operation was originally proposed and performed in 1882, by Dr. B. F. Westbrook, of Brooklyn, N. Y. Prior to this date several unintentional punctures of the heart had been made without being followed by any unfavorable results.

Dr. John B. Roberts reported two cases of this kind at the College of Physicians of Philadelphia, January 23, 1883.[2] He likewise called attention to the fact that "Cloquet,[3] Bouchut, Legros, and Onimus have also observed the apparent innocuousness of wound of the heart made with capillary trocars. Steiner found, ten years or more ago, that electropuncture needles could be quite safely introduced into either ventricle, provided they were at once withdrawn." Dr. F. M. Corwin reports in detail a case in which a puncture was made in the right ventricle, about one inch from its apex, without giving rise to any unfavorable symptoms.[4] Dr. C. L. Dana has reported two cases[5] in which punctures of the right ventricle were made with negative results. The reports in both these cases are so meagre as greatly to diminish the value which they would otherwise possess; but the comments on cardicentesis are unquestionably highly valuable.

Having referred briefly to the literature of cardicentesis, which possesses an important bearing on our inquiry, although we believe this operation has never been performed on the human subject for the relief of chloroform narcosis, we will now briefly state the observation which prompted us to make these experiments.

While working in my laboratory with my assistant on the evening of February 20, 1887, I killed with chloroform a bulldog which weighed forty-one pounds; and about four minutes after the cessation of respiration, made an incision from the base of the neck, in the median line, to the symphysis pubis. This incision was promptly carried completely through the walls of the thorax and abdomen, thus exposing the heart, lungs, intestines, etc. The heart was observed to be entirely motionless and in full diastole, while the lungs were completely collapsed and lying in the posterior portion of the thoracic cavity, in close proximity to the vertebral column. My assistant, at this moment, seized the heart between his thumb and fingers, when the cardiac action was immediately resumed, and the hand was promptly removed. The contractions promptly became full and regular, and during the first two minutes the pulsations were about sixty per minute, while during the succeeding minute they became irregular, and stopped at the end of this period, but only to be stimulated into action by the second touch—action continuing two minutes—and was the third time started up in the same manner, but this time continued to beat only one-half minute, and could not again be roused into action. The lungs, during this whole period, remained completely motionless, and there were no other indications of life.

These observations suggested to me the possibility of arousing the heart into action, even after the entire cessation of its movements, by the introduction of a needle into this organ. The record of our experiments, which will appear at length in the *Transactions of the American Surgical Association*, shows the result of our labors.

Having completed sixty experiments on dogs, forty of which were on animals suffering from complicating traumatic injuries, while twenty were perfectly healthy and entirely uninjured, we will present briefly some of the results, and our conclusions drawn from this experimental study, with such explanations as will aid the reader in more fully comprehending these reports. There will be found incorporated in my report of these experiments the post-mortem description of the gross lesions; and in all cases where this has been omitted, it has been because the examinations were entirely negative.

In the post-mortem examinations of the forty cases where we had a right to expect traumatic complications, they have been observed and described in fourteen cases. In the other twenty-six cases these examinations did not reveal any gross lesions. Commercial chloroform was employed in all our experiments. In the first fifty cases, which have been reported in the order in which they were performed, the chloroform was administered rapidly, and, so far as possible, atmospheric air was excluded from the animals; while, in the last ten, the chloroform was administered slowly, and contained a large percentage of air. It is, therefore, evident that in the first fifty cases the chloroform narcosis was accompanied by a certain degree of asphyxia. In the first eight experiments no other efforts were made for the resuscitation of the narcotized animals, than the puncture; while in the ninth case artificial respiration was resorted to, and afterward used more or less in all the cases—but employed with especial care in the last twenty—which were the uninjured animals. The cessation of the heart's action and that of respiration, as the result of the chloroform narcosis, have been noted in forty-seven of these experiments. In forty-four cases the heart's action ceased before respiration; but in the fortieth expe-

[1] Read before the American Surgical Association, May 13, 1887.
[2] THE MEDICAL NEWS, vol. xlii. page 45.
[3] Ibid. [4] Medical Record, vol. xxiii. page 263.
[5] Ibid., page 140.

riment the heart continued to pulsate one minute after the respiration had ceased, and in the forty-second experiment the heart pulsated thirty seconds after the animal had ceased to breathe, while in the thirty-eighth the action of the heart and respiration ceased at the same time.

In thirty-four experiments where the chloroform was administered rapidly and without permitting the atmospheric air to mix with the vapor of the drug during the inhalation, the average continuation of respiration after the cessation of the heart's action was nearly forty-one seconds, while the maximum in this class stands at two minutes and the minimum at five seconds. There were in this same class of experiments ten cases in which the narcotized animals continued to breathe one minute or longer after the action of the heart had ceased, and only five cases in which respiration continued less than thirty seconds after the heart had ceased to act.

The ten experiments in which the chloroform was administered cautiously—atmospheric air being freely mixed with the vapor of the drug during its inhalation—give us a widely different result. In these ten cases there was not a single instance in which the cessation of the heart's action occurred before the animal ceased to breathe. The extremes are recorded in the report of Experiments No. 55 and 51. In the former the heart's action ceased eight minutes before the animal ceased to breathe, while in the latter case the animal breathed only forty-five seconds after the heart's action was arrested. The average duration of respiration after the cessation of the heart's action in these ten cases was two minutes and twelve seconds.

The punctures made in these sixty experiments were as follows: in the right ventricle thirty-eight; left ventricle six; right auricle six; superior vena cava three; inferior vena cava two; apex of the heart two; not stated one. The resuscitations which followed these punctures were as follows: right ventricle nine; right auricle one. The first forty experiments gave us only four recoveries, while the last twenty yielded six.

The question will naturally be asked, Why this disparity? It should be remembered in this connection that the dogs experimented on in the first series were suffering more or less from traumatisms and consequently possessed less recuperative power than the twenty animals used in the second series—which were perfectly healthy and entirely uninjured. Furthermore, the first series of experiments was made especially for the purpose of determining the effects of cardicentesis in cases of chloroform narcosis, while the second series were intended to demonstrate its efficiency when employed in the treatment of these cases in connection with artificial re-piration. Consequently, there was no resort in the first eight experiments of the first series, to artificial respiration or any other means of resuscitating these animals; and it is likewise true that in making the other thirty-two experiments of this series we were chiefly intent on observing merely the effect of the punctures, and consequently did not make any systematic effort at resuscitation.

The most important question which presents itself here for our consideration is, What are the effects of a puncture of the heart in cases of chloroform narcosis? Let us now carefully examine the record of these experiments and determine their bearing upon this query. We find that there were sixty cardiac punctures, and that the heart only failed to respond in Experiments 38 and 58. A reference to the report of these cases shows that in the former instance the puncture was made one minute and thirty-five seconds after the cessation of the heart's action and one-half minute after the animal had ceased to breathe, while the post-mortem examination revealed the fact that the needle had passed through the base of the right lung, entered the right auricular appendage, and passed through this into the auricular cavity. This needle had failed to indicate any responsive action merely because it was so firmly held by the tissues through which it passed as not to be swayed by the feeble pulsations of the heart. In the latter case the report shows that the puncture was made four minutes after the cessation of the heart's action and one minute after the animal ceased to breathe. In this instance the needle was entirely free to move, and it is, therefore, evident that it entirely failed to excite any responsive action in the heart—probably because of the loss of its vital power.

A further examination of these reports shows that the needle puncture, unaided by any other means, was sufficient to arouse the heart into action in twenty-two of these experiments, while the average time which elapsed between the cessation of the heart's action and the introduction of the instrument was one minute and twenty seconds, the longest period being two minutes, and the shortest, one. The cardiac action thus excited continued in two cases, the other functions were promptly reëstablished, and the animals fully recovered.

The real point of interest now centres in this question, Can the heart which has ceased to pulsate be goaded into action by a needle puncture? If it be admitted that in these twenty-two experiments the heart had absolutely ceased to perform its functions, but was aroused into action by the needle puncture, then the affirmative is proven. Should it, however, be charged that the experimenter had failed to demonstrate the cessation of the heart's action prior to the introduction of the needle, then the value of these experiments would be seriously questioned. Consequently we will introduce other evidence, in order that the value of these experiments may be made more apparent. It will not be denied that the swaying movements communicated to a needle by the pulsations of the heart, when it has been introduced into that organ, should be accepted as positive proof of its action. The needle in this position transmits every movement of the heart as accurately as it is done by the writing lever of the sphygmograph. Consequently the experimenter, who carefully watches these movements, is enabled to comprehend the peculiarities of the same.

An examination of the reports of these experiments shows that in thirty-two cases the heart did not promptly respond to the introduction of the needle, but its action was delayed, in some instances,

as long as three minutes, while in other cases only a few seconds.

The following extracts from the report of these experiments are here introduced for the purpose of illustrating the subject under consideration. The heart was punctured in Experiment No. 21 about three-fourths of a minute after the cessation of its action. The needle had remained in the organ two minutes before there was observed the slightest resumption of the heart's action. In the fifty-fourth experiment the puncture was made one minute and forty-five seconds after the cessation of the heart's action, and forty-five seconds after the animal had ceased to breathe. The heart responded to the needle a half minute after the puncture was made. Artificial respiration was then commenced, and in two minutes the dog was breathing without assistance. The respirations were, at first, very shallow, but gradually improved, and the dog fully recovered.

The last report fully shows that there had been a cessation of the heart's action, and that its resumption occurred without the use of any other means than the introduction of the needle. Additional evidence of this character is found in abundance in the report of our experiments, but it is not considered necessary to proceed any further in this direction.

Attention is now called to the fact that in nearly all our experiments with chloroform we have observed that cessation of the heart's action commonly occurs prior to the stoppage of breathing; but when the needle has been previously introduced into this organ the order is reversed. In support of this the reader's attention is now directed to the following extract from the report of the tenth experiment: The chloroform was reapplied, and respiration ceased after one minute, but the heart still continued to pulsate four minutes. . . . The needle had been allowed to remain in the heart during the whole period of our experimentation.

Having already supplied the essential facts found in the record of the experiments bearing on cardicentesis in chloroform narcosis, the question may be properly asked, Should the puncture be carried into the heart cavity, in order that blood may be abstracted?

The physiological conditions of the heart and lungs in chloroform narcosis are well understood by the medical profession. The heart is always found in diastole, and the veins in the lungs greatly distended with blood. I have made nearly one hundred and sixty post-mortem examinations of dogs killed with chloroform, and have uniformly observed these conditions, except in cases where there had been a very free escape of blood, just prior to the death of the animal. It may, therefore, be naturally claimed that the blood may be advantageously drawn from the right side of the heart in cases of chloroform narcosis. I am likewise fully assured that this procedure is not only theoretically correct, but also entirely practical and highly advantageous.

Let me ask if more rational treatment can be adopted in cases of chloroform narcosis than the puncture of the heart and the extraction of blood. In those cases in which there is already complete cessation of the heart's action and respiration, what are the indications for treatment? The urgent indications are to restore promptly these important suspended functions.

It may, however, be urged against this operative procedure that it is not entirely free from danger, but the same argument may be urged with equal force against any other operation. Furthermore, the desperate condition of a patient who is suffering from chloroform narcosis may justify a resort to measures which, otherwise, should not be employed.

The only deaths observed during my experimentation, which may be fairly charged to the puncture, are those in which the vena cava was punctured. In these cases a profuse hemorrhage into the thoracic cavity unquestionably influenced the fatal termination. The punctures made into the auricle were, in some cases, followed by the flow of considerable blood into the pericardial sac, and are not entirely free from danger. The punctures made into the ventricles are not attended by any leakage from the interior of the organ, but there were occasionally found a few drops of blood within the pericardial sac, which had been poured out from some wounded cardiac vein.

The experimental study of cardicentesis, in cases of chloroform narcosis, has enabled me to reach the following conclusions:

Firstly. The puncture of the heart, especially of the right ventricle, stimulates the muscular contractions, and may be advantageously employed in the treatment of this morbid condition.

Secondly. The best results are obtained when abstraction of blood from the cavity of the ventricle is combined with the stimulating effects produced by the entrance of the aspirator needle.

Thirdly. The puncture of the right ventricle is a safer and more efficient operative procedure than the puncture of the right auricle.

THE POLITZOMETER,

AN INSTRUMENT TO INCREASE FACILITY AND PRECISION IN THE INFLATION OF THE MIDDLE EAR.

BY ARTHUR E. PRINCE, M.D.,

OF JACKSONVILLE, ILL.; OPHTHALMIC AND AURAL SURGEON TO THE ILLINOIS STATE INSTITUTIONS FOR THE DEAF AND DUMB AND BLIND.

THE merit of the method of inflating the middle ear originated by Prof. Adam Politzer, of Vienna, has received universal acknowledgment, notwithstanding the difficulty of regulating the force to be used, and of securing, in the act of swallowing, perfect coördination between patient and physician. The method has justly been criticised as attended by the danger of overdistending the drums, which, besides being an absolute injury, may cause such suffering as to destroy the confidence of the patient. This is especially true with children and timid persons, who may fail to swallow at the proper time and thus misdirect the force of the blast, with the unpleasant consequence of either filling the stomach with air or blowing the water out of the mouth.

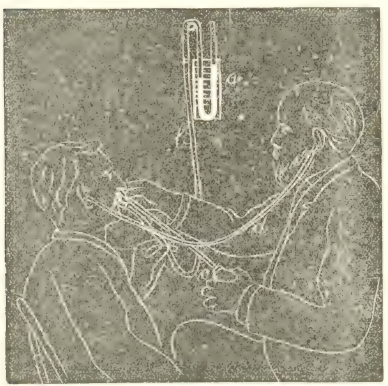
To avoid the disagreeable necessity of repeatedly

swallowing water, Gruber required the patient to pronounce the word "*hock*," holding the *k* sound, in the formation of which the parts are in the same position as in the act of swallowing. This was a valuable suggestion, and when correctly performed is often preferable to the use of water; but, unfortunately, requires too much intelligence to make it very available in just that class with whom trouble is experienced in the use of water.

An appreciation of the difficulties and uncertainties arising from the impossibility of adapting the power of the blast to the condition in hand, the inflation of the drum requiring in one case two or three ounces, and in another as many pounds pressure per square inch, prompts here the recommendation of a means by which these difficulties may largely be overcome.

To this end my thoughts were first directed by an instrument sold for inflating the middle ear, consisting of a simple tube reaching from the mouth to the nose, and through which one may more easily inflate the middle ears than by the Valsalvian method. Its success depends on the well-known fact that in the act of *blowing*, the palate is driven against the posterior pharyngeal wall, closing the naso-pharynx.

FIG. 1.



A. Politzometer. B. Politzometer tube.

My first experiments were made by requiring the patient to make an effort to blow the bottom out of a drachm vial, during which act the air was driven into the middle ears by the compression of the bag in the usual way. The success of this prompted the substitution of a rubber tube communicating with a mercurial column supplied with a graduated scale. This acts as a measure of the resistance required to overcome the obstruction presented to the entrance of air through the Eustachian tube. Such an instrument, for which there occurs to me no better name than that of *Politzometer*, has proved satisfactory during the past four years. Its operation will be made apparent by reference to the accompanying crude outline taken from a photograph of the original instrument in operation. (Fig. 1.) The depression of the column of mercury in fractions of an inch will represent in corresponding fractions of a pound, the pressure by which the palate is forced upward, thereby closing the naso-pharynx. At the same time, in the act of blowing, the tensor palati molis, levator veli palati, and salpingo-pharyngeus muscles, which operate on the pharyngeal mouth of the tube, are favorably conditioned with reference to accomplishing the inflation of the drum. The impulse of the air blown through the nose into the naso-pharynx is resisted by the palate to a degree indicated by the depression of the mercurial column, and a corresponding pressure, plus the momentum of the blast, is expended in dilating these tubes and inflating the tympani. Under normal conditions this will be accomplished by a mercurial depression of one-eighth to one-fourth of an inch.

In my experience I have noted the following advantages to be derived from the use of the politzometer:

1st. The operation becomes one of greater precision, subject to the immediate inspection of the physician, and free from the discomforts which attend the use of water.

2d. By mild measures and a little tact the difficulties met with in the case of children and timid persons, are largely overcome, enabling any intelligent physician to deal successfully with those puerile catarrhs with Eustachian closure, which are so often neglected until no remedy is available.

3d. By ascertaining the minimum of depression required for the inflation in each individual case, overdistention is avoided by the escape of the air into the pharynx.

4th. The minimum of depression constitutes an approximate index for comparing the conditions at intervals during treatment.

5th. By finding the air enter the middle ear with a normal minimum of mercurial depression, the absence of any obstruction is demonstrated, constituting an element of diagnostic as well as prognostic importance.

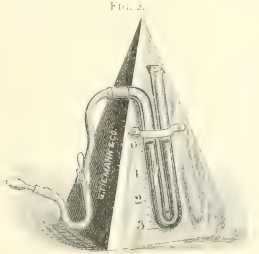
In chronic middle ear deafness, should no obstruction be found, or should obstruction be found to diminish rapidly under treatment, without corresponding improvement in the acuteness of hearing, pathological conditions, independent of the tube, will be found to exist in the drum, rendering the prognosis proportionately unfavorable.

Experience in the use of the instrument has not failed to develop the fact that it falls short of perfection. The success of its operation depends on the power of the expiratory muscles—and since the maximum power of these muscles seldom exceeds

three pounds to the square inch, an obstruction which exceeds that degree must be overcome by the catheter or bougie. In many persons the maximum power is so feeble as to render the use of water or the sound *k* more available.

The nose-piece of the inflating apparatus should have a free opening and be adapted to fit the nostril. Experience condemns the projecting rigid extension which is liable to cause pain, destroy confidence, and rob the treatment of its usefulness. It should be placed in position while the mercurial column is depressed and the remaining nostril closed the last thing before inflating, else the velum palati may drop before the bulb is pressed, when the effort will be expended in driving the air into the stomach.

FIG. 2.



NOTE.—In a conversation with Dr. Tansly, of New York, I was told that he had recommended that in place of swallowing, the patient blow forcibly with puckered lips. In *Ophthalmic and Otic Memoranda* (Roosa and Ely) it appears that Dr. Holt, of Portland, advises closing the lips tightly and distending the cheeks with air.

RECURRENCE OF SYMPTOMS OF POISONING, AFTER SNAKE-BITE.[1]

BY H. C. YARROW, M.D. (UNIV. PENNA.),
OF WASHINGTON, D. C.

IN 1884, I reported, in *The American Journal of the Medical Sciences*, 1884, n. s., lxxxvii. p. 422, a case of copperhead snake-bite, and gave a detailed account of the symptoms, and a *résumé* of some of the literature on the subject of poisonous snake-wounds. Care was taken to state particularly that several cases had been published, in which, after varying periods of time, a recurrence of poisonous symptoms took place, generally on, or about, the anniversary of the bite, and I am now able, after having watched two cases, to add the weight of my testimony in behalf of the recurrent theory.

Before doing so, perhaps it may be well to recapitulate briefly the evidence which we possessed at the date of my previous paper. The first case was reported by Dr. Sweeny, of Rushville, Illinois, in the *Cincinnati Lancet and Observer*, 1860, n. s., iii. p. 318, who stated that his patient, a male, who had been bitten many years before (nearly thirty) by a copperhead, suffered from painful symptoms in the fingers which had been injured, analogous to those which he had experienced at the time of the accident. These symptoms continued for some time. Dr. Wm. Stockbridge, in the *Boston Medical and Surgical Journal*, 1843, xxix. p. 40, reports three cases of copperhead bite with recurring symptoms; the first, a boy, aged ten, who received the wound on his leg. Ordinary remedies were applied, and he recovered, but for eighteen years thereafter, precisely on the anniversary of the bite, he had a recurrence of the symptoms similar to those first experienced. Gradually the attacks became less marked, and finally disappeared. A female slave, who had been bitten, suffered for a period of ten years, and a lady was affected in the same way for twelve years. Dr. R. T. Coleman, in the *Virginia Clinical Record*, 1872–3, ii. p. 137, reports two cases of moccasin bite, in which a scaly eruption showed itself for several successive springs, in individuals under his care. Dr. H. G. Piffard reports a recurrence of a skin affection for several years, in a female bitten by a rattlesnake.

The case of a photographer, bitten by a copperhead, which I reported as before mentioned, I have watched carefully from 1883 to 1886, the last attack commencing on May 30th, the anniversary of his injury, and lasting over a week. His condition about the acme of the attack was as follows: Pulse quick; complains of general malaise; pain and stiffening in the bitten finger, which extends up the arm; surface of hand shows bluish mottling, with lines of redness extending as far as the shoulder along the course of the lymphatics. He had slight chilly sensations, and some fever. Obliged to quit work, as he could not concentrate his attention on it. Has taken nothing but whiskey and quinine. These notes were read to him, and he stated that they represent fairly his condition at each recurring period since the bite.

Dr. W. M. Gray, Microscopist of the Army Medical Museum, secured at this time a specimen of blood from the bitten finger, and reported as follows: White blood cells increased in quantity in the proportion of 3 to 500 of red. They present a highly granular appearance, and contain numerous vacuoles; where some few have burst and exuded the granules, they stain like, and resemble, micrococci. The red corpuscles are normal; but when they assume the crenated form, which is common to them, they differ from the ordinary crenation usually seen, assuming an appearance like chestnut burrs. The drawings made by Dr. Gray represent this appearance. It may be stated that the microscopical examination of the patients' blood made just after the bite, by Dr. McConnell, showed that the white corpuscles were relatively few in number, and that most of the red corpuscles were crenated. Dr. Isaac Ott states that the blood, after copperhead poisoning, shows no microscopic changes in its cor-

[1] Read before the Medical Society of the District of Columbia, Washington, D. C.

puscles or spectrum, but I am unable to say if he has had an opportunity of examining the blood from a person recently bitten by the snake.

The other case under observation is that of Mr. A. Zeno Shindler, one of the artists connected with the National Museum, who was bitten June 2, 1882, by a "Florida harlequin snake" (*Elaps fulvius*), No. 12779 of the National Museum Reserve series, and whose accident was mentioned in the paper which I read. Mr. Shindler informs me that he made an excellent recovery from the bite, under the care of Dr. Taylor, but that in about a year he was troubled with considerable pain in the injured finger, and a small abscess formed at the seat of the bite, with some suppuration; and that each succeeding year since he has been troubled in the same way, and in addition to this he has lost each year the nail from the affected finger. On the last occasion, however, suppuration was prevented by the application of bandages saturated with aqua ammonia, which were used as soon as the symptoms developed.

Is there any explanation to be made of this peculiar occurrence of symptoms long after the original injury? Are they due to neurotic influence or hyperæsthesia of the affected part in consequence of the mind dwelling upon the accident at the succeeding anniversaries? Such might be the case for a few years, but it seems almost incredible that this should be the cause in the cases reported by Drs. Sweeny and Stockbridge, in which the patients suffered for eighteen and thirty years. Mr. Shindler states very positively that in his case he is quite sure that neurotic or mental influence has nothing to do with a return of the symptoms, for he is only aware of the anniversary of his bite by the pain which comes on at this particular time, and generally at night, it being so severe as to awaken him from sleep.

Another interesting fact is that recurring symptoms mostly occur after bites of the serpents of the genus *Ancistrodon* (copperheads and moccasins), but few cases being found on record from the bites of *Elaps* (vipers) and *Crotalus* (rattlesnakes). I have studied the matter carefully, but have been unable to solve the problem, and simply record the facts.

MEDICAL PROGRESS.

MICROSCOPIC EXAMINATION OF THE INTESTINAL CONTENTS OF NATIVES OF INDIA WHO PERISHED WITH CHOLERA.—WEISSER and FRANK, of the Institute of Hygiene in Berlin, have published the results of Koch's examination of a large number of microscopic preparations made at the Sealdah Hospital at Calcutta. Dejecta from 90 cases were examined, in 83 of which the comma-bacillus was found. In the 7 cases lacking the bacillus the presence of large quantities of blood, or defective preparation of the slide, accounted adequately for the failure to find it. The conclusions drawn from these cases were:

1. Microscopic examination alone generally suffices to demonstrate the presence of the comma-bacillus in cholera dejecta.

2. This is true in the most acute cases of cholera.

3. The number of bacilli is generally greater the earlier in the disease death occurs; when the fatal result is late the number is much smaller.

4. In cases dying from cholera typhoid, and not genuine cholera Asiatica, the bacilli are wanting.—*Deutsche medicinische Wochenschrift*, May 5, 1887.

TREATMENT OF VARICOCELE.—DR. THIRIAR, of Brussels, in a clinical lecture on the "Surgical Treatment of Varicocele," after mentioning that numerous methods of operation were in former times proposed and practised—such as castration, the section of the vas deferens, and the ligature of the arteries of the cord, which necessarily interfere with the functional activity of the testis—spoke of the modern or therapeutic method as consisting essentially in the arrest of the circulation in the venous plexuses surrounding the vas deferens. Until quite recently, however, so many accidents—some of them fatal—followed operative procedures of this kind that many surgeons objected to resort to them for an affection which, however trying to the patient, cannot be considered as dangerous to life. Since the adoption of antiseptics, the danger of these operations has been reduced almost to *nil*. The operation practised by Dr. Thiriar is the combination (proposed by Guyon) of Sir A. Cooper's plan of excising the skin with the old method of excising the varicose veins themselves; Heurteloup's plan of excising a flap of skin from the posterior surface of the scrotum he does not approve of, following Guyon and other surgeons in believing that the varicose condition is usually in the anterior plexus. His plan is as follows: An elliptical flap of skin is excised from the front of the scrotum, and the bundle of veins dissected out and tied in two places, the intermediate portion being excised if the tumor is considerable. The dissecting out of the veins is a somewhat difficult matter, as there are several fibro-cellular layers to divide or tear through; the artery has to be carefully separated from the veins, a proceeding which up to the present time Dr. Thiriar has not found attended with difficulty. The wound is washed with a corrosive sublimate solution, and the lips united by a continuous suture, which is the form Dr. Thiriar prefers as a rule; antiseptic dressings and compress bandages are applied, and in a few days the patient is discharged permanently cured.—*Lancet*, April 30, 1887.

ANTIPYRIN IN WHOOPING-COUGH.—SONNENBERGER has treated seventy cases of whooping-cough with antipyrin, in doses from one-sixth of a grain in very young children, to eight and fifteen grains in older children and adults. It was given in water and fruit juices, and was readily taken. Collapse did not occur. All of the cases were favorably influenced, and but five deaths occurred, two from pneumonia, and three from tuberculosis.—*Wiener medizinische Presse*, May 1, 1887.

ARTIFICIAL AND HYPERALIMENTATION IN PHTHISIS.—In an account of the effects of artificial and hyperalimentation, as practised in Professor Pel's wards in Amsterdam, DR. VAN EEDEN states that the meat-powder treatment introduced by Débove (which he had had an opportunity of studying in Paris) is always of service in phthisis

when the disease is not very far advanced, and when it is not of a "malignant" nature. The cases which do best under this treatment are those in which there is no hereditary taint and where the disease has progressed regularly, with a not very rapid loss of strength, and with only slight hectic, anorexia, anæmia, and emaciation. The chances of successful treatment are slight where the disease has made rapid progress, with a continuous high temperature. The existence of a considerable degree of pyrexia is, however, no contra-indication to the use of the treatment. If diarrhœa and gastric irritation are produced by the artificial alimentation, it is best to discontinue it. In order to accustom the stomach to the meat powder, small quantities only should be given at first—not more than about half a pound during the twenty-four hours; this amount may gradually be increased to one pound and a half. The use of the œsophageal sound for the introduction of the food is considered by Dr. van Eeden as advisable in all cases, and imperatively necessary in hyperalimentation. Quantities exceeding three pounds of meat powder per diem, however, are not by any means always required, and should only be given when smaller amounts do not succeed, and where the patient bears the treatment well. The method must be diligently and patiently practised, and the weight of the patient accurately noted. Dr. van Eeden remarks that so little is known of the way in which hyperalimentation controls the development of tubercle, that whoever attempts to practise Débove's treatment must be prepared to meet with many difficulties and disappointments. Notwithstanding this, however, he had witnessed some surprisingly good results from its employment.—*Lancet*, April 30, 1887.

FORMULA FOR THE HYPODERMATIC USE OF CARBOLICUM OXYDATUM.—SCHADEK gives the following formula as used by hypodermatic injections in the gluteal region in ten cases of syphilis:

℞.—Hydrarg. carbolici oxydat.	. .	gr. 30.
Mucilag. gum. arab.	. .	ʒ 1.
Aquæ destillat.	. . . .	ʒ 25.

One-half the contents of a syringe containing three-tenths of a grain was injected every second or third day.

Abscess and infiltration seldom occurred.—*Monatshefte für praktische Dermatologie*, 1887, No. 8.

PHENATE OF COCAINE.—VIAU, of Paris, has mixed one part of phenic acid to two of cocaine, heated gently, and obtained a substance which gave good results in eighty-six cases of extraction of teeth, by producing local anæsthesia. This substance is injected in solution by a fine syringe into the tissues about the teeth, care being taken to avoid the dropping of the substance into the pharynx, after which the mouth is rinsed with cold water. Local anæsthesia is generally sufficiently advanced to allow extraction in five or ten minutes.—*Les Nouveaux Remèdes*, April 27, 1887.

NUTRIENT ENEMATA.—The *Therapeutische Monatshefte* for April, 1887, gives the following formula used by Ewald, and adds further details in the preparation of nutrient enemata.

The simplest enema is prepared by beating up three or five eggs with five ounces of a solution of grape sugar fifteen or twenty per cent. in strength; this should be gently injected as occasion offers.

To allay irritation starch solution or mucilage water may be added, making the liquid of greater consistence; or a few drops of tinct. opii may be used. Before the nutrient enema is given an injection of tepid water or solution of common salt, eight and a half ounces of fluid, should be used, and the nutrient enema not introduced until the bowel is thoroughly emptied. If this precaution is neglected, the nutrient enema may be immediately rejected. An enema should never be larger than eight and a half ounces. It is better when this quantity is given in two or three doses during the day.

Nutrient enemata may be prepared as follows, when more elaborate methods can be followed:

Two or three eggs should be beaten with a tablespoonful of cold water. As much powdered starch as will lie upon the end of an ordinary kitchen knife should be added, with half a cup of twenty per cent. solution of grape sugar (obtainable at druggists); the whole should be heated gently, and a wineglassful of red wine (claret, etc.) added.

The mixture should be gently beaten, care being taken that it is not so hot as to coagulate the albumen of the eggs used. The whole should not exceed half a pint in bulk.

If meat peptone or milk peptone is convenient, a teaspoonful of the peptone should be added to the sugar solution; it is not necessary, for eggs so prepared will be readily absorbed.

The injection should be given with a syringe having a long, flexible tube, or with an irrigator which has a flexible tube with large opening.

After injections the patient should lie quietly upon the back or side for some time.

THE TREATMENT OF CATARRHAL JAUNDICE.—DR. GLUZINSKI, writing in a Polish journal, states that in cases of catarrhal jaundice he has found excellent results follow the treatment recommended by Krull, viz., the repeated injection into the bowel of large quantities of cold water. This increases the peristaltic action of the intestines, and removes any mechanical obstacle to the flow of bile. Again, as has been shown by Röhrig and Mosler, who injected large quantities of cold water into dogs, the bile is thus rendered both more liquid and more abundant, so that it more easily overcomes any obstruction. At first water at 59° F. is injected into the bowel until the patient complains of a feeling of distention in the abdomen. He is then made to retain it as long as possible. Most patients manage to retain two litres for from a quarter to half an hour. The next day the enema is repeated, but with water about 4° higher. The temperature is again raised on each succeeding day, but when 72° has been reached no further increase is made. The reason of the increase is that the repeated introduction of cold water is apt to irritate the mucous membrane of the bowel. Altogether four or five enemata are sufficient to produce the desired effect. The increase of the biliary secretion may be judged of by the color of the feces. Of course, the diet is attended to in order to prevent a recurrence of the affection.—*Lancet*, April 23, 1887.

THE ETIOLOGY OF DIABETES.—The *Lancet* of April 30, 1887, reports, in the recent Congress of German Physicians, the following of interest:

Of very far-reaching and undoubtedly also practical importance will prove the experiment of the young PROFESSOR VON MEHRING, of Strassburg, who produced diabetes in fasting dogs by large doses of florhidein, an extract of the root of the plum-tree, and who expressed his conviction that the sugar is formed solely by decomposition of albumen. These researches and operations seem worthy of special notice, as they are calculated to modify profoundly the views held of this disease. Leube congratulated von Mehring, and gave expression to the hope that we might now succeed in getting animals continuously diabetic.

LIGATION OF THE INNOMINATE.—DURAN'S SUCCESSFUL case is reported in the *Lancet* of April 30, 1887, as follows: The patient, a man of about forty-five years, was suffering intense pain from pressure by a very perceptible aneurism of the second part of the right subclavian. Other means having been tried with no good result, Professor Durante, of Rome, determined upon ligature of the innominate. Accordingly, on March 25th, the operation was performed, with strict antiseptic precautions, the vessel being tied in two places—viz., immediately below the junction of the subclavian and common carotid, and again slightly lower down. The vertebral artery was also tied. The ligature used was No. 3 carbolized catgut. The after-progress, up to the present date (April 5th) has been most satisfactory. Circulation in the right upper limb and side of the head has been completely restored, and the patient's general health is good, with the exception of obstinate constipation, which may account for a rise of temperature having occurred. The external wound, excepting a small drainage aperture, has healed by first intention.

TREATMENT OF PHTHISIS BY MENTHOL.—ROSENBERG has obtained the following results: Inhalations of 3 per cent. solution, and doses of $\frac{1}{8}$ to $\frac{1}{4}$ of a grain, and later 15 grains to 20 grains six times daily were given. Early unpleasant effects—burning in the throat, a feeling of heat, giddiness and headache—disappeared in four to six days. Early good effects were increased appetite and lessened night sweats. Lessening of secretion and irritating cough followed. A decided general benefit resulted. Temperature and bacilli were uninfluenced.

If any permanent benefit can be expected from this treatment it is in beginning phthisis. The following is Langaard's formula for menthol in pill form:

R.—Menthol	gr. 30.
Sacch. albæ,	
[illegible]	[illegible]
Aq. dest.	q. s.

Ft. pil. 20 in num.

Cover with gelatine.

Each pill contains 1½ grains menthol.—*Wiener med-* [illegible]

ABORTIVE TREATMENT OF BOILS BY INJECTIONS.—BIDDER has had excellent results in the treatment of boils by injecting beneath the skin, at the margins of the area of inflammation, a two per cent. solution of carbolic acid. When suppuration occurred an incision was avoided by aspirating the abscess with a fine needle, and injecting the carbolic solution.—*Berliner* [illegible] *Wochenschr.*, 1887, No. 14.

HOW TO SUTURE THE INTESTINE.—SIR WILLIAM MACCORMAC, in an oration on abdominal section reported in the *British Medical Journal* for May 7, 1887, writes as follows:

There are three conditions required to insure successful suture of the intestine:

1. Two adequately broad and sufficiently wide surfaces of peritoneum must be brought into contact.

2. The mucous membrane must be excluded, for when the needle passes through the whole thickness of the gut, peritonitis generally ensues from leakage taking place along the line of the thread.

3. Rapidity of execution is of extreme importance, and that form of suture is the best which can be effectively applied in the shortest time.

In 1826, Lembert introduced a method of bringing the two adjacent serous surfaces into contact, avoiding penetration of the mucous coat. It is the preferable one to employ in all wounds of the bowel; sufficient inversion may be thus easily accomplished without causing obstruction of the lumen of the tube; when the wound is small or incised, the needle may be introduced a line and a half or two lines from the margin, and then brought out at the edge of the serous coat, the same being done on the opposite side. This will suffice in clean-cut wounds; but, where the edges are bruised, it is best to exclude them by entering the needle about three or three and a half lines from the margin, and carrying the suture through the bowel a line distant or more from the edge. The number of stitches must be sufficient to bring the parts everywhere into accurate contact, and care taken not to tie the sutures too tightly, as it may lead to gangrene and consequent failure to procure union. Experimentally, this has been found to be the most frequent cause of non-union. The ends of the sutures are cut short, and the intestine returned to the abdominal cavity. When the surfaces are drawn together sufficiently to bring them fairly into contact, the subsequent swelling will hold the parts firmly until the rapidly formed adhesive material securely glues them together. When the omentum is much injured, it is probably best to excise the damaged parts after applying ligatures.

EXAMINATION OF A STOMACH WHOSE PYLORUS HAD BEEN RESECTED FOR CARCINOMA FIVE YEARS BEFORE.—WÖLFLER, of Vienna, reports a case in which in April, 1881, he had resected the pylorus for carcinoma. Death occurred five years after from exhaustion produced by a disseminated return of the disease; the patient's life had been comfortable, and almost free from stomach disturbances. Examination showed the stomach nearly normal in size. The site of the suture could not be found externally. When the duodenum and stomach were opened a constriction, with folds of mucous membrane, was seen at the former site of the pylorus. On microscopic examination mucous glands but no peptic glands were found, and a compensatory hypertrophy of muscle and connective tissue forming a new pylorus.—*Wiener med. Presse*, May 1, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM IN ADVANCE $5.00

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding registered letters.

Address, LEA BROTHERS & CO.,

PHILADELPHIA.

SATURDAY, JUNE 4, 1887.

WAS IT A DEATH DUE TO ETHER?

WE reply in the negative. The case in question occurred in Philadelphia, last week, and was the subject of comment in the newspapers, and of an extra-judicial opinion by the Coroner. The facts with which we are concerned are these:

A minor surgical operation being necessary, ether was employed as the anæsthetic. No accident happened during the anæsthesia, and no unusual incidents followed the operation until the fifth hour thereafter, when the patient suddenly expired. A jury summoned by the Coroner rendered a verdict which ascribed the death to ether, but implied no censure of the two physicians in charge of the case. The coroner, however, animadverted with no little severity on that lack of skill which failed to detect the "fatty heart." The Coroner's physician, who conducted the autopsy, testified to the existence of fatty degeneration of the cardiac muscular tissue, and without hesitation referred the fatal ending of the case to the action of ether. An examination of the brain appears not to have been made, nor was the vascular system inspected with the view to detect thrombus or emboli. Such omissions, if made, must cast doubt over the conclusions arrived at from insufficient data, and are the more reprehensible since the physicians are held up to public reprobation when innocent of offence.

To ordinary observation, without prejudice, the two facts of the case—the inhalation of ether, the death several hours after—seem too remote to have the relation of cause and effect. The supposed fatty heart bore the strain of the ether inhalation and the surgical procedure, and yet succumbed when the anæsthetic was no longer in action, and the shock of the operation, if any, had passed away. It is no doubt true, as recently stated in these columns, that a fatal result may occur from ether inhalations several days after, because of pulmonary inflammation induced by prolonged contact of ether vapor. It is not alleged that the case in question was of this character; but, finding a fatty heart, the fatal ending required no further explanation. Did this conclusion turn on the naked-eye appearances, or was it decided by a microscopic examination of the muscular elements?

The Coroner seemed to have been outraged in his innermost moral consciousness that the fatty degeneration of the heart had eluded *ante-mortem* examination. We opine that his strictures are not justified by our existing knowledge of the rational and physical signs of this morbid condition. We have the conviction that considerable fatty degeneration may exist without any definite symptoms, and all of the usual signs of this affection may coexist with a normal state of the organ. Assuming that the heart of this patient had undergone, to some extent, degenerative changes, should this condition inevitably preclude the administration of ether? An answer to this question is furnished us by the mode of dying in ether narcosis. It is now conceded on all sides that failure of the respiration is the mode, the action of the heart being rather stimulated than depressed by ether.

To connect the death of this patient with the ether inhalation after several hours had elapsed, is to do violence to every fact; to assume as a cause of the fatal ending a condition of the heart which had passed through the ordeal of a surgical operation and complete insensibility, is to tax credulity above its power of endurance; and to ignore the results of physiological investigations that have demonstrated the nature and character of the dangers in anæsthesia by ether, is to substitute for exact knowledge the vagaries of uninstructed opinions.

To permit the Coroner to give utterance to extra-judicial opinions that reflect on the judgment and attainments of physicians who have the misfortune to come within his jurisdiction, is to touch nearly the honor of the medical profession. To permit the Coroner's physician to announce hasty opinions after insufficient examination that discredit the knowledge and reflect on the integrity of the physicians concerned, is to place in his hands an opportunity for mischief that can hardly fail of being utilized. If post-mortem investigations that involve mortification or disgrace, or merely annoyance, are conducted without giving an opportunity to the physician implicated, to observe for himself, is it not certain that a grievous wrong is being perpetrated, and the good name created by a life of honest endeavor, put at the mercy of caprice, of prejudice,

or of ignorance? We learn that in the case now under consideration, the *post-mortem* was conducted without acquainting the physicians concerned, and thus affording them the opportunity to prepare for their own defence.

It must be obvious to the least observant physician, that there is an increasing distrust of the medical profession, growing out of those personal discussions in which the integrity and acquirements of each other are called in question. The world is apt to adopt that view of a body of men to which they themselves give expression. In these times of combinations, of syndicates, of organizations, the medical profession is apparently engaged in a process of disintegration rather than solidarity.

THE ACTION OF IODOFORM ON SEPTIC MATERIAL

THE fact that iodoform is used so generally, both in this country and abroad, certainly points toward its being a drug of great value, but in reality we have little more than clinical evidence on which to base an opinion concerning it. Quite lately, at the Sixteenth Congress of German Surgeons, this subject was thoroughly discussed by BRUNS, of Tübingen, SÄNGER, of Leipzig, and several other observers, and a large amount of evidence was brought forward to show that iodoform acts upon any septic matter with which it may come in contact with considerable power, and the results given by Sänger of some three hundred experiments made to determine its action on the bacillus of anthrax are extremely interesting.

To be brief, Sänger found that the growth of these bacilli was checked by iodoform, and their reproductive power decreased, while, at the same time, certain degenerative changes seemed to take place in their anatomical arrangement. Experiments made on the mouse by the injection of this bacillus proved that if the culture had been subjected to the action of iodoform for from one to three days death resulted in twenty-four hours, while, if older cultures were used, death was delayed. When iodoform anthrax cultures of six days were injected recovery took place. Other experiments were made by placing bacilli in a "pocket" in which iodoform had already been placed, and covering them with the same drug. Under these circumstances the bacilli, in the course of a few days, became harmless.

Professor Bruns expressed the opinion that the antituberculär action of the drug was established, and detailed fifty-four cases of tuberculous abscess from which the pus had been removed by aspiration, after which the abscess cavity was washed out by from one to three injections of an iodoform solution containing ten per cent. of glycerine and alcohol. Cures were produced in forty of the fifty-four cases, though, in many of them, the cavities were of sufficient size to hold a pint. This observer believes that the drug acts directly on the tubercular tissue, destroying it, and causing its replacement by healthy granulations, and detailed the results of several cases in which histological studies of the abscess walls showed a progressive lessening of the number of the bacilli, with a disappearance of the exudation, and a rapid increase of granulation tissue.

From the evidence before us it is evident that iodoform, as used in surgery, acts much more as a prophylactic than as a true disinfectant, preventing the multiplication of disease germs in a wound, but scarcely capable of influencing those already present before they can effect any ill results.

It is a point not to be forgotten in using any drugs of this class that all the tissues of the human body, being more highly organized than the bacilli themselves, are much more readily destroyed than the germs against which they are used, and the point of difficulty is to find a substance which will act on the bacillus without injuring the man. Iodoform seems to approach more closely this desirable condition than any other substance used in surgical dressings, but the practitioner should never lose sight of the fact that a large number of cases of grave or fatal poisoning have resulted from the spreading of even a small quantity over a raw surface. One or two deaths have occurred in which only a drachm of the powder was used, scattered over a considerable area, and in some cases slow or chronic poisoning has resulted from its use for a long period in large quantities, the lesions after death being found to be those of fatty degeneration.

ETHER IN CARDIAC DYSPNŒA.

THE death of Dr. Wilson Fox, of England, within the last few weeks, has left a gap in the ranks of the profession not easily filled. For many years he had labored earnestly, both as a teacher and writer, in the field of thoracic disease, particularly as connected with the lungs, and it is curious that even in his last hours he indirectly should have brought to our notice the use of ether for the purpose of relieving cardiac dyspnœa, and perhaps no better manner of discussing the subject can be devised than to give a short history of his physical condition as it comes to us through the *Brit. Med. Journ.* of May 7, 1887.

Eleven years ago Dr. Fox had a severe attack of pneumonia complicated by endo- and pericarditis, which left the cardiac valves in a damaged condition, and during the spring of 1886 he had a second attack of pneumonia, from which, however, he quickly recovered. The sudden illness and death of a brother of the same disease, occurring when he was already broken down by a hard winter's work, seemed to be the last thing needed to increase his loss of vitality,

and early on the morning of the fourth day after the death of his brother he himself became a victim of the same disease, the onset of which announced itself by dyspnœa, syncope, and great prostration. Twenty-four hours later the dyspnœa and prostration were suddenly markedly increased, and there was also much pain in the side which, however, was muscular and not pleuritic. His symptoms now pointed to cardiac weakness rather than pneumonia, and although he rallied once or twice it was only to return to a worse condition than before, so that, with total possession of his mental powers, he gradually sank, although death at the last came rather suddenly.

The point in connection with this case to which we desire to call particular attention is, that on three successive days "his sense of dyspnœa was relieved, and he was free from all pain" after the subcutaneous injection of ether. From our knowledge of the physiological effects of ether, the *modus operandi* of its action in such a case is not hard to understand except in so far as concerns the relief of pain, since it is scarcely possible that a sufficient quantity of ether can be given in this manner to produce partial anæsthesia. This is not, however, the point to which we desire particularly to call attention, but to the relief of the more pressing and worrying symptom of dyspnœa.

It will be remembered that ether in small quantities acts both on the respiratory centre and heart-muscle as a stimulant, and that in pneumonia the resistance to the passage of the blood from the right side of the heart through the lungs produces distention and palsy of the right ventricle. Under these circumstances dyspnœa arising from cardiac failure soon asserts itself, but is relieved if, by the aid of cardiac stimulants, we can enable the heart to overcome the resistance and free itself of the abnormal quantity of blood. It is probable, then, by this double action on respiration and circulation that ether in such a case does good; but it is worthy of remark that, as a general rule, less fugacious cardiac stimulants are more desirable, since in the case of ether stimulation the effects pass off as rapidly as they appear. Nevertheless, in those cases in which cardiac dyspnœa suddenly becomes alarming it is well to remember that the hypodermatic injection of small quantities of ether may bridge over the danger till more constant and equally powerful remedies can be given.

WAKING NUMBNESS.

In the current number of *The American Journal of the Medical Sciences*, Dr. Andrew H. Smith describes a curious neurosis characterized by numbness on waking, either general or confined to the distribution of the ulnar nerves. Two of the four cases which he reports had been subjects of organic nerve lesion, but in the others there was no disturbance of motion, and the abnormal sensation seemed purely subjective. The duration was rarely more than a few minutes, though in one case it lasted sometimes for an hour or two. The condition is not serious, and is met with in hysterical or debilitated persons. Dr. Smith is apparently not aware that Dr. Weir Mitchell described the affection some years ago in his lectures on Diseases of the Nervous System, in which he states that "in the more usual cases the sleeper awakens with numbness, or rather tingling and numbness, of one arm or of a leg only, which is unfrequent, or the whole side, including the face, and even the tongue, which is now and then attacked alone. The disorder may be mere tingling, or actual loss, or rather lessening of tactile sensation; but in any case it rapidly fades away, or yields to a little friction."

In an interesting article on "Local Numbness," in the *Lancet* of Dec. 4, 1886, Dr. J. E. Squire gives several cases in which numbness was a characteristic feature on awakening.

Local treatment does not appear to be of service, but measures calculated to improve the general health usually cause a disappearance of the unpleasant symptoms.

The arrangements for the forthcoming International Medical Congress are actively progressing. The Committee have announced that the transatlantic steamship lines have made a reduction in rates to members, and in due time, no doubt, a reduction in railroad rates will also be secured.

The following Addresses are announced to be made in the General Sessions: Prof. Semmola, of Naples, on "Bacteriology and its Clinical Therapeutics;" Dr. Neudorfer, of Vienna, "On the Military Medicine of the Present and of the Near Future;" Prof. Esmarch, of Kiel, "On Bloodless Operations in Surgery;" Dr. Lutaud, of Paris, "On the Influence of the Discoveries of American Surgeons on the Development of Gynecology in Europe," and Dr. Austin Flint, of New York, "On Fever, its Causes, Mechanism, and Rational Treatment."

The complete programme of papers to be read in the Sections will probably be published at an early day, as the last of April was fixed as the latest date at which titles must be handed-in, and from it, in connection with the list of the members who are expected to participate in the discussions, an estimate can be formed of the scientific attractions and the international character which the Congress will present.

The social features of the gathering have not been overlooked. The Government has appropriated $10,000, which, in connection with other available

resources, will insure a liberal public hospitality, while, doubtless, there will be dispensed the same large private hospitality as has characterized the preceding Congresses.

THE thirty-eighth annual meeting of the American Medical Association will be held at Chicago, in Central Music Hall, on Tuesday, Wednesday, Thursday, and Friday of next week, under the presidency of Dr. E. H. Gregory, of St. Louis. The Presidents of Sections are as follows: *Medicine*, Dr. J. S. Lynch, of Baltimore; *Obstetrics*, Dr. F. M. Johnson, of Kansas City; *Surgery*, Dr. H. H. Mudd, of St. Louis; *State Medicine*, Dr. George H. Rohé, of Baltimore; *Ophthalmology*, Dr. X. C. Scott, of Cleveland; *Dental Surgery*, Dr. J. V. Marshall, of Chicago; *Medical Jurisprudence*, Dr. I. N. Quimby, of [illegible].

THE Maine Medical Association will hold its 35th Annual Meeting at Portland on June 14th, 15th, and 16th, under the presidency of Dr. J. B. Walker, of Thomaston.

THE New Jersey Medical Society will hold its one hundred and twenty-first annual meeting in the Baldwin House, Beach Haven, on Tuesday and Wednesday, June 14th and 15th, commencing at 4 P.M. on Tuesday. Dr. Charles J. Kip, of Newark, is president for the year.

IT will be remembered that Dr. Darby, of Morrow, Ohio, was sent to jail for contempt of court in refusing to give expert testimony without compensation. We learn from the *Cleveland Medical Gazette* that the next higher court has sustained the decision, and that a fund is now being raised to carry the case to the Supreme Court.

BELLEVUE HOSPITAL, New York, is about to establish a school for the training of male nurses. The enterprise has received a liberal endowment.

AT the last meeting of the Board of Directors of the New York Post-Graduate Medical School and Hospital, held on May 31st, Dr. Charles Carroll Lee was elected Professor of the Diseases of Women. Associate Professor J. R. Nilsen was also elected professor in the same department to fill the vacancy caused by the resignation of Dr. A. J. C. Skene.

Several new instructors were appointed, among them, Dr. Joseph O'Dwyer, inventor of intubation of the larynx.

The last year's sessions of the school have been attended by more than two hundred matriculates.

SOCIETY PROCEEDINGS.

THE AMERICAN LARYNGOLOGICAL ASSOCIATION.

Ninth Annual Congress,

[illegible]

Specially reported for MEDICAL NEWS.

THE PRESIDENT, DR. E. FLETCHER INGALLS, of Chicago, occupied the Chair. He thanked the Association for the honor conferred upon him by electing him to the office of President, and then offered some remarks on

INTUBATION OF THE LARYNX.

In 1880 O'Dwyer, he said, introduced intubation, and gave to the profession one of the most useful operations of modern times. In the after-treatment, while the tube is in position, no liquids should be allowed. Sometimes small quantities of liquid can be taken, but the danger of exciting bronchitis or pneumonia is so great that fluid should be entirely prohibited. The largest tube that can be introduced is the one most likely to be retained. The danger of the tube being forced into the trachea was referred to. In four or six days, in favorable cases, the swelling and false membrane will have so much diminished that the tube will be coughed up finally, and need not be reintroduced.

He had performed intubation in twelve cases of diphtheritic laryngitis. In three recovery followed. By a coincidence the cases of recovery were the only ones in which he had charge of the after-treatment. One case lived eight days, and then died suddenly an hour after the tube had been removed. Another lived eight days, and then died of pneumonia. Details of the cases treated were given. As a result of his experience he concluded that the treatment after intubation should be: 1. Prohibition of fluids, except by enemata. 2. Some preparation of mercury should be given in large and frequent doses. In case of development of bronchitis, or pneumonia, respiratory and cardiac stimulants should be given frequently, but cautiously.

By correspondence and study of the literature he has collected 514 cases, with 134 recoveries. The percentage of recoveries will be greater when more care is exercised in the use of fluids. When medicines fail, no time should be lost in providing for the free entrance of air, either by intubation or tracheotomy. Intubation can be done more quickly, more safely, with less shock to the patient, and less objection on the part of the parents. The operator should be prepared to open the trachea, if loosened membrane should be forced down into the trachea. When the tube fails to relieve the dyspnœa tracheotomy should be performed, unless there is reason to believe that the latter operation will fail. When membrane is loose in the trachea, no time should be lost in the use of forceps, which rarely succeed, but tracheotomy should be resorted to. The results obtained by intubation are about as good as tracheotomy at all ages, but apparently better in young children.

DR. CHARLES E. SAJOUS then presented

A STUDY OF SOME OF THE OBJECTIONABLE FEATURES OF INTUBATION.

At present, he said, statistics favor the operation of tracheotomy, but he believed that intubation would prove the better operation when the mechanical defects

are overcome. The principal objections, according to the degree of danger, are: 1. The tendency to the obstruction of the tube by fragments of membrane. 2. Crowding down of loose membrane during introduction of the tube. 3. Passage of food into the trachea. 4. Momentary arrest of respiration during introduction of the tube. 5. Liability of the tube to be coughed out. And 6. Slipping of the tube into the trachea.' The tendency to obstruction was attributed to the limited diameter of the tube; the crowding down of membrane to the length of the tube; the passage of fluid, to the weight of the tube; the liability to be coughed out, to the limited diameter of the tube, and the slipping of the tube to the weight of the instrument and the formation of the head.

He exhibited instruments on the principle of the bivalve speculum, which were intended to embody the suggestions made above. This tube obstructs the larynx very little, leaving the breathing space almost as great as normal.

He also exhibited an instrument intended to remove loose membrane from the larynx. The instrument consisted of forceps which could be protruded into the larynx, by an arrangement in the handle, the required distance and the membrane grasped.

Dr. F. H. Hooper, of Boston, stated that he had no personal experience with the operation, but had watched certain cases in the Boston City Hospital. Since last October ten cases of intubation have been operated on with two recoveries. In one case the attempt to introduce the tube caused spasm, and tracheotomy was performed. In every case there was immediate relief of dyspnœa. In three cases the tube was coughed up and swallowed.

Dr. D. Bryson Delavan, of New York, said that an interesting question is with reference to feeding. It has been suggested that feeding with a tube introduced into the œsophagus would overcome the difficulty. This was worthy of consideration. This plan can also be used in cases of tracheotomy.

Dr. Morris J. Asch, of New York, thought there were a few objections which should be brought to the notice of the profession. One of these is that the membrane may be crowded down, which is very difficult to remove, even by tracheotomy. Another objection is the difficulty experienced by the ordinary practitioner in the removal of the tube.

Dr. B. F. Westbrook, of Brooklyn, did not think that the weight of the tube is the cause of the trouble in deglutition, for the muscles which elevate the larynx are quite strong. It seems more likely that the difficulty is due to the rigid tube holding the larynx open. In normal deglutition the entrance of the larynx is closed.

Dr. S. H. Chapman, of New Haven, remarked that one of the most distressing symptoms after the introduction of the tube seems to be thirst. It would be interesting to study the cause of this. Could it not be relieved by the use of enemata and by baths? It may be occasioned by the use of the mercury, which might be introduced in some other way than by the mouth. The use of pilocarpin, which even in small doses causes salivation, might be of service.

Dr. Ingalls said that it is so rare that the tube becomes clogged that it is not necessary to have a skilled attendant. When the tube becomes clogged it is usually coughed up, and, as a rule, it is not necessary to replace it for two or three hours. The attempt to feed these patients through a tube introduced into the œsophagus has been tried in Chicago, but he had not heard any stress laid on this measure.

Dr. J. Solis Cohen, of Philadelphia, then gave a

DESCRIPTION OF A MODIFIED LARYNGECTOMY.

The operation is applicable to those cases in which the disease is not too extensive, and has the advantage over complete laryngectomy of leaving the greater portion of the thyroid cartilage undisturbed while the respiratory portion of the larynx is removed. On the cadaver the operation can be performed in two minutes. In disease limited to the interior of the respiratory tube, especially carcinomatous disease, it fulfils every indication that prompted complete laryngectomy. The advantages claimed for the operation were: 1. Rapidity, ease, and comparative safety for the patient. 2. The small size of the wound. 3. The preservation of the attachment of various important muscles and ligaments. 4. The retention of important structures in their normal relation. 5. A firm natural support is left for the application of any artificial apparatus.

The operation should be preferred to complete laryngectomy, when not precluded by the extent of the disease.

PRESENTATION OF INSTRUMENTS.

Dr. T. A. DeBlois, of Boston, exhibited a portable apparatus for compressing air.

Dr. E. C. Morgan, of Washington, presented a universal powder blower, which could be used in diseases of the nose, throat, vagina, or rectum.

Dr. Allen exhibited an improved form of snare which could be used with one hand.

The following were appointed

THE NOMINATING COMMITTEE:

Drs. Beverley Robinson, of New York; W. C. Glasgow, of St. Louis; and S. H. Chapman, of New Haven.

AFTERNOON SESSION.

Dr. John N. Mackenzie, of Baltimore, read a paper on

THE PATHOLOGICAL NASAL REFLEX: AN HISTORICAL STUDY.

The fact is established beyond doubt that a causal relation exists between diseases of the nasal mucous membrane and other portions of the respiratory tract and many conditions of distant parts of the body. Hay fever can be traced to the time of Galen. The fact that tickling of the nose would arrest hiccough is referred to by Plato. The irritating effects of the odor of flowers were recognized in very early times. Reference was made to the observations of various individuals in regard to reflex conditions due to nasal disease.

Dr. John O. Roe, of Rochester, then presented a paper on

HAY FEVER; ANALYSIS OF CASES, WITH RESULTS OF TREATMENT.

Up to the last hay fever season, the author had treated 42 cases. A study of these cases tends to confirm the opinions expressed in February, 1883. Some of these views have been modified. Of the 42 cases 26 were males and 16 females. The attacks came on between May 1st and August 1st. In all, the active symptoms

subsided soon after the appearance of frost. In some cases the hay fever dated from a severe attack of cold. In every instance there was disease of the nasal passages. The location of the sensitive areas is not constant but they are usually most marked over the areas of greatest hypertrophy. The areas have not been confined to the posterior portion of the turbinated bones nor especially to the anterior portion of the turbinated bones. In the majority of cases the septum was as sensitive as the turbinated bones. Thirty-one patients suffered with asthma. But twelve patients had a distinctly nervous temperament, while nine were distinctly phlegmatic.

The plan of treatment adopted is to restore the nasal passage to as nearly as possible a normal condition and destroy the sensitive areas. These areas are to be destroyed by cauterization. Deep cauterization has been more effective, while superficial cauterization had no marked effect. The condition of the larynx, pharynx, and bronchi must not be overlooked; not infrequently enlarged tonsils will keep up irritation in the turbinated bones. A neglect to cure a bronchitis may account for the return of the disease. 35 of these cases have practically been cured; 17 have remained exempt for periods varying from one to nine years; 4 were not relieved, owing to imperfect treatment; and 4 have been lost sight of. The following conclusions were presented:

1. All cases of hay fever have the initiatory lesion in a diseased condition of the tissue of the nasal fossa.

2. All diseases of these tissues induce in the ganglionic centres connected with them an abnormal activity which is reflected to other organs.

3. The sensitive areas in the nose are not found in any particular parts of the cavity. Nor are there any zones which, when irritated, produce always the same manifestations.

4. The direction in which the irritation is reflected is always in the line of least resistance. Irritation in the same region may be reflected in one direction at one time and in another direction at another time.

5. The disease in the nose may produce disease in other portions of the respiratory tract which may become independent centres of irritation.

6. The affection recognized as hay fever is due to local irritations brought in contact with the sensitive areas in the nose.

7. The affection is not *per se* neurotic; nor is the so-called neurotic condition of the person necessary to render a person susceptible to local irritation applied to the air-passages. It is not necessarily associated with the nervous temperament.

8. The neurotic condition, which is often regarded as the cause of the hay fever, is often the result of the local irritation.

9. By careful and thorough treatment of the disease of the nasal tissue, combined with that of other portions of the respiratory passages below, which have become secondary sources of irritation, we need not fail to cure hay fever.

DR. SAJOUS had reported at the last meeting some cases in which the use of the cautery had been of only temporary benefit. He now believed that the failure was due to the fact that the cauterization was only superficial. Since he had employed deep cauterization, he had cured the disease.

DR. MACKENZIE regarded hay fever as a neurosis. He did not believe that it is a disease of the nose producing reflex symptoms. Where in hay fever disease of the nose is found, the question arises whether this is primary or secondary, or whether it is only an accidental condition. There is, he thought, always some more central cause than the affections of the nose. Where the disease is recent, it may possibly be arrested by the rest given by local treatment; but where the affection is of long standing, he did not believe that simple local treatment of the nose will overcome the difficulty. Last summer, in treating hay fever, he made no application to the nose, and yet his results were better than ever before. He gave zinc, nux vomica, quinine, and arsenic in large doses.

DR. F. I. KNIGHT, of Boston, asked if any of the members had any experience with diversion of nervous influences in any of these cases? In one case coming under his notice, the attack was arrested by the patient breaking his leg. Another patient had the attack arrested after consulting a disciple of mind cure.

DR. W. C. GLASGOW, of St. Louis, held that the evidence shows that hay fever is not a local affection, but that it is a general nervous disturbance. It is difficult to judge of the influence of treatment, for in the same individual the severity of the attack varies from year to year. He believed that constitutional treatment is an important element in the case. Unless the disposition toward the disease can be eradicated, he did not believe that a perfect cure can be attained by the destruction of the mucous membrane of the nose.

DR. F. H. HOOPER, of Boston, had regarded hay fever as a neurosis, and had treated it in the manner spoken of by Dr. Mackenzie. This accomplishes great good, especially in young children. He had at present under treatment a case in which there is hay fever with asthma. Until this gentleman came to the speaker a few weeks ago, his nose had not been examined. In the right nostril there is a sharp ridge running along the septum, and coming in contact with the inferior turbinated bone. On the left side was a similar ridge. With this exception there was no special disease of the nose.

DR. SOLIS COHEN thought that the views of Dr. Mackenzie are very nearly correct. It had been his experience that poor people rarely become the victims of hay fever. He thought that, in addition to the neurotic element, coddling and high living had something to do with the induction of the affection. Many cases occur in those who are overworked, and have resort to stimulants. These patients are often benefited by rest in the mountains or at the seashore. He had obtained benefit by tonic treatment, modifying the diet and restricting the use of meat. The more we look upon this as a constitutional affection, and the less as a local condition, the sooner will we get at the truth. A large number of these sufferers have obstruction in the nasal cavities, but many have no such obstruction.

DR. ROE considered hay fever as the reflection of some irritation from the nasal chambers, which irritation is produced by some foreign substance coming in contact with the mucous membrane of the nose. Irritation reflected from other situations to the nasal chambers is not hay fever. He had never seen any evidence to show that this was a neurosis.

DR. DELAVAN read a paper on

THE TREATMENT OF ATROPHIC RHINITIS BY APPLICATIONS OF THE GALVANIC CURRENT.

Some years ago Dr. E. L. Shurly, of Detroit, recommended the use of the galvanic current in the treatment of dry catarrh of the pharynx and related cases in which benefit had followed its use. He also advocated the same treatment in atrophic rhinitis. There is no disease which is more discouraging to the physician and patient than atrophic rhinitis. Dr. Delavan has tried this method of treatment in certain cases. The positive pole of a constant current battery was applied to the nape of the neck, while the negative pole was applied directly to the mucous membrane by an electrode consisting of a copper wire around which absorbent cotton is wrapped. The strength of current employed varied from four to seven milliampères. In more recent cases of the affection the effect is marked, but even in the older cases the method is not without benefit. The author has found this measure useful in these cases and reported illustrations. The objection to the method is the amount of time which it requires.

DR. T. A. DE BLOIS has applied this method of treatment to two cases, one of atrophic and the other of hypertrophic rhinitis. In the first case there was almost complete loss of smell and taste. The applications were made three times a week for six months. Both cases were improved

DR. KNIGHT asked what experience the members had had with the use of plugging the cavity of the nose. He had used this measure and produced relief of the most distressing symptoms. One side of the nose is thoroughly stopped with a piece of absorbent cotton, which is allowed to remain three hours during the morning. It is then removed and the other side is stopped in the same way for three hours in the afternoon. He never had the least disagreeable effects from the use of the cotton in this way. The bad odor is greatly lessened.

DR. ROE had used the plugs of cotton, but with no other effect than to set up irritation. He had used with marked benefit the application of a weak solution of nitrate of silver five or ten grains to the ounce, the parts having previously been cleaned. This applied every other day almost entirely relieved the symptoms.

DR. SAJOUS remarked that the good effect obtained by Dr. Delavan was probably due to the irritating effect of the negative pole. He had used in two cases with absolute relief of the symptoms the application of chromic acid in a solution made by simply allowing the acid to absorb moisture from the air.

DR. S. H. CHAPMAN, of New Haven, then made some remarks on

MYALGIA OF THE PHARYNX AND LARYNX,

and called attention to certain peculiar conditions of the muscles of the upper air-passages, which occur oftentimes in malarial disorders and which on account of their severity are brought to the notice of the specialist. The muscles most likely to be affected are the pectoral, the muscles of deglutition, and those of the voice.

DR. F. I. KNIGHT, of Boston, opened the discussion on

SENSORY AFFECTIONS OF THE THROAT.

His principal experience has been with hyperæsthesia and paræsthesia. In hyperæsthesia the general condition of the patient is, as a rule, not sufficiently considered. The worst cases are alcoholic subjects and those with digestive disorders. These will often yield to withdrawal of the alcohol and regulation of the diet. Astringents are frequently of service. In the cases of paræsthesia which he had seen, there had been a feeling of fulness, pressure, burning, globus hystericus or the sensation of a foreign body in the throat. In these cases there is impairment of the general nervous system. The exciting cause may be some disease of the throat. Fatigue usually exaggerates these sensations. He had never met with paræsthesia of the larynx as the earliest symptom of phthisis, as had been claimed by some observers. The prognosis in most cases of paræsthesia is good if a careful treatment be carried out. The treatment of the neurosis of sensation must be aimed to cure the constitutional vice.

DR. W. C. JARVIS, of New York, recently saw a man complaining of pain on either side of the tongue which had existed for the past two years. He was suffering from the effects of syphilis and with the neuralgia of the tongue there were frontal neuralgia and pains in other parts of the body. The speaker has another patient who consults him every five or six months on account of a severe pain in the right anterior pillar of the fauces. He believes that it will terminate in cancer. It disappears for a week at a time and then returns. He believed that in this case the trouble is psychical and that there is no pathological lesion to account for it.

DR. SAJOUS has seen two or three such cases. In one there was follicular pharyngitis, and although the pathological condition was cured the pain remained. The pain seemed worse in damp weather and the patient had the habit of bathing every morning in cold water. The history of the case seemed to indicate a rheumatic trouble and such may have been its nature.

DR. GLASGOW said that many of these cases, he thought, were due to malaria and some to the gouty diathesis. Sometimes the trouble is kept up by a single hyperæsthetic follicle. A reduction of the inflammation will be followed by a subsidence of the neuralgia. Sometimes the source of irritation is found with difficulty. In the rheumatic cases there is usually exacerbation at night. These affections in some cases appear to have a tendency to the induction of melancholia.

FRIDAY, MAY 27TH.—MORNING SESSION.

DR. FRANK DONALDSON, JR., of Baltimore, reported some

FURTHER RESEARCHES UPON THE FUNCTION OF THE RECURRENT LARYNGEAL NERVE.

At a previous meeting he had read a paper criticising certain conclusions advanced by Dr. F. H. Hooper, of Boston. The conclusions which Dr. Donaldson reached were, that the constrictors do not cease to act under deep narcosis or suspension of consciousness from any cause; that we do not always obtain abduction on irritation when consciousness is suspended; that the abduction was not reflex and was not dependent on unconsciousness; that it is with weak stimuli that abduction takes place, and the movement passes into adduction as the stimulus is increased. These results invariably followed whether the animal was slightly or

deeply narcotized, or where the medulla was destroyed, or when local death had taken place; that after strong or continued stimuli the abductor muscles became worn out and did not respond to stimuli.

These conclusions had been strongly criticised, and the present series of experiments were performed to test the correctness of the above views. He had shown that abduction of the vocal bands can be obtained without ether, and that it is a physiological fact that opening or closing of the larynx depends upon the strength of the stimulus. With weak stimuli abduction was produced, while with strong stimuli adduction was caused.

DR. F. H. HOOPER, of Boston, then read a paper on

THE ANATOMY AND PHYSIOLOGY OF THE RECURRENT LARYNGEAL NERVE.

He said that the anatomy of this nerve is now complete and exact, but up to a very recent date much confusion existed on this subject. To find out why these nerves are recurrent, it is necessary to begin with the embryo. The recurrence is due to certain changes in the branchial arches and the descent of the heart into the thorax. At one time in the period of development, these laryngeal nerves are straight, but as the heart descends they are brought down. The proof of this is found in the abnormal condition of the nerve in cases of irregularity of the great vessels which branch from the aorta. These nerves (at least in dogs and cats) contain no sensory fibres.

The larynx possesses three functions controlled by three distinct sets of muscles, all innervated by the recurrent nerves. These functions are: 1. Respiration; 2. Sphincter action, which closes the larynx and prevents the entrance of foreign bodies, and plays an important part in expulsive acts; 3. Phonatory action.

Stimuli applied to recurrent nerves produce adduction in certain animals (dogs), and abduction in other animals (cats). Only a few experiments have been made in man, but, as far as they go, they seem to show that stimulation closes the glottis. Under ether or profound morphia narcosis, stimulation of the recurrent nerves produces opening of the glottis in dogs. Three hundred and twelve experiments were reported; some of the animals were under the influence of chloral, chloroform, morphia, or ether. Under ether, dilatation was produced with weak currents, while contraction could not be produced with even the strongest current. As the dog begins to come out of the ether, dilatation cannot be induced with any current, while contraction is brought about by currents decreasing in intensity as the effect of ether passed off. A similar effect was observed in one case after the use of a large dose of morphia. After small doses of ether stimulation produces two effects, first vibration, second closure. Under large doses of ether four effects were observed, according to the intensity of the irritation—vibration, complete dilatation, mixed movement, and closure. After small doses of morphia, chloral, and chloroform, stimulation produces the same effects as after small doses of ether.

DR. KNIGHT said that such different results are obtained in different animals, resulting from differences in size, weight, and other conditions that they must be applied with a great deal of reserve to the human being. He saw some of the experiments of Dr. Hooper. In one case he saw a failure to get the ether effect, which was attributed to the size of the dog.

DR. S. W. LANGMAID, of Boston, said that in one of Dr. Hooper's experiments recently made, the skull was trephined and insensibility produced by pressing a plug against the cortex. In this case dilatation was very marked under stimulation of the recurrent nerve. That was the only case in which he had seen dilatation similar to that which he thought Dr. Donaldson described. In some cases he found it difficult to say exactly what he did see.

DR. M. ALLEN STARR, of New York, recently had an opportunity to see in Paris some experiments by Charcot on hypnotized individuals. It is well known that in this state slight percussion of a nerve will produce contraction in the muscles supplied by that nerve. In one of these cases, slight stroking in the course of the recurrent laryngeal nerve over the trachea below the larynx, produced such adduction of the vocal cords, and so interfered with breathing, that it became a question whether it would not be necessary to resort to tracheotomy.

DR. HOOPER said that he had been trying to get the effect with feeble stimuli which Dr. Donaldson described, but had been unable to do so. The only point on which they disagree was with reference to the effect of weak stimuli in unnarcotized animals. He had done a number of experiments following the method of Dr. Donaldson, but had not gotten his results.

AFTERNOON SESSION.

DR. WILLIAM C. GLASGOW read a paper on

CERTAIN MEASURES FOR THE RELIEF OF CONGESTIVE HEADACHES.

The most severe symptoms in this condition are the pain and sense of constriction of the forehead. If the pain is analyzed, it will be found that it is of two kinds. One gives a dull sense of fulness and occasional throbbing over the temple. The other is of the sharp, lancinating character so generally known as neuralgia. At times both of these varieties are present in the same case. In the one there is fulness of the vessels, and in the other disordered nerve action. Both varieties are often due to the same pathological condition of the nasal chambers. During congestive headache, if we examine the nose we find that the cavernous bodies are full and tense. The degree of tenseness corresponds, to a certain extent, to the degree of headache. The method of treatment which he had adopted during the past four years had been the local abstraction of blood. A knife is not required, a simple prick is sufficient. In many cases the relief is immediate. The operation may have to be repeated in a month or two. He had seen few cases in which permanent relief had not followed a repetition of the operation from two to six times. The amount of blood drawn rarely exceeds an ounce. A number of illustrative cases were cited.

DR. MACKENZIE stated that the paper goes to prove certain views which he had advanced with reference to turgescence of the turbinated bones during the menstrual periods. He thought that a number of headaches occurring during menstruation are due to congestion of

the turbinated bones. Some years ago he advised that in acute coryza an incision be made in the turbinated tissues with a sharp-pointed bistoury.

Dr. C. C. Rice, of New York, said that his experience was somewhat different from that of the author. So far as chronic hypertrophic catarrh is concerned, he had come to look in the cases of headache for hypertrophy over the middle turbinated bone, pressing against the septum. He had seen many such cases; there had not been much congestion, but simply contact. In these cases he had used the galvanic cautery, and had not tried to draw blood. He thought that it is sufficient to cause counter-irritation without bleeding.

Dr. Harrison Allen, of Philadelphia, was more in accord with the last speaker than with the author. The trouble may come from the turbinated bones, but he had attributed it to pressure effects. We know that when the septum is deviated it is usually with the convexity to the left, but if a careful examination is made, it will be usually found that there is in the upper part a deviation in the opposite direction. This brings it in contact with the middle turbinated bone. The proper treatment is to separate the parts. He does not hesitate to etherize the patient, and introduce the finger and push the septum into place. In one case, a lady came to Philadelphia with a complication of disorders. There was astigmatism, and also a lacerated cervix. She was under the care of an oculist and of a gynecologist. Each of these gentlemen attributed the trouble to the condition belonging to his special department. She had reflex headaches which were so severe as to lead to a fear of mental aberration. On examining the nose he found the condition referred to above, and insisted that the headache was due to the trouble in the nose. He etherized the patient and separated the parts with the finger. The headaches entirely disappeared.

Dr. Sajous said that while the lesions described by Dr. Allen may be found in a number of cases, he was more inclined to consider headaches originating in the nose as due to hyperæsthesia. He thought that this is proven by the effect of light cauterization, and the treatment of Dr. Glasgow also goes to show that by depleting the cavity he reduces the stretching and pressure on the nerves, and therefore reduces the hyperæsthesia.

Dr. F. H. Bosworth, of New York, remarked that it is a fact that in many cases where we find contact between the middle turbinated bone and the septum there are no symptoms that can be referred to this condition. Judging from analogy, we have in no other portion of the body neuralgia caused by the contact of mucous surfaces. In the vagina and in the urethra we have mucous surfaces in contact. We may, however, safely say that it is a proper course to pursue to put the nasal cavity into a condition as near normal as possible.

Dr. Glasgow remarked that his paper said nothing at all about hypertrophy. No one recommends bleeding for hypertrophies, for these do not bleed. The fulness of the cavernous sinuses is simply the sign of the fulness of the frontal sinuses. He did not regard it as the cause of the trouble. He takes blood from this part simply because this is the most convenient place to do it.

AMERICAN SURGICAL ASSOCIATION.

[illegible]

[illegible]

[illegible]

Friday, May 13th—Third Day.

Morning Session.

The following surgeons were elected to membership: Charles B. Porter, M.D., of Boston; William M. Mastin, M.D., of Mobile; and Morris H. Richardson, M.D., of Boston.

The Committee on Nominations reported the following list of

OFFICERS FOR THE ENSUING YEAR.

President.—D. Hayes Agnew, M.D., of Philadelphia.
Vice-Presidents.—N. Senn, M.D., of Milwaukee,
F. S. Dennis, M.D., of New York.
Secretary.—J. R. Weist, M.D., of Richmond, Indiana.
Recorder.—J. Ewing Mears, M.D., of Philadelphia.
Treasurer.—Phineas S. Conner, M.D., of Cincinnati.
Member of Council.—John S. Billings, M.D., of Washington.

Dr. L. McLane Tiffany, of Baltimore, read a paper on

SURGICAL DISEASES OF THE WHITE AND COLORED RACES COMPARED.

He stated that the present paper was intended to be only preliminary in character. The statistics presented were prepared from the records of 4930 surgical cases, most of them derived from out-door patients, but some of them were also traced into hospital. Of the 4930, 64 per cent. were white, and 36 per cent. negro. Included among the negroes were also mulattoes. He had observed that, while there is a considerable difference between the whites and the black negroes, in their behavior in disease, this difference was subject to gradations corresponding to the gradations of color.

Most of his observations were presented in tabular form.

The two races were subject to the following diseases in the percentages annexed.

	White	Negro
Abscess	57 per cent.	43 per cent.
Vascular	42 "	58 "
Axilla and breast	44 "	56 "
Hand		
Fingers	75 "	25 "
Paronychia		
Enlarged glands		
Neck		
Axilla	41 "	59 "
Groin		

Pus formations are exceedingly likely to occur in the negro. In syphilis, early adenopathy, sometimes huge masses form in the groin, and these often suppurate. Chronic syphilitic suppurations are often encountered, but less frequently than scrofulous ones.

The following table illustrates the frequency of the diseases named:

	White	Negro
Ganglion	85 per cent.	15 per cent.
Bursal enlargements	92 "	8 "
Hydrocele	94 "	6 "

	White	Negro
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
Hemorrhoids		
[illegible]	[illegible]	[illegible]
Internal	82	18
[illegible]	[illegible]	[illegible]

Spinal caries is most frequently located in the dorsal region of the negro. Cured Pott's disease in the middle aged negro is very rare.

Dislocations are more frequent in the white, as is illustrated by those of the humerus, 82 per cent. white, 18 per cent. negro.

Lateral curvature of the spine is more frequent in the white.

Keloid is characteristically more frequent in the negro than in the white, and presents certain differences of appearance. In the white it is frequently seen in middle life, and frequently commences at puberty. In the negro it typically belongs to adolescence. It is at first smooth, becomes seamed, is not painful. It commences in the skin, may be spontaneous, but is usually from a scar, following slight injuries, as ear-puncture. It is liable to retrograde metamorphosis, and exhibits slower growth with advancing years. In this regard he thought the tendency to keloid formations disappears in later life, and that its removal is then permissible.

Lipoma is most frequent in the negro; sebaceous cyst more frequent in the white (88 per cent.); nævus also more frequent in the white.

Carcinoma has been more frequently encountered in the white. The essayist had never seen an epithelioma of the lip or any part of the face in a negro. Osteosarcoma is, however, frequent in the latter. The pure ovarian cyst is more frequent in the white, but fibromata or adeno-fibroma is much more frequent in the negro.

Gonorrhœa, acute, 50 per cent. white; chronic, 62 per cent. white. It seems not to give the negro much trouble. Epididymitis was encountered in the white in 59 per cent. Gonorrhœal rheumatism is rare in the negro. Chronic urethral discharges were frequently encountered in the negro, which had not been paid attention to and cared for. Inflammatory gonorrhœa was rare in the negro. Carter and McIntosh (*New York Medical Journal*, No. 13, 1886) think stricture rare in the negro as compared with the white, giving the percentage as 1 to 8 in the white, and 1 to 23 in the negro.

Bubo, chancroidal, 49 per cent. white, 51 per cent. negro; gonorrhœal, 37 per cent. white, 73 per cent. negro. Inflammatory phimosis was in the proportion of 27 per cent. white, 73 per cent. negro, usually chancroidal, frequently of the preputial orifice. Rachitis, 37 per cent. white, 63 per cent. negro.

In hospital he observed that the negro bore operations well—better, as a rule, than the white—but their reaction after accidents was not so good as that of the whites.

In conclusion, he offered the following suggestions:

1. Surgical affections pursue different courses in the white and colored races under identical hygienic surroundings.

2. Surgical operations and injuries are better borne by negroes than by whites.

3. Surgical diseases involving the lymphatic system, especially tubercular, are more fatal in negroes than in whites.

4. Congenital deformities are more rare in negroes than in whites.

5. Surgical differences observed between negroes and whites are due to racial peculiarities.

Dr. Christopher Johnston agreed with the conclusions in general, but added that there are individual peculiarities that are as great as any others. He also had observed that the negro bore surgical operations better, and required less hospital treatment, than the whites. He had never observed carbuncle in the negro. He had, however, observed epithelioma in a few cases; the first penis he ever amputated being that of a dark negro for this disease. Fibromata are more frequent than in the white race. Keloid, also, is characteristically prominent in the negro. The skin and lymphatic tissues are more liable to disease than in the white race.

Dr. T. G. Richardson briefly sketched the records of a few diseases in the New Orleans Hospital. Of 28,090 cases, more than 8000 were colored. The diseases appeared the following number of times in each 1000:

	White	Negro
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
Epilepsy	135	46
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
Stricture of the urethra	123	85
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	181	41

He omitted syphilis, for the reason that he could present nothing of value; since syphilitic negroes were not provided with a separate ward, and were treated for the most part at home. He could corroborate the statements of Drs. Tiffany and Johnston that it is rare to find congenital deformities in the negro. He concluded by calling attention to the fact that his statistics gave only the number of cases treated without taking into consideration the relative proportion of each race.

Dr. E. H. Gregory considered it a striking contrast that pus formation is so frequently associated with syphilis in the negro. His experience might not correspond with that of others, but he has very seldom found pus formed in connection with the local manifestations of syphilis, and he has never regarded a suppurating local lesion as syphilitic in character. He has always been accustomed to regard such a lesion as local, and not as an evidence of constitutional infection. He agreed with Dr. Tiffany, that the most extraordinary examples of keloid that had come under his observation have been in negroes. He had never seen multiple keloid in the white, whereas it is common to find several of these tumors in the negro. Nor had he seen a keloid as large in the white as in the negro. The point that the disease is less likely to form after middle life was new.

The inference to be drawn from Dr. Tiffany's paper is that the negro is below the white man, that he is not

[illegible]

a standard organism. If it be a fact that the negro is more apt to produce pus, it follows that his resistance to the incursions of disease is less than that of the white man. He assumed that all strumous disease is due to the presence of a microörganism, usually being associated with tubercle. Now it is the weakest of all organisms that will entertain the bacillus tuberculosis, the weakest of all microörganisms. It always seemed to him that the reparative process is in proportion to the energy of the body, and whenever we lower the scale of the organism, our reparative processes are relatively feebler; but if the negro have stronger power of resistance, he did not see how he can be more liable to these diseases. It may be harder to persuade the negro that he is sick. The indifference of the negro may play some part here. The negro cannot be supposed to form any adequate idea of the magnitude of a surgical operation, as it would appear to a white man. In this way we may account to some extent for the fact that he stands surgical operations better than the latter.

He had never seen a cancer on the lower lip of the negro, and thought it singular that stricture of the urethra is uncommon in the negro; whereas he had frequently thought certain strictures partook of the nature of a keloid formation, which is of acknowledged frequency. He had never seen a ganglion in the negro, although they are common in the white man.

From an examination of the records of the hospital in St. Louis, he had arrived at the conclusion that the negro bears surgical operations about as well as the white man, but he could not say that he had any advantage in that regard. Negroes are tubercular, and mulattoes are even more exposed to the disease than the black negro, so that they ought to make the worst subjects of surgical operations.

DR. W. T. BRIGGS had prepared no statistics on the subject, but his experience confirmed in a remarkable degree the statistics of Dr. Tiffany. The negroes in Memphis, he added, live mostly in little low cabins; they live on the cheaper articles of diet, eat enormously, and consequently, it is not remarkable that they are of a lower degree of vitality than the whites, and that they are subject to scrofula. It is seldom that a negro is not the subject of a scrofulous diathesis. They are, therefore, more subject to suppurations; almost any occasion will give rise to a suppuration. Nearly all operations will have a suppurative action; and sometimes they are very prostrating. Nnegros bear a surgical operation probably better than whites, the mere operation itself, because they can have no appreciation of the magnitude of an operation, or the dangers to them; nor do they care much as to the result. They have more religion than white men and are not so much afraid to die. When in the hospital they are better off than at home, and do not care to get out, and for this reason their convalescence may be longer. Their temperature seldom rises so high as that of the white man, but that they recover as rapidly as the latter, he did not believe. In regard to malformations, while he did not think that they are so frequent in the negro, yet he had met with all kinds of malformations; he had seen half a dozen club-feet in the negro, and he has operated upon the negro for harelip. Spina bifida he had seen on several occasions; hydroceles do occur; the first case he operated upon was in a negro, and was of enormous size, reaching almost to the knee; and he sees a case, on an average, once a year. Keloid is common, and if removed returns twice as large. Cancerous affections are not as common as in the whites. Lupus of the face is frequent, and is frequently seen upon the penis also. Uterine fibroids are very common in the negro, and the greatest number of tumors in the negro race belong to that class—fibroids or fibro-cystic tumors. He had twice a typical ovarian tumor in a negro.

DR. D. W. YANDELL agreed in almost every particular with the remarks of the previous speaker, but he had never seen keloid in the white man. Epilepsy is exceedingly rare among negroes. Tetanus is exceedingly common. He had never seen a case of internal hemorrhoids, and only two cases of fistula in ano. Livingstone, in his travels in Africa, as the speaker had been informed by President McGuire, reports no hemorrhoids and no dyspepsia among the Africans. He thought the latter statement correct, because they can eat anything and everything, and are always ready to eat. Stricture of the urethra, in his experience, was exceedingly common.

DR. KINLOCH desired to call attention to two points: first, the liability of the negro to suppuration, and, second, his power to undergo operations and recover from them. He thought it a mistake to class all negroes together in regard to the liability to suppuration. It is difficult to separate the negro from the hybrid mulatto. He differed from some of the speakers with regard to the liability of the pure negro to suppuration, for he thought this liability much less than in the white man. He did not think that the pure negro is as strumous as the mulatto, nor that the former is affected with the extremes of syphilitic disease; the poison seems to die out more readily in them. The mulatto, on the other hand, is almost always strumous; we constantly see them in our hospitals with suppuration in the glands of the neck and groin. Syphilis rarely ends with them, but passes on and becomes mixed up with struma, and it is difficult to say whether you are treating syphilis or struma. The negro, he thought, recovers well. This is in part probably owing to the character of his nervous system. The negro is more apathetic, as Dr. Briggs has said, and has not to contend with the peculiarly depressing influences on the nervous system.

DR. A. VANDERVEER stated that his experience in connection with the Albany penitentiary, where a large number of negroes were received from the South as government prisoners, was that the vast majority of these who died, succumbed to some form of tuberculosis. Of those who come and are examined at the time, many are found to have soft chancres and the suppurating bubo which accompanies the chancre is slow to heal; but when they get a true Hunterian chancre, they present the true bullet bubo, which compares well with that of the white race. There is a much greater number of perineal abscesses after urethral strictures than in the white, but when they are operated upon there is a less percentage of urethral fever, and they generally recover well.

DR. L. MCLANE TIFFANY thought that it should be remembered that the true negro is at present very seldom seen. The difference between the resistance of the true negro and that of the mulatto is well illustrated in the teeth. The negro seldom loses his teeth, but the

mulatto has teeth of no resistance at all. Studying the peculiarities of the negro race, he said, is a sort of laboratory work. It is at present a question, what soil is best suited to the cultivation of the infectious organisms. Just as in the laboratory we learn what soil, whether gelatine, potato, bouillon, or what not, is best suited to the cultivation of a particular germ, so we must ascertain what race is most susceptible to the growth of peculiar germs.

Dr. B. A. Watson then related

AN EXPERIMENTAL STUDY OF THE EFFECTS OF PUNCTURE OF THE HEART IN CASES OF CHLOROFORM NARCOSIS.

(See page 619.)

Dr. N. P. Dandridge remarked that the interest in such experiments as these is the practical deductions we can draw from the investigations on animals to man, and here he thought we should be exceedingly careful not to apply too freely these deductions; for the conditions which present in the human being under chloroform are very different from those in the animal under experimentation. In animals the anæsthetic is pushed purposely to a dangerous degree; in some instances the anæsthetic was given at first in a fatal dose. The accidents which happen with chloroform very often occur when only a small amount of chloroform has been taken—in the beginning of the giving of chloroform and before the operation has commenced—the result being probably due to its inhibitory action on the heart.

It appeared to him that there was one point in which the experiments did not illustrate fully what was desired, and that was the question how long after the failure of the heart the puncture will stimulate the cardiac action. It is not at all unusual in cases of accident with anæsthetics, for recovery to take place after apparently fatal failure of the heart's action has occurred, without the adoption of any such measure as that referred to in the paper. If in the experiments the puncture has been successful after the lapse of five or ten minutes, the result would have been much more valuable. In the paper presented by Dr. Senn on "Air Embolism," a few years ago, it was shown that in animals in which there was impending death from the introduction of air into a vein, a certain number could be relieved by direct aspiration of the right auricle, provided it was done rapidly, and provided the amount of air was not excessive. The object of his experiments, however, was to relieve distention and not simply to stimulate by the traumatism the muscular fibres of the heart. With reference to the comparative safety and efficiency of puncturing the right auricle and the right ventricle, he thought that in the human subject it would be much easier as well as safer to puncture the auricle.

Further, the comparative availability of this measure with artificial respiration, the inhalation of the nitrite of amyl, and the hypodermatic injection of the sulphate of atropia should be carefully considered. The preliminary injection of morphia and atropia has, he thought, a particular influence in the prevention of heart failure.

Dr. John B. Roberts thought the paper instructive in two directions, one intentionally instructive, the other, perhaps, unintentionally so. Dr. Watson has shown the stimulating effect of puncture of the heart, especially if the ventricle be struck; he has shown, also, the almost constant possibility of producing death by the inhalation of chloroform. In his experiments he has shown not only that the stimulating action is greater if the ventricle be punctured, but that the danger is less. That puncture of the auricle would be more dangerous would be naturally supposed from the fact that its walls are much thinner than those of the ventricle, and consequently less likely to prevent the extrusion of blood.

The point raised by Dr. Dandridge, that in these experiments a large quantity of chloroform is given, whereas in the human subject only a very small quantity is often given, led him to take rather the opposite ground, for he thought the measure would be more likely to prove successful in man under a small amount of the anæsthetic than it would in dogs under a large amount, provided dogs and men are susceptible to the same treatment. The paper of Dr. Senn was *à propos* in this connection, inasmuch as that author found that the withdrawal of blood from the heart cavity stimulated its action. With reference to the injection of atropia in chloroform and ether narcosis, he thought that there could be no doubt as to the drug being a cardiac stimulant, but its physiological action is slow, probably more so than that of digitalis. Reference was also made to the experiments of Westerbrook on the human subject under the idea that he could probably relieve the engorgement of the heart by withdrawing blood. The speaker was particularly gratified to hear Dr. Watson say that it is safer to puncture the ventricle than the auricle, for Dr. Westerbrook had taken the ground that the right auricle could be more safely punctured than the right ventricle, which seemed to him erroneous.

Dr. L. McLane Tiffany thought the record of experiments was open to marked criticism. First, it is well known that the dog under chloroform behaves in such a peculiar manner, that for experimental work in laboratories chloroform is never used. The dog behaves absolutely differently under chloroform from the human being. It is not, therefore, proper to make deductions from the dog to the human being. Another point was with regard to the conclusions adduced by the experimenter, that it was advantageous to puncture the heart in chloroform narcosis; but whether it was the heart of a dog or that of a human being was not stated. If the human heart was meant, he could not agree with Dr. Watson. It is very different to do a thing in the laboratory and advise others to do it in practice from actually carrying it into practice.

Dr. R. A. Kinloch had punctured the heart in a case of chloroform narcosis. He was about to operate upon a patient for diffuse abscess of the skull. Instead of using the "A.-C.-E." mixture as was his custom, his assistant anæsthetized the patient with chloroform. It was seen that the patient was about to die. All the usual expedients were resorted to, but the patient appeared to be dead. An assistant suggested puncture of the heart. The ventricle was twice punctured. No effect was observed. A long hypodermatic needle was used.

Dr. W. A. Byrd called attention to the combination of bromide of ether, chloroform, and ether which he had been using. Only a drachm or two is required to produce anæsthesia, and he had used it many times with no bad symptoms.

Dr. Thomas J. Dunott, of Harrisburg, reported a

case in which the heart had been twice punctured. The first puncture was made for the removal of pericardial fluid. The case was one of dilated heart, with general dropsy, œdema of the lungs, etc. The patient fell into the hands of some irregular practitioners. They borrowed an aspirator from a neighboring surgeon and aspirated the patient. They stated that they had withdrawn a large amount of fluid from the pericardium, which immediately coagulated; but it was otherwise learned that the fluid was pure blood. The patient seemed benefited by the operation and recovered. Subsequently, however, the operation was repeated, and the patient died.

DR. WATSON, in closing the discussion, replied first to the remark of Dr. Dandridge, that there was no clear statement in the paper as to how long after the cessation of the heart's action remedial aspiration may be accomplished. The experiments, as read by him, on the contrary, show that he had repeatedly excited the action of the heart three minutes after its cessation. In one instance he had punctured four minutes after and got no response. It is quite certain that vitality remains and that there is a certain irritability that remains for a certain period, possibly not a fixed period after cessation of the respiration; but to determine this period would require a vast number of experiments.

With reference to the puncture of the right auricle and ventricle, he had arrived at two conclusions. First, the walls of the auricle are very much thinner; there is much less muscular tissue to be irritated. It is in every sense the reservoir of the heart. The propelling power resides in the strong muscular ventricles. There is another reason for not puncturing the right auricle; because, since the walls are thin, the puncture endangers the life of the patient from the consequent leakage. The needle, when left in the walls of the ventricle, does not produce laceration, but it does so if left in the thin walls of the auricle; and he thinks the same occurs when the auricle is punctured. There is no leakage from the right ventricle, or, if any, it is from the cardiac veins, and not of any consequence. The main hemorrhage from the cardiac veins was in his experiments comparatively trivial; with regard to the difference between the action of chloroform upon the animal and the human being he was familiar. The difference, however, is all in favor of the man, and not of the dog. Chloroform cannot be continued as an anæsthetic any length of time in the dog. At a former meeting of the Association he had shown that when attempting to make some experiments under chloroform, half his dogs were lost. The same pathological conditions are found when chloroform is used upon the dog, as when it is used upon man. It is found constantly that the heart is in diastole, and that the veins of the lung are engorged, unless previous hemorrhage have taken place.

Now the object of the heart puncture, he continued, is twofold: First to irritate the muscles and cause contraction. He thought that his paper would lead to the conclusion that the puncture does, by its irritation, cause muscular contraction. Now you may have muscular contraction still taking place, but if the heart is distended with blood, and if the heart does not contract strongly enough to propel this column of blood what occurs? The heart becomes paralyzed. Now he thinks that in addition to puncturing the heart it is advisable to enter the ventricle and withdraw some blood. The walls of the heart are paralyzed by overdistention, just as occurs when the walls of the bladder are paralyzed by overdistention. The experiments showed better results when he succeeded in withdrawing some blood, than when he simply punctured the ventricle.

With regard to atropia, he expressed greater confidence in a needle thrust into the heart than in atropia. The rapid use of chloroform, he added, does not produce the most favorable condition of the animal for resuscitation. Professor Sayres believes that chloroform should be given rapidly, by excluding all atmospheric air. His experiments showed that in two instances, where chloroform was thus given, the heart's action continued a little longer than respiration; and that when it was cautiously given, he found that in every instance its action was more uniform, and that it did not kill the animal so quickly. Sometimes in experimenting on dogs one finds that the animal dies suddenly after having taken only a very small amount of chloroform, while in other instances a large amount is required. In one instance the animal breathed eight minutes after the cessation of the heart. The dog could be aroused two or three minutes after the heart ceased to beat. It is better, therefore, to give chloroform cautiously, and with an abundance of atmospheric air. In the first forty experiments he had determined to kill the dog as quickly as possible; while, in the latter, he was not so rapid with the anæsthetization, and he had resuscitated six of the last twenty dogs.

(To be concluded.)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 19, 1887.

THE PRESIDENT, A. JACOBI, M.D., IN THE CHAIR.

DR. L. EMMET HOLT read a paper on

SPONTANEOUS ABSORPTION IN EMPYEMA IN CHILDREN, AND THE RELATIVE ADVANTAGE IN CHILDREN OF ASPIRATION AND EARLY INCISION.

He said that more than one-half of all cases of empyema occur in subjects under ten years of age. The prognosis, however, is better at this than any other period of life; there being different causes in the different classes of cases. Spontaneous absorption may possibly occur, but it is exceedingly rare, and he had been able to find but two cases of this on record in which the diagnosis was verified by the test of the hypodermatic syringe. Formerly, evacuation through a bronchus and an external opening had been regarded as the most favorable termination of the condition, but he had not succeeded in finding much definite information in regard to its frequency or results. Pneumothorax, he believed, is very rarely produced in children. On the whole, it is evident that the chances of recovery by means of nature's unaided efforts, are extremely small.

Having remarked that empyema is in reality nothing but an abscess with the peculiarity of having its outer wall rigid, and its inner wall yielding, he said that the indication for treatment is to try to get rid of the pus in the easiest and safest manner possible, and that the

only methods which he should discuss were those of aspiration and free incision. The advantages claimed for aspiration are: (1) simplicity; (2) freedom from danger; (3) that it does not remove the fluid rapidly; (4) that it does not require general anæsthesia; (5) that it does not require the confinement of the patient to bed; and (6) that many cases are cured by aspiration alone. As a matter of fact, he said, these alleged advantages, with the exception of the last, are not superior to those possessed by incision. Of 121 cases of aspiration collated by him, 23 cases, or 19 per cent., were cured, and 6 died. The remainder were subjected to other methods of treatment. In all but one of the 21 successful cases the empyema was localized, and in 8 a single aspiration was sufficient to effect the cure.

Aspiration has many obvious objections, and among them are the following:

(1) The entire quantity of fluid cannot be removed by this means. (2) Where septa exist in the pleural cavity, but one division of the latter may be evacuated. (3) The terror excited in children, especially when the aspiration has to be repeated a number of times, constitutes a serious obstacle to its success. (4) There are certain cases in which aspiration is not available, and if the case is allowed to go on for a considerable time without evacuation, septicæmia, and other dangerous consequences, are likely to ensue.

Among the advantages of incision are, first, its universal applicability, and, secondly, the fact that it enables the surgeon to explore the pleural cavity thoroughly. While the exposure of the cavity and the admission of air were formerly well-founded objections, since the introduction of antiseptics this is no longer the case. As to the use of general anæsthetics, Dr. Holt said that in two instances he had seen death result from this cause, in consequence of the rupture into a bronchus. He had never known of this untoward result to occur in children, but these cases ought to be sufficient to warn us against the employment of general anæsthetics when emphysema is present. He did not know whether local anæsthesia by cocaine had been resorted to in this connection, but he should suppose that this would answer every purpose.

Considering the results that were met with, it is no wonder that a low estimate was entertained of the operation by the older surgeons, and Dr. Holt quoted the opinion of Sir Astley Cooper and others, whose experience led them to regard it as almost necessarily fatal. He had collected 59 cases in children, performed at a later period, but before antiseptics had come into as general use as at present, in which there were only 8 deaths. Out of 63 cases in which the operation was performed with strict antiseptic precautions, however, there were but two deaths, and he thought that no more complete evidence could be furnished of the advantage of antiseptics than this. As to duration, out of 80 cases in which antiseptics were used, 5 cases lasted four months, or more, and in the remaining 75 the average duration was six weeks. In 21 the duration was one month, or less. In cases in which antiseptics were not employed, the average duration was six months.

The conclusions at which he had arrived were as follows:

(1) All methods yield better results than non-interference. (2) A case should never be left to the unaided efforts of nature. (3) Aspiration holds out a possible chance of cure. (4) If, after two aspirations, the fluid continues to accumulate, this method should not be persisted in. (5) In large effusions, it is well to make one aspiration before resorting to incision. (6) In all other cases a free incision should be made, preferably under local anæsthesia.

Finally, he said, no better guide could be observed than that contained in the words of Wagner: "Early incision, perfect drainage, and complete antisepsis."

DR. F. HUBER read a paper on

ACUTE EMPYEMA IN CHILDREN.

He claimed that no medicinal agent has any effect in producing absorption, but symptomatic and palliative remedies are of service, and it is important that the patient should be placed in the best hygienic surroundings possible. As regards surgical interference, the more promptly this is made, in general, the better will be the results obtained; provided it is not during the first few days of the attack. As a rule, he had found it better to wait until a week or ten days had passed, so as to allow the acute febrile symptoms to subside, and give the patient a chance to rally. After this judicious delay, aspiration might be tried first; the hypodermatic needle having been previously inserted at the point where the aspiration was to be made, in order to be sure of the presence of pus in this situation. Anæsthetics are not required in this operation.

If, after aspiration, the pus is found to be laudable and inodorous, and if it does not accumulate very rapidly again, aspiration may be repeated; but, as a rule, more radical measures are called for. Incision should not be longer delayed, because the disease is characterized by fibrinous deposits, as well as purulent effusion, and the fibrin is liable to become decomposed and infectious. The incision should be from an inch to an inch and a half in length, and a drainage tube inserted; after which the cavity should be washed out with antiseptic fluid, and an antiseptic dressing applied. He had found local anæsthesia by cocaine to be all that was required for this operation.

Of thirteen cases in which he had performed it, three had proved fatal; one of the children dying from exhaustion, one from gastro-intestinal catarrh, and one from erysipelas. All but two of the remainder had made perfect recoveries, and the average duration of the trouble was seven weeks. He had used injections of bichloride solution (1:5000) in all his cases; and for the final injection a solution of 1 to 10,000. A good rubber tube is essential, and he is in the habit of employing the plan proposed by Baxter for preventing it from slipping into the cavity. The retraction of the chest remaining on the affected side, he had found could readily be overcome by suitable gymnastics and exercise in the open air.

DR. ROBERT ABBE then read a paper on

GENERAL CONSIDERATION OF THE SURGICAL TREATMENT OF EMPYEMA.

In the treatment of empyema, he said, it is necessary to abandon all idea of securing absorption, and the first thought should be how to rid the patient's chest of the accumulated pus most promptly. Aspiration may be repeated a number of times, and in a certain number

of simple cases it is competent to secure recovery. As a rule, it is of more service in children than in adults. It is somewhat repugnant to the surgical mind, however, to leave even a small amount of pus in such a place as the pleural cavity, and if the trouble continued for any length of time after aspiration, complete evacuation should be practised. By far the best results have thus far been obtained with free incision, followed by drainage; and experience shows that the eighth or seventh intercostal space is, as a rule, the best position for the incision. Two large drainage tubes, of the thickness of the little finger, are usually advisable.

In performing this operation, he uses a spray of carbolized solution of three per cent. strength, produced by means of a simple hand-bulb. As soon as the flow ceases on aspiration he dresses the wound with sublimate gauze and iodoform.

What we want, first and last, said Dr. Abbe, is a thorough outlet, and the purity of the wound is the other important factor. In the great majority of cases, he thought, there is no need of injecting the cavity. When there is a hectic condition, however, antiseptic injections, followed by hot water ones, should be employed; and bichloride solution (1 : 8000), or a weak iodine solution, might be used for the purpose. Two serious results have been observed from injections, viz., toxic symptoms from the agents employed, and sudden death due probably to either thrombosis or reflexes from the pleura.

The presence of the drainage tube occasionally causes denudation of the periosteum of a rib, which has been erroneously called necrosis. When this occurs, it is necessary to perform resection, but he considered it unjustifiable to resort to this procedure at first.

As regards anæsthetics, a few whiffs of chloroform will answer perfectly well for children, but in adults local anæsthesia with cocaine is preferable. A four per cent. solution should be injected into the tissues, and the incision not made until about fifteen minutes afterward, when the anæsthetic effect has reached its maximum intensity. When there is decomposing fibrin, resection of a piece of rib is sometimes necessary in order to secure free irrigation; and occasionally, in cases where a suppurating cavity remains after empyema, Estlander's operation of resecting several ribs proves very satisfactory. Dr. Abbe also alluded to "through drainage" and Hewitt's method of "perflation," the latter of which, he thought, can never supplant free drainage.

DR. T. H. BURCHARD had operated in eleven cases of empyema, all of which were of chronic character. The shortest duration up to the time of incision was two months, and the longest, thirteen months; the average time being six or eight months. The youngest patient was three years of age, In all the cases the operation was identical, and all were cases which had previously been aspirated either by himself or some other physician. He made a free incision from one and a half to two and a half inches in length, along the eighth rib. The amount of purulent fluid evacuated varied greatly. In one boy, of seventeen, whose case was one of the most chronic met with, there were only seven ounces, while the largest quantity evacuated was twelve quarts. This was taken from the left chest of a young man of twenty-eight, in whose case one and a half pints had been removed three days previously by aspiration. In this instance two drainage tubes, six inches in length, were employed, and, notwithstanding the fact that they were secured with plaster to the chest-walls, they slipped into the cavity during the night. He was not permitted to go on with the case, and it was not until a year afterward that they were removed by resection of the ribs, the operation being performed by the late Dr. James L. Little.

As to the results of his cases, he has followed up seven of them for at least one year. Three entirely recovered; two developed phthisis and died, and a third, a year and a half after the operation, now had phthisis; one died of dysentery, of tubercular origin, fourteen months after the operation. In two cases he had observed in children, one of which was among his own cases and the other of which he had seen in consultation with Dr. J. Lewis Smith, hemorrhage sufficient to cause death had resulted from the operation; and it seemed to him that this accident is analogous in character to that which sometimes happens in the case of old men where too sudden and complete evacuation of the bladder is made, resulting in capillary extravasation. In these cases no artery was cut and no hemorrhage occurred from the wound, and he thought the matter is one worthy of serious consideration, especially as he has been able to find no reference to such an occurrence in medical literature.

As to the time of performing the operation, he thought it should be done early. If delayed too long, the patient is liable to die either of phthisis or tubercular disease of the bowels.

DR. H. N. HEINEMAN said that empyema in children and empyema in adults are two entirely different affections, and in the former, when it is on the left side, it is very apt to be complicated with pericarditis. Having referred to the differences in the physical signs in the two classes of cases, he said that in children especially, on account of the gurgling met with, the affection is liable to be mistaken for phthisis. The use of the hypodermatic needle is always desirable for diagnosis. As regards treatment, the indications had been very well stated by the previous speakers. If after aspiration the pus remained sweet, he thought it well to resort to this procedure a second time; after which incision should be practised, In the last ten years he has made use of only one form of incision, and that is the one known as "thorough drainage." This had been well described by Chassaignac as early as 1857, and he wondered that it had not received more attention than was the case, since it was, as a rule, followed by the best results.

DR. E. G. JANEWAY having stated that in his own practice, if one aspiration failed to produce relief, he resorted, with very few exceptions, to immediate incision, spoke of some comparatively rare conditions which had not been alluded to in the discussion. The first of these was empyema as an accompaniment of pyæmia, which was usually due to a gangrenous focus. Again, there are extreme cases in which there were double empyema and purulent endocarditis, when the result was rapidly fatal. There are other cases in which, although the fluid is septic, we are debarred from operation, and one of this kind he related. The patient suffered from pneumonic consolidation, pyo-pneumo-

thorax, and sepsis, and the fluid in the chest was very foul. Yet at the highest possible point at which an incision would have been practicable only blood could be drawn with the hypodermatic syringe. It was, therefore, necessary to leave the case to the efforts of nature, and, strange to say, the patient had made a complete and perfect recovery. In making an incision it is sometimes necessary to choose a different site from the axillary space, and in such cases we should select the spot where we can get pus. He thought it a good rule always to insert a hypodermatic needle at the point where the incision is to be made immediately before operating.

DR. A. L. LOOMIS had been accustomed to regard the pleurisies of children as very different from those of adults. Thus, acute suppurative pleurisy is very common in children; and, indeed, whenever he found that a child's chest filled rapidly he felt pretty confident that empyema was present. The treatment which he adopted in such cases was such as had been described here to-night, and he had found it very satisfactory. But acute suppurative pleurisy in adults is a very different affair. It is a dangerous affection, and often rapidly fatal. He had come to regard it as infectious, and it is usually associated with some acute pneumonia in the other lung. We have, therefore, to contend with an acute disease, which cannot be cut short by removing the products of inflammation. After the acute stage had passed, however, he believed that incision did good, and was called for.

In his opinion these cases are fibrinous pleurisies at the beginning, and after this condition has continued for about twenty-four hours the chest rapidly fills with pus. Chronic empyema is not a simple pleurisy. We have not simply the pleural cavity to deal with, but a constitutional condition, and it is necessary to seek for the cause of the pus. It is not enough to operate; but, in addition, the physician is called upon to sustain the patient's vital powers in every possible way.

DR. J. WEST ROOSEVELT took exception to the use of the carbolic spray, as advocated by Dr. Abbe, since it is confessedly inefficient in destroying germs, and he also thought that antiseptic injections are entirely useless, on the ground that no solution that can be employed can have any possible effect on the walls of the pleural cavity on account of the thick covering of fibrinous exudation with which they are coated. As to the proposed method of "inflation," he thought that if a good way of producing perforation of the lung is desired, this procedure should be adopted.

DR. CAILLE objected to the use of carbolized injections in children, on account of the danger of producing toxic constitutional effects.

DR. J. E. WINTERS said that he had careful records of ninety cases of pleurisy in children, and in only four of these was there empyema. In the latter, this condition existed when the patients were first seen, and of the remaining eighty-six cases, not a single one terminated in purulent effusion. It was also a fact that not one of these cases had been lost sight of. Owing to the results thus met with in his experience, he felt obliged to take exception to the statements made here to-night in regard to the frequency of purulent effusion in children. In the simple pleurisies commonly met with he had often seen the temperature go up to 103° and 104°, but under the employment of rest, hot applications, and sedatives the cases almost all terminated in resolution in the course of a week or so. In no instance under his care had empyema resulted. Two cases were operated on on account of the mechanical pressure produced by the large effusion present, and while they both proved fatal, at the autopsy no pus was found in either case. He had never seen a case of empyema in a child in which there was not an abundance of serum, and he, therefore, considered that the fluid in such cases was capable of absorption. Hence the condition was very different from that existing in empyema in adults, and he should not deem it advisable to resort to surgical interference except to relieve the effects of mechanical pressure upon the viscera. Children with empyema invariably lay upon the affected side, and, therefore, in order to facilitate aborption he encouraged them to sit up in bed as much as possible. Dr. Winters decidedly objected to the use of the hypodermatic syringe or the aspirator until such procedures were absolutely necessary, as he believed that the entrance of the needle into the pleural cavity directly tended to produce pus; and Dr. Francis Delafield, he said, had expressed the same opinion to him. The termination in empyema, as he had said, is naturally very rare in children; but when it did occur, and operative procedure was called for, he was decidedly in favor of free incision in preference to aspiration.

DR. HEINMAN related a case in which there were symptoms of collapse due to hemorrhage, produced, no doubt, in the same way as in the cases mentioned by Dr. Burchard, in which the child was apparently saved by the injection of a certain amount of fluid which was allowed to remain in the cavity.

THE PRESIDENT stated that he had frequently observed severe coughing to be set up by the removal of the fluid from the pleural cavity, and that this could only be arrested by partially filling the cavity again by injection. This seemed to him to be due to the irritation caused by the sudden filling up of the bloodvessels in consequence of the bronchial dilatation resulting from the evacuation.

DR. ABBE said that in his opinion the phenomena sometimes noted after the withdrawal of the fluid were of reflex origin; and he mentioned a case in which there resulted aphonia, disorders of vision, and reflex hemiplegic symptoms.

THE PRESIDENT thought that the symptoms mentioned might probably be explained by sudden hyperæmia of the larynx, with temporary anæmia of the brain.

NEWS ITEMS.

THE CLIMATOLOGY OF ST. AUGUSTINE, FLORIDA.—DR. FRANK F. SMITH writes us as follows: Though temperature is but a factor in that product which we call climate, its study may prove of interest to many physicians who desire for their patients a mild winter climate with abundant pure air, sunshine, and opportunity for outdoor exercise, such as St. Augustine, by the sea, affords. In the table appended it will be seen that in the one hundred and eighty-one days of the six cold months, ninety days (about one-half) present a maximum temperature above 70°. Again, in this

same period, one hundred and fifty-six days show a temperature above 60°, leaving but twenty-five days in six months possibly unsuitable for the outdoor life of invalids. With such a temperature, but twelve rains in the daytime, only three fogs in the whole winter, an average cloudiness of 4.18, and softened tonic sea breezes, which no record can estimate, St. Augustine may well urge a strong claim to public attention.

ST. AUGUSTINE, FLORIDA, 1886–87.

THE TENNESSEE STATE MEDICAL SOCIETY held its fifty-fourth annual session at Nashville last month and the following officers were elected to serve for the ensuing year:

President.—Dr. P. D. Sims, of Chattanooga.

Vice-Presidents.—Dr. T. J. Happel, of Trenton; Dr. Richard Douglas, of Nashville; and Dr. J. M. Masters, of Knoxville.

Secretary.—Dr. Ambrose Morrison, of Nashville.

Treasurer.—Dr. Richard Cheatham, of Nashville.

APPOINTMENT OF HOSPITAL PHYSICIANS IN CHICAGO.—The Board of County Commissioners has recently removed the appointment of the attending staff of the Hospital from the domain of politics. It has voted the present staff shall remain during good behavior, and that any vacancies in its membership shall be elected by an Advisory Board of five medical men, whom it has appointed. In case of a vacancy, the staff is to nominate three persons from whom the Advisory Board is to elect one. The Advisory Board, as at present constituted, has a representative from each of three regular medical colleges.

A SURGEON REFUSED HIS FEE.—The newspapers give prominence to a dispute between Dr. Marion Sims and Nat. Goodwin, husband of the late Eliza Weathersby, the actress. Payment is refused on the old ground that "the treatment did no good." Dr. Sims was called in consultation by the attending physician, Dr. T. S. Robertson, who was in doubt as to the nature of an abdominal tumor from which his patient suffered. The result of the consultation, that an operation afforded the only hope of cure, being communicated to the patient, she earnestly requested its performance. The outcome being fatal, the husband claims that the operation did no good, and should not be paid for! Under this extraordinary theory surgeons would soon have to abandon their work. Such actions as those indicated above are particularly unjust. Many surgeons undertake desperate operations against their own inclination and even interest, solely to give the patient an only chance. In such cases the attempt to escape the payment of the fee by claiming that "treatment did no good," furnishes an illustration of colossal meanness, beyond the power of dramatic art to exaggerate or even burlesque.—*Medical Record*, May 28, 1887.

UNAUTHORIZED USE OF PHYSICIANS' NAMES IN ADVERTISING.—The profession in Chicago is now contemplating the outrageous position into which a physician may be placed by an unscrupulous advertiser. The vender of a sulphuretted mineral water seized the opportunity of the present popularity of the rectal injections of gas for consumption, to improve his trade by a flaming advertisement of the water, with a cut of the apparatus used, and fulsome statements that the gas from this water was a sure cure, etc. From reports of a meeting of the Medical Society, he learned the names of a number of physicians who were using the measure, and embodied their names in the advertisement in such a way as to make it appear that they endorsed in full the statements it contained. The performance has been denounced in a card by all the physicians whose names were used, but this only slightly counteracts the effect of the outcry. It is interesting, anent this subject, to note how generally the profession here is now reaching the conclusion—the only one that ever ought to, or could logically have been formed—that the most desirable, as the only definite and exact way to secure the sulphuretted hydrogen for this kind of medication is through the well-known artificial compound with the sulphide of sodium, and not by means of any natural water.—*Boston Medical and Surgical Journal*, May 26, 1887.

PROFESSOR SEMMOLA has succeeded in founding a Chair of Clinical Therapeutics in the University of Naples, to which he has been called.

THE BERLIN MEDICAL SOCIETY AT THE CONGRESS.—A press cablegram, dated Berlin, May 27, states that a committee of the Berlin Medical Society has considered the suggestion made in certain American quarters that the Society be officially represented at the Medical Congress to be held at Washington. Professor Virchow states that the Committee has decided against the suggestion.

DEFENCE OF PROFESSIONAL INTERESTS BY FRENCH LAW.—*The British Medical Journal* of May 14, 1887, reports the following: A case was recently decided in France, the result of which shows how much keener an appreciation law takes of professional interests in France than in our own country. A journal, the *Echo de l'Est*, had thought fit to announce to its readers that Dr. Bernard, of Thiancourt, had just performed a surgical operation, in consequence of which the patient had succumbed. Dr. Bernard immediately brought an action against the journal for libel, inasmuch as it was inferred that the death of the patient was attributable to the operation. The Court of First Instance of Bar-le-Duc, looking at the matter as one of public interest, author-

ized the incriminated journal to substantiate the allegation. On appeal, however, the court at Nancy quashed the decision of the other court, and declined to allow the journal to plead, declaring the allegations to be groundless; adding, moreover, that, "inasmuch as they were based on a fact of an essentially private nature, altogether outside public discussion, and quite independent of journalistic criticism," the journal was not warranted in making any such statement, and was condemned to pay 10,000 francs damages to the practitioner whose reputation had been assailed. It is quite refreshing, in these degenerate days, to see that, in one country, at any rate, the reputation of a medical man is recognized as having an appreciable value. The interesting feature of the case, however, lies in the decision of the tribunal that such cases are beyond the competence of a newspaper to criticise, and are, in any event, of an essentially private nature. It would be a great boon if such a sentiment could be imported into this country. A few decisions like this would doubtless have a salutary effect in checking the by no means disinterested curiosity of scandal-mongers, who appear to consider themselves competent and at liberty to comment upon both the malady and the treatment, to the annoyance of the patient and the discomfort, and even damage, of the medical attendant.

THE CLIMATE OF COLORADO SPRINGS FOR THE PHTHISICAL.—A gentleman who had tried the favorite resorts of Europe and America, describes the advantages of Colorado Springs as follows in the *New York Tribune* of May 22, 1887:

No climate is absolutely perfect, so I shall first call attention to the only blemish in the climate of Colorado Springs. We have some wind and, at times severe wind, yet the number of days when an invalid is compelled to remain indoors on account of strong wind is not more than the number he is compelled to spend indoors at Davos, in Switzerland, on account of the falling of snow. Furthermore, if an invalid finds the wind objectionable he can readily escape it by changing to Manitou Springs (ten minutes by rail), which is even more sheltered than Davos.

Now as to the advantages of Colorado Springs:

1. Its altitude is six thousand feet above sea level. To the north the land rises gradually, thickly wooded, to the height of 7500 feet. Six miles to the west runs a spur of the Rocky Mountains culminating in Pike's Peak, 14,200 feet high. Thus the city is sheltered to the north and west and is open to the south and east.

2. The sunshine is almost uninterrupted. During the winter there is no rain, no cloudy or foggy weather, and hardly any snow. Snow falls very rarely, and when it falls it disappears quickly and almost miraculously, leaving neither mud nor dampness behind.

3. As the city lies open to the east and the higher mountains to the west are at some distance, the daily duration of winter sunshine is very great—fully forty per cent. greater than at Davos.

4. The character of the soil is porous. This is a very important advantage. If rain or snow falls at Denver, for example, the result is mud, and mud means continued dampness. There is no mud at Colorado Springs.

5. The invalid is not restricted to hotel life. Boarding-houses and furnished houses abound. Housekeeping, owing to the presence of a large number of very superior stores, is made easy. Should the invalid prefer hotel life, he will find the hotels first-class, but be it said that no American hotels are so carefully managed as to comfort nor so particular as to ventilation as are the hotels of the Riviera or of Davos.

6. There is nothing of the hospital character about Colorado Springs. Of its 7000 inhabitants, many never were sick, and many who once were are now perfectly cured. The invalids are scattered to such an extent, there are so many amusements and points of interest to disperse them, that one never feels the depressing influence of being in a great consumptive hospital.

7. Amusements are very plentiful. There are few cities in the world that offer such a variety of beautiful rides and drives. Invalids are out riding or driving nearly every day in the year. Many people of wealth and culture reside here, society is pleasant and clubs of all kinds abound—social clubs, reading clubs, musical clubs, fox-hunting clubs, etc. An invalid here has neither time nor disposition to mope.

8. One of the objections I found to Davos and the Riviera was that when spring came the patient was chafing to get away. I do not find this at Colorado Springs. Nor is it necessary. The summer climate is just as healthful and just as exceptional as the winter climate. In fact, the reputation of Colorado summers brings thousands of tourists here every summer. The days are warm, not uncomfortably so, and the nights are always cool enough to make a heavy blanket necessary. Some invalids go up into the beautiful near-by mountain parks (8500 to 10,000 feet high), and live at a farm house or camp out. Some change to Manitou Springs and enjoy witnessing the summer gayety. The majority remain here and are equally benefited.

9. If a patient feels disposed to make a change during the winter, he has a large choice of places which he can visit with safety. He may go to Denver or to any of the towns between Colorado Springs and Pancha Springs inclusive. This belt of territory is all favored with an exceptional climate. On the other hand, if an invalid finds that the climate does not agree with him, he can travel hence to Southern California quickly and comfortably.

COMPLAINT REGARDING THE CONDITION OF THE VIENNA HOSPITAL.—In a recent session of the Austrian Parliament a complaint was made regarding the condition and administration of the Vienna General Hospital. The charge was answered in a general way, and is now undergoing investigation.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MAY 28, 1887.

DEANE, C. W., *Passed Assistant Surgeon.*—Detached from the "Dale" and ordered to hospital, Mare Island.

HARVEY, H. P., *Surgeon.*—Orders to "Iroquois" revoked, and wait orders.

DIXON, S. H., *Passed Assistant Surgeon.*—Detached from Navy Yard, Washington, D. C., and ordered to the "Dale."

WORCESTER, I. K., *Surgeon.*—Detached from the "Iroquois" and wait orders.

WHITE, S. STUART, *Assistant Surgeon.*—Ordered to Receiving Ship "St. Louis," Navy Yard, League Island.

FIELD, DR. JAMES G., of Gordonsville, Va., commissioned Assistant Surgeon in the Navy, May 23, 1887.

VOL. L. SATURDAY, JUNE 11, 1887. No. 24.

AMERICAN MEDICAL ASSOCIATION.

THIRTY-EIGHTH ANNUAL MEETING, CHICAGO, 1887.

THE PRESIDENT'S ADDRESS.

Delivered June 7, 1887.

BY ELISHA H. GREGORY, M.D.,

OF ST. LOUIS.

CELL-ANTAGONISM.

OBVIOUSLY, force and matter "make up" the universe. Force implies antagonism, antagonism perpetuates motion. The living cell is the embodiment of nature. Cell-antagonism is life. Multicellular organisms represent a community of vital unities. A model organism in equilibrium is health. Cell struggle is the gist of modern pathology. Every organ and every element is vulnerable. The strength of resistance in elements and organs, reinforced by the harmony and precision of coördination, and the vigor of counter agencies are the momentous questions.

In seeking for a comprehensive title for our address, we fell upon the the two simple words "cell antagonism," which form the foundation of symptomatology and pathology, conjoined with cell changes, the basis of pathological anatomy, embracing at once the universe of life and all the possibilities of life; disease being but one of the multitudinous phases of life.

Prof. Huxley has likened the body to an army. "Of this army, each cell is a soldier; an organ, a brigade; the central nervous system, headquarters and field telegraph; the alimentary and circulatory system, the commissariat. Losses are made good by recruits born in the camp, and the life of the individual is a campaign, conducted successfully for a number of years, but with certain defeat in the long run."

A model organism assumes that every soldier is a stalwart; every organ, a body of stalwarts with corresponding machinery of coördination and precision, all alike concerted and vigorous to meet the myriads of counter forces, many of which are too cunning for our ken, but ever ready to take advantage of the least failure of our strength, to penetrate our vitals. This force of vital resistance forms the basis of therapeutics; this "vis medicatrix naturæ" will always be the indispensable auxiliary of the physician, without which early abandonment of the art would be inevitable.

The morphologist distinguishes two classes of elements within the organism. One class represents the fixed cells, cells which occupy the fortifications within the intercellular substance; the other class provides for the formation of new tissue, and represents the standing army, sometimes called embryonal substance. Before Cohnheim, our knowledge of the mobile elements—the mobilized army—of the body, was nothing; now most of the literature heretofore relating to neoplasmata is, or has become, obsolete. Now coagulable lymph is impossible without the white corpuscles. Organizable fluids have vanished. Through the industry and ingenuity of the great German pathologist a revolution has been worked in medical thought. The study of the mobile elements of the body—the relatively independent elements—promises much. We can almost see daybreak in pathology, a dawn before the coming light which is to illuminate some of the dark places of this most intricate subject. Already leucocytes substitute fibrine. The latter is the product of the former. Wherever there is localized impairment of nutrition referable to irritation, or defective maintenance of nutrition, the result of inherent weakness, there the leucocytes concentrate, feast on the devitalized structures and thereby develop into a tissue replacing that which they have consumed. When the surgeon wishes to dispose of an adventitious structure—a cyst, for example, in the connective tissue, he lowers the vitality by over-stimulation,—irritation, when he confidently expects the leucocytes to congregate and destroy the cyst, substituting a granulation tissue, which in time becomes scar tissue. Now an organizable fluid as the essential product of inflammation, cells playing a passive part, is a thing of the past. Now cell potency, cell subtlety, and cell antagonism constitute the pith and marrow of medical science. There was a period in the history of pathology when all the neoplasmata sprang from the tissue cells, now the place and destiny of tissue cells are fixed. When the fixed elements yet contain some undifferentiated protoplasm, proliferation is possible, otherwise not probable. The mobile cells constitute the mobilized army; the great coördinating centres assemble them at any moment, ready to antagonize hurtful agencies. Irritation always provokes a concentration of the white cells. Irritation means injury. It may be simple or specific. Either way it is a signal for moving the army in solid phalanx to confront noxious agencies, and the combat is hotly contested till victory or discomfiture.

Inflammation, the keystone of medical science, the standard process by which all other pathological conditions are measured, is only to be explained on the theory of cell-antagonism; it is practically a struggle between irritant bodies and white blood-corpuscles. Foreign bodies are invariably invaded by leucocytes, their swarming having for its object to repel or render inert the offending cause. Observations directed to the white cell have been followed by an inspiring increase in our knowledge of the vital properties of cells. The quality of spontaneous motion once accepted, the idea that the cell played a passive part quickly disappeared and in its stead came the conception of autonomy, the fact that the cell nourished itself, is not nourished, that the cell specialized food for its own purposes, actually breaking up compounds and adapting the products to its own growth and development, strikingly illustrated by an independent form of government, for example,

the government of the United States. A great statesman has said ours is a "government of the people, by the people, and for the people." Cells live of themselves, by themselves, and for the whole body. The cells make the central government. The coördinating machinery is formed by the cells, and the cells are in their turn centralized and harmonized by this power. The tissue elements are in direct continuity with the centre, but it is otherwise with the floating, wandering cells; yet their behavior gives evidence of their concern for the well-being of the entire organism. Again, the free cells take into their substance the most refractory substance, digesting solid bodies; sponges and green plants yielding to their digestive and assimilative processes. Observations the most patient and trustworthy in the lower vegetables have demonstrated the fact that bacteria have been seen in the substance of amœboid cells; others have been seen pursuing bacteria, ultimately capturing and destroying them. Throughout the whole animal kingdom mesoderm cells use their ingestive power for destroying microörganisms. Further, this property seems to be utilized for the removal of larval organs. Colorless corpuscles present the same appearances and have similar properties and the same mode of origin in the entire range of living beings. When the irritant or harmful agency is particularly obdurate, white cells exhibit a very strange habit of throwing out processes which unite with a similar process from neighboring cells, until a considerable mass of protoplasm is formed by their confluence, constituting a giant cell. Thus an army of giants may be improvised on occasions of extreme emergency: for example, when the tail and gills of the tadpole are to be swept off, this powerful division is ready for the Herculean task.

Apply these facts to the inflammatory process in mammals. Suppose a foreign body lodged, that moment leucocytes leave the bloodvessels and congregate for the purpose of opposing the intruder. In such diseases as tubercle, leprosy, etc., the giant-cells appear, and in their centre their substance, the specific bacillus, is found. Koch found the bacillus of anthrax and the bacillus of septicæmia in the mouse, enclosed by white blood-cells. We say, with these observations before us, inflammation exhibits a new aspect; cells conquering cells as a process of normal physiology; simply the free cells, the white cells resisting injury, there being a provision not only for concentration, but for increasing their number and augmenting their strength corresponding to the emergency. A recent authority, Mr. Sutton, says: "If we summarize the story of inflammation as we read it zoölogically, it should be likened to a battle. The leucocytes are the defending army, their roads and lines of communication the bloodvessels. Every composite organism maintains a certain proportion of leucocytes as representing its standing army. When the body is invaded by bacilli, bacteria, micrococci, chemical or other irritants, information of the aggression is telegraphed by means of the vasomotor nerves, and the leucocytes rush to the attack; reinforcements and recruits are quickly found to increase the standing army, sometimes twenty, thirty, or forty times the normal standard. In the conflict cells die and often are eaten by their companions; frequently the slaughter is so great that the tissues become burdened by the dead bodies of the soldiers in the form of pus, the activity of the cells being testified by the facts that the protoplasm often contains bacilli, etc., in various stages of destruction. The dead cells, like the corpses of soldiers that fall in battle, later become hurtful to the organism they in their lifetime were anxious to protect from harm, for they are fertile sources of septicæmia and pyæmia, the pestilence and scourge so much dreaded by operative surgeons. The analogy may seem to some a little romantic, but it appears to be warranted by the facts." Just here the question obtrudes, "Are the action which follows mechanical, chemical, and thermal injuries, and the action caused by vital injuries alike inflammatory processes?" In the one, that resulting from physical causes, the nutrient processes are not disturbed, simply increased. In the other, that resulting from vital causes, the cell processes are disturbed, thwarted, and vitiated. It seems unfortunate that the action which succeeds to traumatism should be confounded with that which succeeds to specific germs. The nutrient changes come into vigorous play after an ordinary injury, altered in one particular only, viz., the presence of a palpable neoplasm, which substitutes the structures doomed by the injury. The addition of new material is invisible in ordinary nutrition, growth, and maintenance for example, the substitution being atomic. When a structure is destroyed bodily, as in traumatism, the substitution is corpuscular, therefore, palpable. It is certainly perplexing to assume, as does Sir James Paget, that a visible neoplasm is produced by inflammation, but its development is impossible till after the withdrawal of the inflammation. To get rid of confusion, though we do not emerge from error, is to make a step toward truth. The full effect of traumatism is immediate and complete; it cannot increase itself; therefore, its effects are always limited and within the possibility of estimation, for the reason that cause and effect are in precise correspondence; besides, antiseptics do not influence the changes in any particular. On the other hand, the most extensive and severe injuries of vascular parts, involving bones, joints, the great cavities, etc., are possible without producing inflammation, provided antiseptic precautions be taken. When such complication ensues, it is a wound accident, not a wound incident, and the result of infection. There is no disturbing factor in the process incident to repair; no waste products. If pus is found, it is the result of the intrusion of some noxious agency, some contagion, some pestilence; in short, a specific cause.

If it be agreed to call the action inseparable from ordinary injury, physiological repair, the term inflammation is limited to the series of events referable to a vital agency, which, until very recently, has eluded detection. A specific agency determines a class of diseases as distinctive and definite as the living creatures studied in natural history. Cell-antagonism after physical injury is simply a substitution, through the development of mobile cells, of the tissue which has been spoiled. The fixed elements multiply and develop in the expansion and perfection of the several structures of which they are components, but take no active part in the process of repair after injury. After the perfection of the body, the factors favoring proliferation and those which inhabit it must be in a state of balance. In functional hypertrophy, the balance is toward the side

of proliferation. On the other hand, in non-functional activity, the problem is not so simple; the balance is disturbed toward proliferation by some mysterious agency. How strikingly different when the cell-antagonism is with a vital injury, cell mysteries clash! The bacteria enter into conflict with the mobile and fixed cells, but it is not possible to know how the conflict is carried on. Certainly a series of disturbances ensue in the normal metabolism of the elements. The functional, formative, and nutritive activities, which are the expressions of cell life, must be altered; their vigor perhaps lessened; and their susceptibilities modified. Exceptionally their life is enfeebled or extinguished. The issue of a bacterial affection is either the death of the patient, or the destruction and elimination of the bacteria. It follows that this disturbance of cellular activities is always at the bottom of morbid symptomatology; and observations have shown that disease of this kind, successfully withstood, leaves the elements in a peculiarly unsusceptible condition, insuring an immunity, almost or quite complete, against a fresh invasion of the same or kindred bacteria. This modified susceptibility was practically understood by Jenner. Pasteur, resuming and systematizing the great Englishman's work, successfully modified cell forces, rendering them harmless by cultivation, and sending them on the important mission of destroying the natural proneness to the deadly assaults of the uncultured cells. Whilst we may despair of ever understanding the essential nature of vitality, the study of the causes which regulate life, and their subordination to conditions which may be determined, has led the way to the grandest achievements of recent times. Pasteur and Lister are the great apostles of modern practical thought.

Prof. Huxley has suggested that it may be possible to introduce into the economy a molecular mechanism which, like a cunningly contrived torpedo, shall find its way to some particular group of cells and cause an explosion among them, leaving the rest untouched. Pasteur's cell mechanisms exceed the conception of the great scientist, for they cunningly change the vital qualities of the elements without destroying them. May we not look forward to some great advance in therapeutics in the direction to which Pasteur's genius points, by the study of cell mechanism? Certainly vital subtleties may but cope with vital subtleties. Study of the conditions in which infective agents arise by ascertaining the circumstances which limit or facilitate their diffusion, has already raised surgery to a proud preëminence. With therapeutics it is otherwise, as it is doubtful whether the new facts have yielded the slightest increase of power against the diseases of mankind. Let us not despair. Knowledge must come first, then wisdom brings its practical application. The study of cell possibilities, their readiness and energy in rendering inert noxious agencies, whether introduced from without or arising from within, exhibiting an antagonism at once potent and direct, rather tends to dampen one's therapeutic enthusiasm. The thoughtful student sees nothing abnormal in disease. To be sure there is a physiological emergency, but there is no disorder in the cell processes, rather the perfection of order. If a physical or chemical cause intensifies the cell changes, in other words, determines the physiological emergency, every cell movement is direct, purposive, and efficient, ending only when the intruder is ejected, encysted, or accommodated. On the other hand, if the offence be a vital one, a living cell, a microphite, the spectacle is that of one living creature preying upon another, a declaration of the first law of nature, not an enemy, but an intruder struggling for self preservation, simply a physiological fight for life. Can we hope an ideal tonic for cell-antagonism, such as would innervate the cells on one side and enervate them on the other; the "old chestnut," "Prevention is better than cure," is not yet wormeaten.

Cell-antagonism implies a struggle. The duration of the struggle is determined by the quality of the irritant and the strength and resources of the antagonists. Acute inflammation is a sharp and decisive action; chronic inflammation is slow and indefinite. There are two strikingly important chronic conditions: viz., the interstitial inflammation and the infective granulomata, interesting alike to the physician and surgeon; both are alike disastrous, the one, interstitial inflammation, destroying by cicatricial contraction; the other, infective granulomata, by stopping at the fibroplastic stage, retrogression replacing development. The quality of infection, and the failure to develop beyond the stage of granulative tissue is the exact condition as illustrated by tuberculosis, syphilis, lupus, etc.; in contrast with which is fibrosis of the liver, cirrhosis, fibrosis of the kidney, Bright's disease, fibrosis of the brain, sclerosis, interstitial inflammation, destroying the tissue elements by strangulation, infective granulomata by contamination. Again, the two varieties of inflammation referred to declare that the quality of the irritant determines the effect of the inflammation, the interstitial variety being caused by physical agency, and the infective by a vital one. Cells antagonize physical causes without losing any of their vital qualities. Not so when cells antagonize vital causes. When cells are pitted against cells they may be despoiled of their highest quality, as, in the infectious granulomata, they have parted with formative activity. In short, the knowledge that pertains to the presence of a vital irritant, epitomizes all that has been taught of infective disorders. The symptomatology and pathology of this class of diseases are but the life history, the play of cell activities, metabolisms, and catalysis of antagonizing organisms; as likewise the knowledge pertaining to the presence of a foreign body or physical irritant, is the knowledge, in brief, of fibrinosis; in general, of that entire class of disorders known as interstitial inflammation. A persistent irritant injury, with its attendant concentration of leucocytes; their inevitable development and ultimate transformation; the history of the capsulation of a foreign body, whether it be animate or inanimate, is the history of cirrhosis of the liver; fibrosis of the lung; morbus Brightii; atrophy of the heart; atrophy of voluntary muscles in general; sclerosis of the brain and bone; in short, diffuse capsulation. Some disseminated irritant, say alcohol, determines a sclerosis of the liver; and how? Every particle of alcohol being a foreign particle, having its capsule, it follows that capsulation is as uniformly distributed as the cause. An artisan inhales fine particles of steel or other foreign material, and fibrinosis of the lung is the consequence. The irritants of gout and rheumatism are lodged in the kidney; the interstitial tissue of the organ increases, and in the end strangu-

lates the tubules and Malpighian bodies; results in shrinking and total disorganization of the organ, constituting Bright's disease. Like changes occur in the heart coincident with the development of the interstitial fibrous tissue, with atrophy of the muscular substance, substituting a fibrous induration for its normal structure. A similar change in the voluntary muscles occurs in the curious disease known as pseudo-hypertrophic paralysis, chiefly afflicting children. The connective tissue between the muscular fibres increases so much that the muscles affected may exceed their normal size three times. Later, however, the new tissue shrinks, and the contractile material of the muscles is spoiled. The condition of sclerosis in bones corresponds to cirrhosis of the liver, and Bright's disease of the kidney. In the nerve centres the interstitial tissue—neuroglia—takes on the same chronic overgrowth, strangling the nerve strands and cells, giving rise to the most singular and complicated nervous phenomena. The changes thus induced are recognized by the general term sclerosis. If it involves the fasciculæ of Burdack and the columns of Goll, locomotor ataxia results; if the medulla, bulbar paralysis, etc.

We have purposely avoided reference to diathesis, as also to the precise neurological relationship of cells, not because we deny their influence, but because too little is definitely known. On the contrary, the behavior of cells relatively to irritants is well understood. The presence of a foreign body is at once and directly resisted by the leucocytes, a zone of inflammation, its destruction, transportation or encapsulation, even parasites which resist the death-dealing assaults of the leucocytes, are at least imprisoned in cases of fibrous tissue.

There yet remains for our consideration a mysterious possibility relating to cell life of great practical moment, viz., that of entering upon a life of independence, separating from the central nervous system "headquarters," disregarding the "field telegraph," oblivious to the morning "drum-beat," and wholly ignoring the restraining and directing influence of environing structures. We have learned that however much irritation may affect the vital qualities of cells, their fidelity is always preserved, there being no sign of disaffection, the army ever intact, the fealty of the soldiers supreme. Physical causes—traumatism—may crush or impair the tissues, but the cells come to the rescue with all vigor and directness. The prolonged presence of bacteria may impair the forces of the cells, enfeeble and extinguish them, but as long as life lasts their efforts are in harmony with the purposes of the organism. Thus it appears that alienation is not possible through the agency of irritation, however intensified, modified, or prolonged. The question constantly obtrudes, Is alienation possible to a mature element, to an element that has assimilated itself physiologically as well as anatomically, with the surrounding tissues, taking part in its functions, concurring and coöperating in all the processes of the economy? This question seems to have confronted Cohnheim, when his ingenuity suggested the embryonal hypothesis, viz., that the tumor germ was congenital; that there were in the natural body embryonal elements and tissues not utilized in the elaboration of the normal structures, latent, embryonal rudiments; small, embryonal cells so diminutive as to elude observation, inactive, perhaps, till some exciting cause awakens activity. Is not an embryonic element in a mature organism an alien? Is it not already an independent element? Are not patches in the skin, pigmented moles, islands of cartilage in mature bone, congenital angioma, etc., independent structures, already tumor-germs, congenital rudiments of tumors? Accept the hypothesis of the great German pathologist, and the problem of tumor etiology is almost solved; it remains only to find the exciting cause: the predisposition is inherited: irritation, simple or otherwise, may be nearly allied to the awakening impulse. The difficulty is to reconcile cell-antagonism with the proposition. This doctrine includes the idea that all discordant bodies are treated as intruders, either ingested, transported, or covered up. We can conceive the possibility of the existence of an inoffensive tissue or element, one that simply draws its nourishment from adjacent tissue, without any serious disturbance of their normal metabolism. We would gladly adopt the theory of Cohnheim, which ascribes the origin of tumors, neoplasms, to persistent germinal rudiments. Certainly it has much to recommend it. Countless latent embryonal structures, relatively independent, are tolerated by the organism, remaining inactive till favored by some concurrent event, the nature of which is incomprehensible, when they may grow according to their bent. Is it not quite as possible that there may be similar relatively independent elements, ready when stimulated to multiply independently? Congenital angiomata often grow without definite limit; pigmented moles—black, slightly raised patches in the skin—with which all are familiar, are composed of tissue exactly resembling sarcoma; always suspicious because of their disposition to proliferate independently. It is most difficult to believe in the infidelity of covenant cells, of sundering the compact which unifies the organism. Emancipation seems almost out of the question. We must not only believe that dependent benignant elements become independent, but indifferent, vicious, impetive. In short, the elements of the host become the elements of a parasite—a parasite so vigorous, corrupt, and wicked as to destroy its source.

The painful part of the retrospect of a year is that which recalls those who have been taken from us. The past year has had a very special grief for our Association in the death of one of our ex-Presidents, Dr. William Owen Baldwin, who died at his residence, and the place of his birth, Montgomery, Alabama, May 30, 1886. He was among the early members of the American Medical Association, and its President in 1869, presiding at New Orleans. His address on that occasion abounded in Christian and patriotic sentiments, eminently befitting the good and great physician. The committee charged with the organization of the Ninth International Medical Congress, which meets at Washington City, this year, had named him as one of its Vice-Presidents. Dr. Baldwin was remarkable for his culture, the eloquence of his speech, and the beauty of his diction, and will be remembered as an imposing figure in the history of this great Association.

I need scarcely remind you, gentlemen, that we shall have, after a few weeks, assembled in our midst, the medical men of all nations. Soon we shall extend the hand of friendship to those with whom we have hereto-

fore been united in interest and sympathy in the cause of science. We know that everything is being made ready, and that success is assured. Again, you will join me, I know, in the declaration that a hearty American welcome awaits their advent, and that the Ninth Meeting of the great Congress will be memorable in the history of its organization.

ORIGINAL ARTICLES.

THE INFLUENCE OF BEER ON SALIVARY AND GASTRIC DIGESTION.

BY H. A. HARE, M.D. (UNIV. OF PA.),

DEMONSTRATOR OF EXPERIMENTAL THERAPEUTICS AND INSTRUCTOR IN PHYSICAL DIAGNOSIS IN THE UNIVERSITY OF PENNSYLVANIA; PHYSICIAN TO THE CHILDREN'S DISPENSARY OF THE UNIVERSITY HOSPITAL, AND TO ST. CLEMENT'S HOSPITAL AND DISPENSARY.

THE physician is frequently puzzled when prescribing for a convalescent, as to which alcoholic beverage of a mild and pleasant character he can recommend with the least fear of "upsetting" the stomach. The writer has, therefore, attempted to decide this question, and the results are tabulated further on.

Before passing to a direct consideration of the methods employed and the results obtained, it is necessary that a few physiological and therapeutical points be brought forward. Everyone knows that alcohol retards digestion in the test-tube, but aids it in the stomach; and while these facts seem somewhat paradoxical, they are, in reality, perfectly logical, for the following reasons:

In the test-tube we have a given quantity of digestive fluid on which the alcohol may act, and we cannot have any increase in the quantity of that fluid, because it is surrounded by glass walls. In the stomach the alcohol acts quite as much on the digestive ferment as it does in the test-tube, but it also, by its presence in that viscus, excites the gastric glands to such an extent that an excess of gastric juice is secreted sufficient to counterbalance any anti-digestive influences. In other words, the action of the spirit on the living tissue is greater than its action on the digestive ferments.

Theoretically, alcohol should never be used in indigestion or in conditions of gastric weakness; practically, every physician of experience or education gives alcohol under just these circumstances, and, very properly too, gives the stronger alcoholic preparations instead of the weaker. In typhoid fever we give brandy or whiskey in the first stages, almost solely for the purpose of increasing digestion.

It is, therefore, clear that any experiments made by means of artificial digestion do not give us results which can be looked upon as comparable to true digestion. At the same time it is a fair supposition that beer which retards digestion the least in the test tube, will also retard it the least in the stomach, unless it can be proven that it contains scarcely anything but water, in which case the condition of affairs is exactly reversed.

It is also known by those interested in such matters in the profession, that beer aids digestion but little or at all by means of its alcohol, since that constituent is present in so diluted a form and in such small quantity that it can neither aid digestion to any extent by acting on the coats of the stomach nor retard it by influencing the digestive fluid. It should not be forgotten that while all alcoholic fluids theoretically retard gastric digestion, that beer does so much less than brandy or whiskey owing to its small amount of alcohol, and while, as has already been shown, this fact rather obtains against its practical use, that this is overcome by the carbonic acid and bitter principles of the beer, which stimulate, excite, and act as bitter tonics on the gastric glands.

Beers to be wholesome should, therefore, contain carbonic acid and bitter principles to a fair degree, the alcohol taking a subservient and almost useless *rôle* so far as digestion is concerned.

So far in this paper the influence of alcoholic beverages on gastric digestion has received our entire attention, simply because it is by far the most important part of the subject.

In some recent experiments made by Duggan, of Baltimore[1], it was decided that alcohol in all its forms very markedly retards the conversion of starch by diastase; and, although it is a general impression that beer contains enough diastatic power to aid, at least, somewhat in the reduction of starch, it would seem probable that any such action would be set aside by the alcohol present, and the results of my experiments support this view.

The question of the influence of beer on salivary digestion is, however, of so little importance that it is hardly to be considered, so that, without further comment the method of these experiments will be described.

In the experiments on gastric digestion thirty minims of a standard solution containing forty grains of Fairchild's scale pepsin, and ten minims of hydrochloric acid to the ounce, were placed in each test-tube, which was immersed in a water-bath at 110° F.[2] To this were added thirty minims of beer, and finally one grain of hard-boiled egg albumen, care being taken that each piece of albumen should be of the same shape as the others, in order that an equal amount of surface might be exposed to the digestive fluid in every instance. In order that the dilution might be equal in both the control and beer tubes, thirty minims of water were added to the former.

Twenty-four experiments were made with each beer, and the space of time elapsing between entire digestion in the control and beer tubes carefully noted in every case. The figures in the table, therefore, show the average retardation of digestion as it occurred in twenty-four experiments, and accurately represent the status of each brand examined.

The tests performed with salivary digestion were made in much the same manner as those on the gastric, ten minims of a standard solution of boiled starch being used in every test along with thirty minims of saliva and an equal quantity of beer. In

[1] Studies from the Biological Laboratory of Johns Hopkins University, vol. iii. No 9. February, 1887.

[2] The writer is perfectly aware that this amount of pepsin is many times as great as it need be, but as the object was not to test the amount of pepsin necessary, but the action of the beer, and as time was of some moment, this strength was arbitrarily employed. It should also be remembered that the addition of thirty minims of beer dilutes the digestive fluid *one-half*, and it was for this reason that ten minims of acid to the ounce were used instead of the ordinary quantity, viz., five minims.

the control tubes water was introduced in place of the beer, as it was in the former experiments. The method of determining that all the starch was digested was the iodine test, the reagents used for the qualitative estimation of glucose being valueless, owing to the fact that they do not prove entire conversion of the starch, and also because of the presence of glucose already free in the beer itself. The starch in any one tube was not considered converted until there was no longer any blue color produced when iodine was added.

To sum up the results of these experiments, we find that the beers examined varied in their action as much as fifty-nine minutes, and that while most beers do not retard digestion in all probability in the stomach, that others, such as those mentioned in the first part of the table, aid digestion very materially. Thus, in the case of the Bergner & Engel Brewing Co's Tannhäuser, it will be noted that even in the test-tube the average delay in gastric digestion equalled but one minute and thirty seconds.

While we can use beer as a tonic and stimulant to digestion, we cannot regard it as a beverage possessing any real nutritive value, since its chief nourishing constituent is glucose, which is, however, in very small amount, the greater part of it having been transformed in the fermentation into alcohol and carbonic acid.

If, however, we use the term "beer" as do our English cousins, then we include a large number of the "heavier" liquids of this class, which, of course, contain a larger proportion of nutritive matter.

EXSECTION OF THE KNEE-JOINT FOR TUBERCULOSIS.[1]

BY ARPAD G. GERSTER, M.D.,

[illegible]

WHITE swelling of the knee-joint in adults of the laboring class can, for various external reasons, rarely be treated by orthopædic measures. In children a rational mechanical and general treatment will often reward the patience and skill of the physician by excellent results. Exsection of the knee-joint in infants is to be avoided as long as possible, on account of the great shortening that is caused by the removal of the epiphysis adjoining the knee, on which depends the growth of the thigh and tibia. In adults exsection is the shortest and safest way of eliminating tedious morbid processes and substituting firm ankylosis for a useless joint.

Arthrectomy, or exsection of the capsular ligament alone, as suggested by Volkmann, has not been attended with good success in the experience of the writer. Two cases, one in an adult, the other in a child, resulted in relapse of the tubercular affection, although great care was taken in removing the entire capsule. A third case was permanently cured. The following are brief synopses of these cases:

CASE I.—S. L., metal worker, æt. twenty-seven. On February 28, 1882, arthrectomy was

[1] Read at a meeting of the New York Surgical Society, May 24, 1882.

performed, the patella being removed for fungous arthritis of the knee-joint. Primary union occurred. On March 22d the disease recurred in the cicatrix, and gradually involved the articular surface of the femur and tibia. Amputation was performed by Dr. J. Adler.

CASE II.—Fred. O., æt. five and one-half. Tubercular arthritis of the knee-joint. On January 26, 1887, arthrectomy was performed at the German Hospital. On March 22d the entire cavity was opened and scraped because of recurrence of the disease. At the present date the boy is still under treatment.

CASE III.—George K., butcher, æt. twenty-six. On July 6, 1882, arthrectomy was performed at the German Hospital; a carious patella being removed. On November 5th he was discharged cured, with slight mobility of the joint.

In children exsection should be made only under very urgent, especially vital indications, and should be strictly limited to the removal of diseased parts. By following Schede's plan of dressing the wound, the hollow spaces remaining between the opposite joint-surfaces will be filled by an organizing blood clot, and firm union without suppuration may be obtained.

CASE IV.—Eva G., æt. eight. Osseous tuberculosis of the knee-joint, with a sequestrum in the external condyle; granular osteitis of internal condyle, and multiple cheesy deposits in the thickened capsule; subluxation backward of the tibia, with rectangular contraction. On August 12, 1886, partial exsection of the knee-joint was performed at Mt. Sinai Hospital. After the removal of the sequestrum a deep recess was left behind the intercondylar notch. The patella and the entire capsule were removed; the hamstring tendons were divided to prevent recontraction. The tibia was pared superficially, and the bones were held in apposition by a nail driven diagonally through the femur and tibia. A plaster-of-Paris bandage was applied over Schede's dressing. The patient had an attack of erysipelas. By reason of these complications healing was delayed.

On February 27, 1887, the patient was discharged cured, with firm ankylosis.

Total exsection of the knee-joint is usually performed by the writer in the following manner: After careful scrubbing and disinfection of the region of the knee, the foot, the leg, and the thigh of the diseased limb are enveloped in clean towels, wrung out in corrosive sublimate solution. The limb is elevated vertically for five minutes, in order to deplete its vessels, and the constricting band is applied high up on the thigh. The knee is flexed, and an incision, commencing at the middle of one condyle of the femur and extending in a semicircular line *above* the patella to the middle of the other condyle, is carried into the joint. The transverse incision above the patella, proposed by Eugene Hahn, of Berlin, has many advantages over the incision made below the patella. The chief one is the free access which it affords to the bursa of the quadriceps, which must be carefully exsected along with the capsule.

The crucial ligaments are divided close to their attachment to the femur, and the patella, the semilunar cartilages, and the entire capsule, together with the bursa of the quadriceps, are exsected with mouse-tooth forceps and curved scissors. Care must be taken not to overlook some small bursæ situated behind the head of the tibia, which regularly communicate with the interior of the joint. The condyles of the femur are sawed off, the plane of section corresponding to the transverse diameter of the epiphysis of the femur. Disregard of this rule will lead to ankylosis in such a position that the patient will be bow-legged. The articular surface of the tibia is sawn at a right angle to the long axis of this bone. All visible orifices of vessels are secured by ligatures; they can be recognized by compressing the vicinity of the wound with both hands.

If the transverse incision was not made long enough to permit of an easy arrangement of the drainage tubes in the angle of the wound, it should be sufficiently lengthened. The inner ends of the tubes should reach into the popliteal space, just behind the sawn surfaces, and the tubes must not be compressed and occluded by the tension of the soft parts surrounding them. The limb is placed upon a long cushion covered with a clean towel wrung out of corrosive sublimate solution, and, while the sawn surfaces are held in exact apposition, from two to four long steel nails, previously well disinfected by heating in an alcohol flame, are driven diagonally through the femur and tibia, so as to lock the bones firmly in the desired position. The cutaneous incision is united by a sufficient number of catgut sutures. The limb is raised by the foot from the cushion, which is then removed. Strips of disinfected rubber tissue are slipped under the safety-pins securing the ends of the trimmed drainage tubes, and an oblong compress of iodoform gauze is laid over the entire line of union. A suitable number of sublimated gauze compresses are arranged around the knee-joint, and two short lateral splints of veneering, or thin board, are firmly bandaged on, to serve as a deep support. Over these is placed an ample external dressing of corrosive sublimate gauze, also firmly secured by a gauze bandage. The towels are removed, and the uncovered parts of the limb are enveloped in a layer of borated cotton, so as to equalize its outline. Two long lateral pasteboard splints, secured by muslin or crinoline, complete the dressing for children or adolescents.

In adults, the limbs being stouter, are better secured by a firm circular plaster-of-Paris splint. The limb is elevated vertically, and the constricting rubber band is removed; the return of the circulation is attested by the pink color of the toes. As soon as these turn pale, the extremity can be brought to the horizontal position.

If asepticism was well maintained the operation will be followed by slight aseptic fever, and no severe pain. The dressings should remain undisturbed for thirty days, so as to afford a good chance for bony union. After this period the splints and dressings can be removed, and the nails and drainage tube can be withdrawn. The remaining sinuses are dressed lightly, the limb is encased in a silicate of soda splint, and the patient is ordered to walk

about on crutches, whether osseous union is present or not. Gradually the crutches are dispensed with, and the patients generally learn to walk very well on an elevated sole, which compensates for the shortening.

Of twelve cases of total exsection performed by the writer for tuberculosis, eleven recovered, and one died of meningeal tuberculosis. The history of the fatal case was as follows:

CASE V.—Fred. F., æt. seven. Osseous tuberculosis after arthrectomy performed by Dr. F. Lange, in June, 1885. On March 4, 1884, total exsection was done at the German Hospital. The operation revealed two periarticular abscesses, and five cheesy foci in the tibia and femur. Suppuration of the wound occurred. On March 10th an abscess on the outer aspect of the knee was incised. On April 23d separation of the epiphysis of the tibia took place; the separated epiphysis was firmly united to the femur. Symptoms of meningeal tuberculosis developed, to which the patient succumbed, May 31st.

In one of the remaining eleven cases amputation of the thigh became necessary on account of suppuration. The following is a brief synopsis of this case:

CASE VI.—H. D., professional athlete, æt. thirty. Extensive destruction of the right knee-joint by tuberculosis, complicated with pyogenic infection. The knee, leg, and thigh contained a large number of abscesses; there was profuse secretion from seven fistulæ. The case was not suitable for exsection and amputation was advised; but, at the patient's earnest request that an attempt should be made to save his limb, total exsection was done at the German Hospital, on February 14, 1884. As suppuration was expected, the extremity was fixed to an interrupted dorsal suspension splint, made of hoop iron, by plaster bandages. Profuse suppuration followed, attended with evident prostration. On April 19th the thigh was amputated. The wound healed by granulation, and in June the patient was discharged cured.

Ten cases were cured, in which the limb was preserved; in nine of these firm, bony ankylosis was secured. In one there was ligamentous union, viz.:

CASE VII.—Nicolas G., carpenter, æt. fifty-four, synovial tuberculosis, with high temperature and emaciation, following slight traumatism. Contraction of the knee at an acute angle, with constant violent pain. On February 19, 1886, a puncture was made at the German Hospital, a small quantity of turbid, bloody serum being withdrawn. Under an anæsthetic the limb was straightened, and the joint was incised, irrigated, and drained. The fever at once disappeared, but flocculent pus commenced to flow from the tube, confirming the assumption that tuberculosis was present. In view of the patient's age, and his wretched general condition, which was due partly to disease and partly to chronic alcoholism, amputation was thought to be advisable. The plan of operation was changed at the operating table, and total exsection of the knee-joint was done. Hemorrhagic synovitis, and a large cheesy deposit in the bursa of the quadriceps, were found. Five nails were introduced, and an aseptic dressing was applied, with pasteboard splints. Temporary compression with Martin's bandage was employed, in order to control the secondary oozing. The dressing was changed on the twenty-second day. Four nails were found to be loose, and were withdrawn. On May 8th, the drainage tracks were scraped, and the fifth nail was removed. Ligamentous union had taken place. A plaster-of-Paris splint was applied. By June 12th the sinuses had healed, and the patient was walking without a stick or crutches, wearing a light silicate-of-soda splint, though union of the bones was not perfect.

The following are brief notes of the other nine cases:

CASE VIII.—Willie B., æt. three and a half. Osseous tuberculosis with fistulæ. Total exsection was performed, February 2, 1879. April 2d, patient was discharged, cured.

CASE IX.—Charles H., æt. twelve. Osseous tuberculosis, with fistulæ; contracture, and subluxation backward. Total exsection, June 13, 1884, at German Hospital. Hahn's incision was made, two nails were introduced, and a plaster-of-Paris splint applied. Some fever, and deep-seated œdema of the region of the knee followed. The sawn surfaces and the flesh wound united by first intention. The nails being withdrawn on the twelfth day, some pus exuded from their tracks, showing that they had apparently not been well disinfected. Several revisions were required on account of the development of unhealthy granulations in the drainage holes. On February 4, 1884, the patient was discharged with firm ankylosis, and no fistulæ.

CASE X.—S. B., æt. nine. Osseous tuberculosis, several fistulæ, subluxation. August 26, 1885, total exsection at Mount Sinai Hospital. Nails were introduced, and a plaster-of-Paris dressing applied. September 25th the dressing was changed, and the nails and drainage tubes were withdrawn; firm ankylosis. October 10th, patient discharged, cured.

CASE XI.—Leonard P., waiter, æt. nineteen. Synovial tuberculosis, no fistulæ. August 27, 1885, total exsection at the German Hospital. September 27th, plaster-of-Paris splint, dressings, drainage tubes, and nails removed. October 9th, sinuses healed. October 19, discharged cured, with firm ankylosis.

CASE XII.—Bertha D., æt. twelve. Synovial tuberculosis of five weeks' standing. Continuous high fever, with rapid emaciation. A puncture yielded a small amount of bloody serum. January 21, 1886, total exsection at Mt. Sinai Hospital. The capsule was found studded with innumerable miliary tubercles. The fever disappeared immediately after the operation. February 20th, the plaster splint was renewed, and the wound was found to have healed by first intention. March 10th, the patient was discharged cured, with firm ankylosis.

CASE XIII.—Lizzie B., æt. twenty. Osseous tuberculosis of eighteen years' standing; rectangular contraction with subluxation backward. February 12, 1886, total exsection at the German Hospital. March 10th, change of dressings, three nails and the drainage tubes being removed; primary union.

April 4th, patient complained of a good deal of pain in walking. A hard body could be felt under the skin on the outer aspect of the tibia. An incision exposed the head of the fourth nail, which had not been found at the first change of dressings. It was withdrawn with some force, a little blood exuding from its track. May 9th, patient discharged cured.

CASE XIV.—Anna L., æt. twenty-two. Synovial tuberculosis with ulceration of the articular surfaces of both the femur and the tibia. May 10, 1886, total exsection at the German Hospital. June 12th, first change of dressings. Primary union of the soft parts; delayed union of the bones. August 1st, discharged cured, with firm ankylosis.

CASE XV.—Synovial tuberculosis, with caseous deposits in several recesses of the capsule, notably around and behind the crucial ligaments. Caries of the articular surfaces. May 18, 1886, total exsection at the German Hospital, the operation being followed by slight fever. Dressings removed May 26th, showing marginal slough of the upper edge of the skin-wound. June 17th, nails removed. Firm ankylosis. July 26th, patient discharged cured.

CASE XVI.—Emma F., æt. twenty-seven. Synovial tuberculosis, with caries of the articular surfaces. April 18, 1887, total exsection. April 22d, considerable amount of secondary oozing, necessitating a change of the external dressings and plaster splint. There was some fever. May 23d, dressing changed; primary union, with firm ankylosis. The tubes and three nails were removed; a fourth nail could not be found. To prevent the disagreeable necessity of cutting down in search of a nail buried in the tissues, Dr. F. Lange's suggestion of fastening a silk ligature to the head of each nail before driving it in, seems to be very appropriate. June 4th, an incision was made over the seat of the fourth nail, which had healed in completely, and it was withdrawn.

CHLOROFORM AND FORCEPS.

BY J. E. FREE, M.D.,
OF HARRISBURG, PA.

OPINION is, perhaps, equally divided upon the question of the applicability of chloroform. It is customary for the advocates of either side of a controversy to publish remarkable successes when reached through the medium of their favorite drugs and methods, but the humiliating disappointments are buried in oblivion; thus sometimes a conclusion, which is apparently sustained in current literature, receives a rude shock in actual practice.

Up to within a few days I have been a firm believer in the value of anæsthetics in parturition. They have frequently helped me where there was severe suffering to be relieved, and heretofore have never increased the patient's risks.

But my series of successful cases has been broken by a most discouraging result. My father, who has had a wide experience, is a determined opponent of what I consider scientific aids to delivery. He has been remarkably fortunate without them, and consequently insists upon their inutility.

Recently we had an opportunity of bringing the point at issue to a trial. Mrs. F., a petite blonde, well developed and in excellent health, was confined on April 22, 1887. I say she was in good health, but previously, at the time of fecundation she had serious trouble with her stomach, and for the first three months of pregnancy was in bed. All of the usual remedies for this condition were tried without avail, and in despair she swallowed a teaspoonful of oil of rue, hoping thereby to induce an abortion. The result was sharp gastro-enteritis, which was relieved with orange juice. After taking the rue the appetite for the oranges developed, and in two weeks she consumed a whole box of Florida oranges.

The *modus medendi* in this instance is strikingly obscure; there was a substitution of one morbid process for another when the rue was swallowed, but when it subsided the reflex influence ought to have again appeared.

Labor pains were first felt at 3 A.M., they were far apart and slight for several hours; then they suddenly increased in frequency and force, and at 10 A.M. the head passed the upper strait and seemed about to engage in the pelvis. But no progress was made. The amniotic fluid was discharged, strong expulsive pains came on, and still the head lingered. The woman was restless and wilful, and would not make the proper effort to help herself. Therefore, being an advocate of chloroform in just such conditions, I thought the case a proper one for its use.

My father, who was called as consultant, did not favor any interference, and gave it as his opinion that the labor would terminate favorably—sometime, but if chloroform was used we would have post-partum hemorrhage, and with forceps we would most probably have a ruptured perineum. If he had not condemned anæsthetics and instruments on general principles, I would have been disposed to heed his advice. Unfortunately for my theory, I insisted upon terminating the labor with all possible speed.

The chloroform caused the pains to relax, which was what was prognosticated of it. But having the forceps in position the desire to terminate the delivery was too strong to be resisted, and I made traction on the head. It yielded gradually, and when the perineum began to stretch I tried to slip the forceps off, but only had time to get one blade away before the head came out with a rush, rupturing the perineum through the sphincter ani.

The child was cyanosed, and died the following evening.

The placenta came away with the child, and for a few minutes we devoted our attention to the latter. All the methods known to us for the resuscitation of asphyxiated children were tried, especially those recommended recently by Drs. Blackwell and Smith.

The mother bled rapidly, and before we could control the hemorrhage with ergot, ice, and pressure, the bedclothes and mattress were saturated and the blood was running to the floor.

After the flooding was stopped an immediate operation upon the perineum was proposed with cocaine as an anæsthetic to the surface, but it proved unsatisfactory, and chloroform was again administered.

To-day, May 9, 1887, our patient is doing re-

markably well, but the case has taught me a severe lesson. The result was most disastrous when it is remembered that it was made the test for the advisability of giving chloroform and using the forceps in a protracted labor.

MEDICAL PROGRESS.

Antisepsis for the Newborn.—Miller, at the Second Congress of Russian Physicians, stated that the newborn become ill with septicæmia and pyæmia very easily: the ground for the frequency of such illness is neglect of antiseptic precautions. In the asylum at Moscow 700 to 800 newborn perish each year from pyæmia.

These cases may be divided in three classes:

1. In one class the infection appeared in the first three days of life when the cord is still fresh or is just beginning to decompose. In such cases the infection must have occurred during intrauterine life. The post-mortem examination in such cases reveals extensive disintegration of the blood without marked lesion of any organ.

2. In these cases pyæmia appeared on the fourth or fifth day of life, simultaneous with the separation of the cord. Post-mortem appearances are purulent and fatty degeneration of different organs, inflammation of the peritoneum and pleura, and ulcerative endocarditis. This infection has its source in the umbilicus.

3. Cases of late pyæmia. The cause of these infections is found in the bad condition of the foundlings' asylums, and this infection is a frequent complication of inflammatory processes. Post-mortem examination in these cases reveals the umbilicus healthy and the exciting cause is found in stomatitis, intertrigo, and anal fissures following rectal prolapse.

Children suffering from *blennorrhœa neonatorum* frequently develop inflammation about the umbilicus; such children should be treated with especial care.

The writer recommends Ringer's method of treating the cord, drying, powdering with boric acid and wrapping in salicylated cotton.

When suppuration occurs carbolic lotions and iodoform should be used. Other diseases likely to cause pyæmic infection must be treated with especial precautions.—*Centralblatt für Kinderheilkunde*, May 2, 1887.

Antipyrin as an Analgesic.—Germain Sée finds that antipyrin allays pain by suppressing sensibility and reflex excitability without disturbing the rhythm of the heart or the force of the circulation.—*Gazette Hebdomadaire*, April 22, 1887.

Treatment of Serpiginous Ulcers of the Cornea.—Dehenne reports the following treatment in *L'Union Médicale* of May 7, 1887:

1. Incise the superior and inferior lachrymal puncta, and irrigate the lachrymal duct freely with an antiseptic solution (boric acid 4 to 100).

2. Irrigate the conjunctival sacs with sublimate solution 1 to 2000.

3. Cauterize the ulcerated surface with a fine thermocautery point at white heat.

4. If there be pus in the anterior chamber, perforate the cornea with the same point and evacuate the pus.

5. Drop into the diseased eye four times daily five or six drops of a neutral solution of sulphate of eserine, 1 to 200.

Treatment of Diarrhœa by Iodoform and Charcoal.—Picchini treated eight cases of diarrhœa, with symptoms of fermentation, with the following:

Iodoform	grs. 9.
Ether	ʒ 3ß.
Vegetable charcoal, finely powdered	ʒ 3ß.
Glycerine, ...	ad. ʒ 12.

The iodoform must be dissolved in the ether, and the powdered charcoal thoroughly mixed. After the ether has evaporated the glycerine should be added. To take in twenty-four hours, by teaspoonful or tablespoonful, suspended in a glass of water.—*Journal de Médecine*, May 1, 1887.

The String Drain, a Supplement to the ordinary Drainage Tube.—Dr. Jenkins proposes the following expedient in *The Annals of Surgery* for May, 1887:

The method proposed is a simple adjunct to the drainage tube, and is, in so far as the writer is aware, novel. The liberty is taken of calling it "the *string drain*."

It consists in introducing one end of 30 or 40 feet of rough string, highly hygroscopic, and completely aseptic, through the usual "Chassaignac drainage tube," so that, when the last is placed in the wound, the string may be drawn through, from time to time, as will be explained hereafter.

The string may be of cotton, linen, or wool, that has been freed of fat and disinfected, for which purpose it is recommended that it be treated after the manner that v. Bergmann prepares his gauze—by immersing the absorptive string for one hour in the following: Sublimate 1, glycerine 50, alcohol 100, water 150, warmed, to be dried, and kept in hermetically sealed glass jars; it will then hold 1/3 per cent. sublimate, and is very absorbent. The end of the string being passed into the tube, and the tube placed in the wound, and it closed, then the strings and aperture or apertures of tube are covered by the usual protective of "gutta-percha paper," or "Lister's oiled silk," to hinder evaporation or gluing of the string. The string is now tried, to see that it draws freely, and is so placed that it lies along the line of least resistance, and closely applies to the body's surface; over the gutta-percha paper and string, the gauze and cotton, etc., are to be placed. The coil of the string may be kept in an antiseptic magazine, such as a glass bottle, which can be included in the bandage or left out, as desired; in the last case, when not being used, the bottle should be tightly stoppered, and covered by an antiseptic bandage. The draw-end should be left out and can be drawn upon from time to time, as may be necessary, until it comes free from secretion.

The soiled end of the string can then be cut away, and it and the bandage, at its emergence, disinfected with a saturated solution of iodoform in ether.

The other end should be protected most rigidly against infection, as mentioned above.

Or the string might be placed in a coil in the wound

itself, in form of tampon, and passed out through a drainage tube.

This might apply in wounds such as would be left after the removal of tumors (as lipoma), or might thus be used with Martin's drainage tube in "Douglas's fossa."

The process advocated is recommended during the first forty-eight hours, when the wound is pouring out a large quantity of serum, before granulation is established on the wound's walls, which follows especially operations in which "carbol" or other irritants are extensively employed, and in this time the tube is most likely to be stopped by coagula.

ARSENIATE OF STRYCHNINE AND PEPSINE.—AURILLAC has found the following useful in dilatation of the stomach and constipation:

Pepsine	grs. 1½.
Ext. of malt	♏ 2.
Arseniate of strychnine . . .	gr. $\frac{1}{30}$.

For four capsules or wafers.—*Les Nouveaux Remèdes*, May 8, 1887.

THE TREATMENT OF PHTHISIS.—DETTWEILER, at the recent Congress for Internal Medicine, read a paper on this subject, whose conclusions are as follows:

1. There is no specific treatment of phthisis.

2. The essence of treatment consists in regulating tissue changes: best accomplished by fresh air, the cultivation of bodily endurance, nourishment, and exercise.

3. A climate free from phthisis does not exist; that climate is best which best permits the treatment described.

4. Phthisis is curable; the effort must be made to cure every case, especially in its early stages.

5. These points are best gained by treating the phthisical in buildings and localities especially fitted for them.—*Berliner medicinische Wochenschrift*, April 27, 1887.

THE TREATMENT OF WOUNDS.—TREVES, of London, detailed, at a recent meeting of the Harveian Society, his method as follows:

Dealing first with wounds of the lower extremities, he dwelt on the greater mortality attending these injuries, and the reasons assigned for healing taking place more slowly and imperfectly. In his opinion bad ventilation is one cause; the atmosphere under the bed-clothes is close and stuffy, if not positively fetid; the limb may be wrapped up in cotton-wool, but ought to be freely exposed to the air. Again, in wounds about the toes and feet, the large sheaths of the tendons are opened; no care is taken to close them, and they become practically open tubes, in which pus accumulates. In removal of the toes, healing is often prevented by sloughing of the flaps; this is due to the operator neglecting to respect the integrity of the artery which supplies blood to the flap. In cases of fractured patella no treatment is better than the use of Malgaigne's hooks, provided these are scientifically applied; the author described his method of applying them. Mr. Treves protested against the use of plaster in putting up compound fractures of the lower limb; his plan is always to fix these fractures by the use of straps and buckles, to expose the limb freely to the air, and to keep the wound constantly powdered with iodoform until a firm scab formed. While dealing with wounds of joints, the author remarked on the great value of irrigation, and gave notes of a case in which amputation of the lower limb for desperate disease of the knee-joint had been avoided by keeping a stream of water flowing through the joint for a month. In discussing the dressing of operation-wounds, the relative merits of iodoform, corrosive sublimate solution, etc., were discussed, but preference was given to dry sponge dusted over with iodoform. Great stress was laid on the different drainage of abscess cavities and wounds; for large abscesses, as in suppurating hydatids of the liver and psoas abscess, the tubes ordinarily used were quite inadequate.—*British Medical Journal*, April 30, 1887.

ATTEMPTED REMOVAL OF A NEEDLE FROM THE HEART.—The following case is reported by the *British Medical Journal* of April 30, 1887, from the recent German Surgical Congress:

A student of the Polytechnic School had endeavored to kill himself by driving a needle into his heart. Though the needle entered the heart, the attempt failed. The needle could be distinctly felt. The pericardium was opened, but the needle was not found; a second operation was undertaken, and the operator was successful in seizing the needle, but failed to extract it, so that it slipped completely into the heart, where it could be felt. The operation having been abandoned at this stage, the patient made a good recovery.

FORMULA FOR THE USE OF CARBONATE OF LITHIUM AND ARSENIATE OF SODIUM IN GLYCOSURIA.—VIGIER gives the following:

℞.—Lithii carbonat.	gr. 1½.
Sodii arseniat.	gr. $\frac{1}{20}$.
Extr. gentian.	gr. ¾.

for each pill.

One pill should be taken morning and evening.—*Journal de Médecine*, April 24, 1887.

SIMPLE TREATMENT OF CHRONIC ENLARGEMENT OF THE TONSILS.—DR. BERESFORD says: "By the use of a strong solution of tannic acid injected two or three times a week, with the daily use of a gargle of the same, the knife never need be resorted to. I have used the above treatment in the case of a man, aged twenty years, with good success. I made an application of muriate of cocaine before inserting the needle, and used the injection every three days."—*Technics*, May 3, 1887.

TREATMENT OF PHTHISIS BY INHALATIONS OF THE VAPOR OF A BOILING SOLUTION OF PICRIC ACID.—HUA and BRUÈRE, in the *Gazette Hebdomadaire* of May 13, 1887, call attention to their observation, made originally in 1885, that phthisical workmen employed where they inhaled these fumes, were much benefited. They referred the matter to the Academy of Medicine in December, 1886, and now report four cases of human beings greatly improved by the treatment; they also report rabbits inoculated with tuberculous matter as favorably influenced by picric acid fumes. The writers promise further investigations.

EXTIRPATION OF THE SPLEEN.—At the recent congress of Russian medical practitioners, DR. A. G. PODREZ, private-docent in Kharkuff, read a paper on extirpation of the spleen, including the notes of a case in which he himself had recently performed this operation. The patient was a woman with ague-cake, associated with ascites and extreme cachexia. The operation was performed on the 22d of November last; the patient subsequently went on well, being able to get up on December 10th. The weight increased, and the ascites disappeared. On the 16th, however, she had a rigor, and the urine contained a large quantity of albumen and hyaline casts. Death occurred on the 27th, and was due, as shown by the necropsy, to diffuse parenchymatous nephritis. The total number of cases of extirpation of the spleen collected by Dr. Podrez (including his own) is 42. Of these one was performed in 1549 by Saccharelli, and one in 1711. The rest all belong to the present century. If his own case is reckoned as a recovery, the mortality is 73 per cent.; if otherwise, the mortality is 76; the recoveries being 12 or 11 out of the 42 cases, according as this is or is not reckoned as belonging to that category. The cause of the 11 deaths was septicæmia in one case, peritonitis in one case, and hemorrhage either during or shortly after the operation in all the others. Dr. Podrez thinks that an improved method of performing the operation is required, in order to obviate the tendency to hemorrhage. It is also to be desired that, by means of further observations, the indications for the operation in cases of enlarged spleen associated with both ague and leukæmia may be defined. —*Indian Medical Gazette*, No. 3.

HYPODERMATIC PURGATION.—DR. GEORGE DALTON HAYS, in an article in the *New York Medical Journal* of May 21, 1887, reports his observations on the use of purgatives hypodermatically as follows:

Various substances have been vaunted by different observers as being efficacious when introduced in this way. The most noted is sulphate of magnesium, which Luton stated, from experiments on himself and on his patients, provoked diarrhœic stools when administered in injections of ten centigrammes. It has not proved equally successful in the hands of others. I have lately been making some experiments upon my own person with colocynthin, the glucoside of colocynth. I have employed it hypodermatically in one-third grain doses, dissolved in water, and combined with one grain of cocaine. Without this latter the injection is painful. In the course of three or four hours it has produced several diarrhœic stools. My experiments have not been sufficiently numerous, as yet, to enable me to draw any wide conclusions. The value, in some conditions of the body, of a drug which will produce prompt and thorough catharsis when introduced hypodermatically, is evident.

DR. PEACAN'S TREATMENT OF CHOLERA.—DR. L. PEACAN, of Buenos Ayres, warmly recommends a plan which he has for many years past pursued with much success in the management of cholera. When a typical case with vomiting and diarrhœa comes before him, he immediately applies a cautery behind the right ear over the condyle of the lower jaw, with the object of stimulating the pneumogastric, and thus paralyzing the action of the sympathetic on the abdomen. He then administers six centigrammes (six-sevenths of a grain) of calomel, which dose is repeated every five hours. Half an hour after taking the first of these powders a mixture is commenced consisting of phosphoric acid, carbolic acid, tincture of opium, tincture of ginger, chloric ether, and mint-water, which is supposed to arrest vomiting and diarrhœa, to allay thirst, and to calm spasm—being, indeed, he states, sufficient to cure mild cases by itself. When the cramps are severe, ten drops of Battley's sedative solution of opium are added; and when there is marked prostration of the nervous system, tincture of coca. If the diarrhœa continues, three grammes (forty-six grains) of glycerole of tannin are given in coffee three or four times a day, and forty centigrammes (six grains) of Dover's powder for three or four nights in succession. The patients are allowed to have as much sulphuric acid lemonade as they care for. In addition to internal medication, warm frictions and sinapisms are applied, especially over the epigastrium. *Lancet*, May 14, 1887.

DIET FOR THE NEUROTIC.—DR. DANA, of New York, recommends the following in the *Journal of Reconstructives* for April, 1887:

In persons of a sensitive and irritable nervous system, those who are classed popularly as "nervous," neurasthenic, or hysterical, the same rules as to a nitrogenous diet, plus as much fat as can be digested, apply. There is a class of nervous persons who, of themselves, find that they cannot take anything sweet without producing headaches, rheumatic pains, and dyspeptic symptoms. These persons should live on meats, fish, with plenty of butter, oysters, cream and milk with soda-water, the yolk of egg with sherry. Beef-tea with the white of an egg, or some peptonoids forms a very nutritious dish. It has been the canon of medicine for many years that animal food must be the soul of the neurotic's diet.

Most nervous persons find, in addition, that green vegetables, like spinach, agree very well with them. Stale bread can be taken twice a day freely, plenty of butter being used upon it. The dietetic breads from which the starch has been removed are sometimes useful, but are, as a rule, unpalatable, and soon cause disgust.

When a rigid diet is to be laid down, there is no better list for nervous invalids than the following:

Beef, and its preparations.
Mutton and lamb.
Fowl.
Fish, boiled or broiled.
Oysters.
Milk.
Butter.
Egg, raw or soft-boiled.
Graham bread and gluten bread.
Spinach.
Stewed fruits, slightly alkalinized.

Nervous patients, especially hysterical patients, should not use alcohol at all. Tea and coffee can be taken in very moderate amounts. The various mineral waters may be used with impunity, but none of them have much effect in relieving nervousness, or curing the nervous temperament.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM IN ADVANCE. $5.00
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JUNE 11, 1887.

INTESTINAL ANTISEPSIS.

THE subject of self-infection with products formed in the digestive tract has been studied with increasing interest since Selmi, in 1872, discovered in the results of cadaveric putrefaction, and even in fresh tissues, in flour, bread, etc., certain substances closely resembling the vegetable alkaloids, to which he gave the name of *ptomaines*. Gautier, Tanret, Brieger, Brouardel, Bouchard, Dujardin-Beaumetz, and others, have continued these investigations, and the opinion is growing that certain grave cardiac, respiratory, and cerebro-spinal disturbances, hitherto known as typhoid or adynamic conditions, are due to the absorption of these toxic materials from the intestinal tract.

Under normal circumstances these substances are formed chiefly in the large intestine, but owing to their small amount and their ready elimination by the kidneys and liver, their absorption is harmless. In conditions of disease, however, owing to defective or vitiated secretions, the contents of the digestive tube undergo abnormal processes of fermentation and putrefaction, and toxic alkaloids are developed to an extraordinary extent. For example, if the gastric juice be deficient, and, therefore, its well-known antiseptic action with reference to albuminoid substances diminished, the microörganisms introduced in large quantities with food and drink may find a medium suited to their growth, and give rise in the stomach to fermentations which, continuing in the intestine, will produce an abnormal amount of poisonous products, such as leucin, tyrosin, ptomaines, phenol, indol, skatol, etc. The same reasoning applies to the biliary secretion, of which the amount, and consequently the antiseptic properties, are diminished in all febrile affections.

The intestine having been proved to be a species of laboratory in which are formed virulent poisons capable of aggravating, or, as some hold, even of originating disease, the idea of arresting or limiting the formation of such substances is one that naturally arises. This question is ably treated by MARTINI, in an article on thymol as an intestinal disinfectant, in the *Annali Universali di Medicina e Chirurgia*, for February, 1887. In an interesting summary of the work done in this direction, Martini claims that Semmola, who twenty years ago employed the alkaline and earthy sulphites with the object of destroying toxic and pyogenic substances in the intestine, was the first to introduce a treatment based upon the idea of intestinal antisepsis. In recent times a large number of substances have been employed for this purpose, and in the article quoted their merits and demerits are discussed. Antiseptic enemata have disappointed the expectations naturally raised concerning them, because the most efficacious germicides are too irritating to be thus employed. Powdered charcoal, iodoform, creasote, magnesium benzoate, sulpho-carbonated water, naphthalin, etc., have been given *per os*, with more or less benefit, to arrest or control abnormal processes of fermentation and putrefaction in the digestive tract. Each of these drugs has a more or less enthusiastic advocate. For example, Dujardin-Beaumetz speaks of sulpho-carbonated water as a "heroic remedy" in dilatation of the stomach with putrid dyspepsia, and Goetze, who gave naphthalin in doses of seventy-five to one hundred grains a day to thirty-five cases of typhoid fever, claims that it aborted the disease in seventeen.

Martini, in the article quoted, reports a number of cases in which he employed thymol in doses of from 20 to 120 grains per diem, the usual dose being from 30 to 60 grains. He claims that thymol is of value in chronic intestinal catarrh not associated with grave lesions of the intestinal wall, and in the diarrhœa of cachectic and marasmatic individuals; that in chronic dysentery with profuse diarrhœa complicated with intestinal ulceration, it sometimes reduces the number of discharges, which still remain liquid, but at others it is perfectly useless; that it is, however, of service in acute dysentery; that it is indicated in the diarrhœa of pulmonary tuberculosis, not yet arrived at the last stage; that it is of decided value in diarrhœa caused by the ingestion of an undue amount of food, or of food that is indigestible *per se*, or of altered quality; and that, finally, it is efficacious in summer diarrhœa, and in the diarrhœa of dentition.

Observations as to the antipyretic effect of thymol demonstrate that it does not lower the temperature of

healthy subjects, or of those affected with non-febrile diseases. In febrile disorders not complicated with gastro-intestinal disturbances, its action is uncertain, sometimes producing slight and transient reductions of temperature, at others having no effect whatever. In febrile processes accompanied with gastro-intestinal disturbance, for example, in typhoid fever, it is of decided antipyretic value.

That thymol exerts its beneficial action by disinfecting the intestinal contents, is proved by its great insolubility, and by the fact that, during its administration, phenol disappears from the urine. This substance, one of the most constant products of intestinal putrefaction, is eliminated, for the most part, by the urine, where it is found even in health, and experimental therapeutists regard its amount in that fluid as a test of the effect of an intestinal antiseptic.

THE VALUE OF ANTIPYRETICS.

At the meeting of the Association of American Physicians held at Washington last week, there was a most interesting discussion upon the value of antipyretics, an abstract of which appears in another column. The speakers represented the professional opinion of a wide area of the Union. Dr. H. C. Wood, who led the discussion, spoke almost solely on the action of antipyretics from an experimental standpoint, while the paper of Dr. Minot, of Boston, viewed the matter from its clinical side.

Dr. Wood reminded his hearers that there are two classes of antipyretics, viz., those which reduce bodily temperature by lowering arterial pressure, thereby increasing heat dissipation, and those which, acting in some as yet unknown manner, prevent the production of heat. The first of these are, in reality, false antipyretics, the second, true antipyretics; for the first only aid in dissipating heat already formed, while the second class prevent its formation, and thereby do away with the tissue waste which plays so important a part in lessening the vitality of the sick man. To the false antipyretics belong aconite, veratrum viride, and similar cardiac depressants, while antipyrin, antifebrin, and perhaps quinine, belong to the second class.

The paper of Dr. Minot dealt particularly with the use of antipyrin and thallin in typhoid fever, and the conclusion arrived at by this observer, and the speakers who followed him, was that antipyrin is in all probability more preferable in every case, notwithstanding its larger dose and cost. The discussion, however, soon passed beyond the necessarily limited remarks of the speakers named, and most interesting reports of the varying experiences of the members were brought forward.

Notwithstanding the comparative youthfulness of antifebrin, it was surprising to hear how generally it had been used and how satisfactory the results obtained from its use had been; the whole tone of the discussion being decidedly in favor of its employment in preference to any other drug of the class. Antipyrin occupied a second place, while but few favorable remarks were made in support of thallin.

Among other collateral questions which arose, the one regarding the comparative value of the cold bath and antipyretic drugs was of great interest, and the fact that the cold bath acts not merely by abstracting heat, but by preventing its development, was well brought out. The opinion of most of the speakers was that while both means of reducing fever are useful, neither one can supplant the other, and that in some cases antipyretics perform all that is to be desired, while in others nothing but the cold bath will accomplish the purpose.

No discussion was held as to the relative value of antipyretics other than those named, no mention being made of them except to deny their usefulness. The cold water treatment first introduced by Brandt did not receive favorable notice, although none of the speakers seemed to have used this method.

DETECTION AND TREATMENT OF MORPHIA-TAKING.

The physcian who has been worried and deceived by the lying and cheating of the confirmed morphiomaniac or opium-eater will be grateful for any help toward the diagnosis of this disease, which does not depend upon the morbid imagination or the torpid conscience of the patient. Dr. Oscar Jennings, of Paris, has earned some of this gratitude by following his previous studies of morphinomania with one on its diagnosis and treatment. He suggests first the examination of the urine for morphia or opium salts. The reagents he uses are (1) the double iodide of mercury and potassium ($HgCl$ 13.546, KI 49.80, H_2O to a quart). This gives a yellowish-white precipitate with the alkaloids. (2) The iodized iodide of potash (I 10, KI 20, H_2O 500), the precipitate from which, in the presence of morphia salts, is brown or yellowish. If the quantity be too small to discover by one of these reagents, boil the urine to a third, treat with tartaric acid, then dissolve the tartrate of morphia thus formed with amylic alcohol; decompose the salt with ammonia, and if morphia be present the solution should show a blue color on adding the perchloride of iron. A slightly less troublesome proceeding will detect meconic acid and prove the taking of opium: evaporate, wash with alcohol and boiling water, neutralize with magnesium carbonate, and treat, after filtration, with solution of iron perchloride. A blood-red color is characteristic of meconic acid.

Still further, Dr. Jennings says that the most marked objective symptom of deprivation of morphia in the confirmed habitué is enfeeblement of the heart's action, and this is shown by the peculiar sphygmographic tracing. It differs from the normal in presenting a truncated apex in place of a pointed one, due probably to a capillary obstruction to the movement of the blood. The tracings given show, too, a lessened amplitude of beat—while those taken five minutes after the injection of the customary dose have increased in amplitude, have lost the "plateau" at their joint, and seem entirely normal. From this Dr. Jennings deduces the necessity of using, in the treatment of such cases, a circulatory stimulant of some kind to replace the withdrawn morphia; of such medicines he has found nitroglycerine to produce the same improvement of the pulse as morphia, and patients taking it declare the sensation of warmth and comfort following its use is like that which they experience on first receiving morphia after deprivation of it. Valerian, bicarbonate of soda, a hammock instead of a bed, faradization, dry friction, and the Turkish bath are his other weapons.

The whole study is an interesting one, and especially suggestive to life-insurance examiners, who occasionally suffer from inability to get truthful answers on the subject of the opium-habit.

PICRIC ACID IN FUNGOUS ENDOMETRITIS.

CHÉRON, in the *Revue Médico Chirurgicale des Maladies des Femmes* for May 25th, strongly recommends a uterine injection of picric acid in cases of fungous endometritis. The curette is first used, so that the uterine cavity is freed from the exuberant growth of mucous tissue. This operation leaves a bleeding surface with many open lymphatics and capillaries, and it is necessary thoroughly to cleanse it, in order to prevent the retention of blood in the uterine cavity, and the reproduction of the fungous growths, which is very liable to occur if there be prolonged suppuration.

A most valuable agent for these purposes is found in picric acid, which promotes the prompt healing of the wounded surface. It should be used in solution, the strength being one drachm of the acid to a pint and a half of warm water; the solution should be injected by means of Bozeman's catheter, every day, or once in two days. Picric acid is both antiseptic and analgesic, and on account of these properties is especially suitable for use in cases of fungous endometritis after thorough curetting.

M. TRÉPANT, of Amiens, has called attention in the *Revue de Thérapeutique* for May 1, 1887, to a mode of inducing anæsthesia devised by him, which has, apparently, succeeded perfectly. The method consists in giving every five minutes a spoonful of the following mixture, until all is taken: Syrup of morphine (French Codex) ʒiv; chloral hydrate 46 grains. Allowing twenty minutes for the absorption of this medicament from the stomach, chloroform is then given by inhalation in the usual way. The patient quickly passes into the anæsthetic condition, without excitement, and without nausea and vomiting, and the time of the insensibility is prolonged without further use of chloroform, of which but a small quantity is required to produce entire insensibility at first.

It is obvious that M. Trépant's method is only a modification of that known for several years as "mixed anæsthesia," and it is probably not more efficient than the latter, whilst it may be more dangerous.

No satisfactory theories have yet been presented explaining the origin of fibroid tumors of the uterus, or of cystic tumors of the ovaries. But GALIPPE and LANDOUZY, in the *Gazette des Hôpitaux*, have recently suggested that the agents in the production of these growths are microbes. They have discovered in two cases of fibromyomata of the uterus, and in a like number of cystic ovarian tumors, microorganisms which, they suggest, act as irritants, causing proliferation of tissue. They sustain this hypothesis by analogous facts derived both from animal and vegetable pathology.

Whether this view will be confirmed by accumulation of similar proofs remains to be seen, and until then it can only be regarded as a possible hypothesis.

AT the recent meeting of the Sixteenth Congress of German Surgeons, the proceedings of which may be found in the *Wiener med. Presse*, No. 18, 1887, RYDYGIER recorded three cases of resection of the pylorus. In one, practised for ulcer, the patient was doing well at the end of three years; in the second, done for carcinoma, the patient died in two years and a half; while in the third, performed likewise for carcinoma, the woman was in the best of health at the expiration of six years, and had borne two children. This last case is the only one out of upward of one hundred operations in which a cure has resulted.

WE are informed that Dr. J. Ohage, of St. Paul, on May 29th, performed Cæsarean section by Sänger's method, on a rachitic dwarf, 3 feet 10½ inches high. The mother unfortunately was attacked by acute sepsis and died on the fifth day, from diphtheritic endometritis. The child weighs seven pounds, and was doing well at the last report.

WE regret to announce the death, on May 15th, of typhoid pneumonia, at the age of 50 years, of DR. JOHN FULTON, of Toronto, who, for seventeen years ably filled the editorial chair of our esteemed contemporary *The Canada Lancet*.

SOCIETY PROCEEDINGS.

THE ASSOCIATION OF AMERICAN PHYSICIANS.

[illegible] at Washington,
[illegible], 1888.

THURSDAY, JUNE 2D.—MORNING SESSION.

The meeting was called to order at 10 o'clock by THE PRESIDENT, S. WEIR MITCHELL, M.D., of Philadelphia. He referred briefly to the purposes of the Association as being purely scientific, and said that neither ethical questions nor medical politics had a place in its work. He referred to the great desirability of making the meeting of the Congress of American Physicians and Surgeons, to be called in the autumn of 1888, a success, and in conclusion he reported the death of three members, Dr. Thomas F. Rochester, of Buffalo; Dr. Thomas A. McBride, of New York; and Dr. E. D. Hudson, Jr., of New York.

DR. R. PALMER HOWARD, of Montreal, read a paper which was entitled

CIRRHOSIS OF THE LIVER IN CHILDREN.

He reported two cases in which cirrhosis of the liver was present in children, brother and sister, and he exhibited sections of the organs.

DR. WILLIAM H. WELCH, of Baltimore, reported a case of cirrhosis in a child twelve years of age, who had come from the coast of Africa and suffered with malaria. Both liver and spleen were deeply pigmented. The clinical features of the case could not be obtained Most of the cases of cirrhosis of the liver of malarial origin have been reported from the coast of Africa. Very little has been brought forward in this country with regard to the malarial origin of cirrhosis.

DR. F. FORCHHEIMER, of Cincinnati, had seen two cases that might possibly be called cirrhosis. One was that of a child of eight years. At the post-mortem the characteristic hobnail liver was found. In this case he considered the cirrhosis due to syphilis. The second case is now under observation in the Children's Hospital of Cincinnati, the patient being in the last stage of cirrhosis. In this case there is a history of syphilis and the child has hereditary syphilis of the nervous system. To his mind it was clear that syphilis is the most common cause of cirrhosis of the liver in children.

DR. WILLIAM PEPPER, of Philadelphia, reported a case in which cirrhosis of the liver followed measles in a child eight years of age. There was no syphilitic history. During the attack of measles, there were symptoms of hepatic disorder, as shown by occasional attacks of catarrhal jaundice. Subsequently the symptoms of developing cirrhosis made their appearance and death in a comatose condition finally occurred. The whole duration of the case could not have been less than a year. At the autopsy a typical hobnail liver was found. The liver had been much enlarged, but it gradually contracted so that at the time of death it was about the normal size.

DR. JOHN GUITÉRAS, of Charleston, read a paper on

OBSTRUCTIVE SAFETY VALVE ACTION IN THE HEART, AND DIRECT FUNCTIONAL MURMURS.

In a previous paper on malignant endocarditis he said he had referred to the significance of mitral direct presystolic murmurs, which were proven by the autopsy to be unconnected with any lesion of the mitral orifice. The lesions were those of intense aortic regurgitation. He had attributed the murmurs to the recoil of blood upon the mitral leaflets holding them tense against the stream of blood coming from the auricle. In the opinion of the late Dr. Flint, direct functional mitral murmurs were limited to a smaller number of cases of aortic regurgitation, but the author thought that functional mitral murmurs were not so rare. Obstructive functional murmurs are common in aortic regurgitation.

Pulmonary systolic murmurs are more frequent than any other form of cardiac murmurs. In examining one hundred consecutive cases, he had found in sixty-two, systolic pulmonary artery murmurs. In these the murmurs were present during tranquil breathing or during respiration in such a way as to produce changes in the pulmonary circulation. If account is taken of the bruits heard in this region the proportion becomes greater. The clearness with which these murmurs are heard depends upon the proximity of the artery, the thinness of the chest walls, the nature of the surroundings, and, finally, the proximity of the main trunks to the capillary distribution. Systolic pulmonary murmurs can be developed in the majority of healthy individuals, if we exclude those with thick chest walls and those who are not intelligent enough to modify their breathing as directed. He held that such a murmur is a dynamic obstructive valvular murmur, and is produced by the effect of changes of blood-pressure upon the semilunar valves. A certain degree of pressure in the artery must tend to prevent the opening of the valve. This causes a slanting position of the valves and a narrowing of the orifice with the production of a sonorous whirl.

The fact that such murmurs are not more frequently developed at the aortic orifice is due to the greater power of the ventricle and the wider distribution of the systemic circulation. There are, however, cases in which increased arterial tension is expressed not only by accentuation of the aortic second sound, but by an aortic systolic murmur. He had heard it in atheroma and in Bright's disease where there was no marked anæmia. Pulmonary artery murmurs as heard in ordinary breathing are confined to the expiratory act and are loudest at the beginning of the act. The murmur is sometimes only heard with the first beat that occurs with expiration. In order to develop further this murmur, it is only necessary to arrest respiration. It is better to stop breathing during expiration, especially at the end of normal expiration. A full expiration makes the murmur louder. At the end of inspiration, it is more difficult to develop the murmur for several reasons, 1, because it requires entire arrest of respiration to produce engorgement of the main trunk, 2, because prolonged inspiratory effort is accompanied by a continued hum of the intercostal muscles, 3, because the expansion of the lung interferes with the transmission of any murmur that may be present. A slight murmur is frequently heard in inspiration if the arrest of breathing is pushed far enough. The speaker asked, Are we not justified in assuming that there is a safety valve action in this attitude of the pulmonary valve, which, together with the leakage at the tricuspid orifice, tends to prevent engorgement of the lungs by retardation of

the flow of blood in the systemic veins, so that continued for a time it does no harm?

In reference to the murmurs of anæmia, he thought that they were due to some disturbance of the valvular apparatus. In this condition there is a marked reduction in the quantity of blood. The valves require a certain amount of expansion of the vessels, in order to allow them to apply themselves to the walls. Venous hums and basic murmurs he thought to be of valvular origin.

DR. A. L. LOOMIS, of New York, said that many different explanations of murmurs within the heart cavities had been given. We should recognize that they are due to many different causes. Many are obstructive in character, while others are due to the impinging of currents of blood upon each other in the heart. They are also due to the force with which the blood current is carried from the heart into the vessels. They are also due or greatly intensified by the condition of the blood. He thought that they may also be due to irregular action of the heart produced by nervous conditions. The obstructive mitral murmurs referred to are of frequent occurrence in connection with aortic disease, where there are dilatation and feebleness of heart power, but on autopsy he had always found such changes in the mitral valves as seemed to him to account satisfactorily for the murmur heard.

He had heard the murmurs so readily produced during respiration, but where these murmurs have been persistent, he had always found conditions of anæmia and failure of the right heart. It seemed to him that the explanation is either hæmic or failure of heart power. As we study the cases more we shall find that they are due not so much to changes in the valvular orifices as to changes in the heart cavity, and in the heart walls. Murmurs have come to be of very little pathological significance to him, unless there are other changes associated with them. The worst cases of heart disease that he had met with have had the simplest and least distinct heart murmurs.

DR. E. T. BRUEN, of Philadelphia, stated that in a case of anæmia which he had recently studied, the blood corpuscles were reduced from the normal and there was a great reduction in the hæmoglobin. There was also great relaxation of the vascular system; so much so that as the arm hung out of the bed, there was a venous pulse at the back of the wrist. This was attributed by Dr. Osler and himself to relaxation of the capillary vessels to such an extent as to permit the systolic impulse of the left ventricle to force the blood through the capillaries into the veins. There was no venous pulse in the neck. In this case there were murmurs at each of the valves of the heart. As the anæmia improved and the crasis of the blood was restored, the venous pulse disappeared and the murmurs gradually lessened and the man has now no murmur whatever. This case is corroborative of the view of the author, that in anæmia the murmurs are due to some functional disturbance of the valve.

DR. F. P. KINNICUTT, of New York, said that it has been claimed by certain observers, that pulmonary systolic murmurs are transmitted from the mitral valve into the auricular appendage. The condition required that this may occur is said to be dilatation of the appendage, causing it to approach the chest wall. In some anatomical examinations made a few years ago, he had found that in the normal condition the auricular appendage was concealed beneath the pulmonary artery, and when fully dilated its tip only could be seen beyond the edge of the artery. It was even then one and a half inches from the internal surface of the chest.

DR. F. C. SHATTUCK, of Boston, remarked that when auscultation was first introduced all cardiac murmurs were considered of bad omen. It was then discovered that many systolic murmurs were practically of no importance. We are now finding out that all diastolic murmurs are not of evil import and that they may be transitory and functional. A murmur by itself is next to nothing; there must be something beside the murmur to make it of much importance.

DR. SAMUEL C. CHEW, of Baltimore, with reference to the diagnosis between aortic regurgitant and mitral direct murmurs, said that the diagnosis can usually be made by attention to the following points: An aortic diastolic murmur, although it may be intense at the apex, becomes manifestly louder as we reach the right side of the sternum in the second intercostal space. It will then occupy the whole diastole. If the murmur is mitral in origin it generally will be presystolic, and will be also heard in the scapular region. The aortic murmur is not apt to be heard in the latter situation.

DR. BEVERLY ROBINSON, of New York, had found occasionally in acute strain of the heart, not necessarily brought about by great muscular exertion, murmurs which unquestionably had nothing to do with organic changes in the heart, and cannot be explained as due to any special modification in the blood. The murmurs seemed to be due to more or less acute dilatation or obstruction of the mitral orifices. If these murmurs do not receive careful attention and proper treatment they may continue for a considerable length of time and then become of more or less grave import.

DR. I. T. DANA, of Portland, had had under his observation two sisters, one forty years of age, and the other thirty-three. The mother died of organic heart disease. Both of these sisters have had a mitral regurgitant murmur. In the older sister the murmur, after remaining for five or six years, disappeared. It remained absent for one or two years and then returned, and has continued for the past two or three years. In the second case, the murmur after having been present for five or six years, disappeared and has since remained absent. He asked if it were possible that a murmur connected with organic heart disease should disappear with improvement of the health and reappear when the health again fails.

DR. HOSMER A. JOHNSON, of Chicago, then read a paper on

PNEUMATIC DIFFERENTIATION.

He had compared the results obtained by the cabinet with those obtained by the Waldenburg apparatus, and he held that the former accomplished no more than the latter. The pneumatic cabinet he considered cumbersome and expensive, with nothing to commend it especially in the treatment of pulmonary diseases.

DR. JOHN S. BILLINGS, U. S. A., then read a paper on

METHODS OF LITERARY RESEARCH.

He referred to the best way of using libraries, with especial reference to medical literary work. He also

spoke of the great importance of carefully prepared catalogues of books.

AFTERNOON SESSION.

DR. H. C. WOOD, of Philadelphia, opened a discussion on

THE ANTIPYRETIC TREATMENT OF FEVER.

In order to make the matter as brief as possible, he had prepared certain propositions which he would state, and then give what he thought to be the proof of their correctness. The *first* proposition was, "Fever is a disturbance of calorification in which, through the influence of the nervous system, heat dissipation and heat production are both affected. If there be a fever which is produced by the direct action of a poison, independently of the nervous system, we have at present no proof of its existence."

If an animal's temperature rises, there must be a certain number of heat units used in producing that rise. If the temperature falls, there must be a corresponding lessened production of heat. In his experiments the agent used to produce the fever has been the pyogenic principle found in ordinary commercial pepsin. After the substance has been introduced the animal is put into a calorimeter. The animals used in the experiments have been dogs. In the normal animal, heat production and heat dissipation are correlated functions. When the poison is injected it is found that heat dissipation increases at the time that heat production is diminishing, so that the fall of temperature was in part the result of heat dissipation and in part the result of diminished heat production. It is impossible that there should be this wide disturbance of these two functions simultaneously, unless the poison which produces the fever acted upon some one central organ, and that must be the nervous system. McCallister, of London, while believing that fever is often produced through the nervous system, thinks that at times it may be produced by widespread tissue change caused directly by the poison, his reasoning being that in the advanced stage of fever the temperature is higher than at the beginning. He says that the time when the poison is at its maximum does not correspond to the time when the fever is at its maximum. The objection to this argument is that we do not know that the poison of the disease is the direct cause of the fever. The poison which causes the disease in scarlet fever, etc., is probably not the poison which causes the fever. The latter is probably generated in the system.

Second. "Heat production is regulated by a nervous apparatus, our knowledge of which is still imperfect. There is certainly an inhibitory centre which depresses or controls the production of heat. It probably does this by acting upon the trophic cells of the gray matter of the spinal cord. It is possible also that there is a centre which, when excited, increases tissue change, but its existence has not yet been proven." The speaker then gave a *résumé* of the experiments which he had performed which, in his opinion, proved the truth of the above proposition.

Third. "Heat dissipation is regulated through the vasomotor system, so that vasomotor paralysis is followed by an enormous loss of animal heat, and under unfavorable circumstances by death from cold." If section of the cord is made in such a way as to get vasomotor paralysis without destruction of the respiratory centres, the heat dissipation rises enormously. If the animal is kept in a temperature of 50° or 60°, it dies in a few hours of progressive loss of heat. If kept in a warm chamber, it lives for days. The cause of the rapid heat dissipation is the opening of the bloodvessels of the surface of the body.

When these remarks are applied to a study of antipyretics, it is seen that drugs may lower bodily temperature in health or in fever by increasing heat dissipation. In this way act all agencies which cause vasomotor paralysis. Antipyretics acting in this way may be called false antipyretics. Then it is conceivable that there may be drugs which act on heat production through the inhibitory nerve apparatus, of which mention has been made. Such drugs may for convenience be called true antipyretics. Aconite, veratrum viride, and drugs of that class belong to the false antipyretics. Whether or not there are any true antipyretics has until recently been a question which we have been unable to answer. With regard to antipyrin, certain experiments made in the University of Pennsylvania seem to give some positive results. Care must be exercised in these experiments not to confound a normal defervescence with the action of the drug administered. In the dog the use of antipyrin diminishes both heat production and heat dissipation, the former being diminished more than the latter. It is probable that heat production is primarily affected. The question arises whether this result be due to an effect on the circulation. He has found that antipyrin has no effect upon the circulation. The blood pressure was uninfluenced by its administration. He therefore concluded that the action of antipyrin upon the bodily heat was entirely independent of any action upon the circulation, and the probabilities are, of course, that it acts through the nervous system. Beyond this our present knowledge does not extend.

DR. FRANCIS MINOT, of Boston, then presented some remarks on

THE TREATMENT OF TYPHOID FEVER BY ANTIPYRIN AND THALLIN,

based on the observation of twenty-four cases treated in the Massachusetts General Hospital, the object of the study being to ascertain the proper dose of the drugs, their general and specific effects upon the patients, the results from their continued use as compared with those from their occasional employment, any unfavorable results, and the general effect of antipyrin and thallin upon the course of the disease.

The following conclusions were reached: 1. Both antipyrin and thallin have a remarkable power of reducing the temperature in typhoid fever. 2. In no case was the use of these refrigerants apparently followed by any unfavorable effect upon the course of the disease. 3. The general condition of the patient was more confortable after taking antipyrin and thallin, which were often followed by sleep. 4. The refrigerant medication by antipyrin and thallin appears to have no specific or decided effect upon the course or issue of typhoid fever. It often contributes much to the patient's comfort, perhaps indirectly promotes his safety. 5. The effect of antipyrin and thallin in promptly lowering the temperature, shows that the danger in typhoid

fever does not consist in high temperature alone, and that the latter is rather an index of the violence of the abnormal condition which we call fever, though perhaps adding somewhat to the danger. 6. By the internal use of antipyrin and thallin, all the effects which are claimed for the treatment of typhoid fever by the cold bath are readily obtained without the trouble and inconvenience of the latter method, and without exposing the patient to the dangers of exhaustion and shock consequent on the fatigue of removal from bed. 7. These remedies may be given without danger to the youngest patients in suitable doses; and, indeed, their beneficial effects are more decided and the unfavorable consequences are less observable than with adults.

DR. ATKINSON, of Baltimore, said that so far as the temperature reducing power of these agents is concerned, there can be no question that we are coming more and more to realize that elevation of temperature is far from being all there is in pyrexia. As regards the relative merits of thallin, antipyrin, and antifebrin, the tendency to chilling after the use of thallin is decidedly greater than after the use of antipyrin, while the latter is more apt to produce nausea and vomiting. He was disposed to disagree with the statement that the use of these drugs can take the place of the external application of cold water. It has recently been reported that one observer abroad had treated two hundred cases in private practice by the use of baths with a mortality of nothing, in army hospitals he has had a mortality of five per cent., and in ordinary hospital practice a mortality of less than eight per cent. Although with antipyretics we can reduce the temperature at pleasure, yet the duration of the case is not lessened, and in some cases it has been thought to be prolonged.

DR. WOOD remarked that we must not look upon the use of cold water as acting merely by the abstraction of heat. Its action is more than this. It probably exerts some influence through the superficial nerves.

DR. GEORGE L. PEABODY, of New York, had found that a certain proportion of cases which does not bear the cold bath will bear the use of antipyretic drugs, while on the other hand, the bath may be used in a certain number of cases in which antipyretics cannot be applied. From clinical experience he was convinced of the truth of the statement of Dr. Wood, that the cold bath accomplishes more than the simple reduction of temperature. Its soothing effect upon the nervous system is greater than that accomplished by the reduction of temperature by antipyretic drugs. He believed that in many instances the course of the disease is favorably modified by the use of the cold bath. Another important matter is that since the introduction of these methods of antipyresis, the number of relapses seems to be greater and more fatal. He differed from Dr. Wood on the point that antipyrin acts solely by diminishing heat production, and that it does not increase heat dissipation. It seemed to him that the increase of heat irradiation from the surface is very great, not only where it produces sweating, but also where it does not.

DR. W. H. WELCH, of Baltimore, said that it was a question how far rise in temperature is an important element in fever, and an element which calls for interference on the part of the physician. There is comparatively little evidence that the grave symptoms of fever are referable to the elevation of temperature. There is no doubt that temperatures of 110° to 113° produce serious symptoms, but whether or not ordinary temperatures of 105° to 107° exert any serious action on the body, is a question which is certainly unsettled. It has been shown that rabbits can be kept in a box with a continuous rectal temperature of 107° for at least two weeks, provided the precaution is taken to keep the box well ventilated and the animals supplied with moist food. Patients may have a perfectly clear brain and no grave symptoms, with a temperature of 106° or 107°. On the other hand, there are severe and fatal cases of typhoid fever in which the temperature has never registered a great height. While in most cases there is a certain proportion between the height of the temperature and the severity of the disease, yet there are certain cases in which this proportion does not exist.

DR. WILLIAM PEPPER, of Philadelphia, had been disposed from his experience, to think that antipyrin and antifebrin are superior to thallin. Between the two former he had not noticed any marked difference. He had used both largely in a variety of cases and had not seen any of the dangerous symptoms which have been mentioned by some writers. The action of these drugs seems to be purely through the nervous system. He had seen no effect upon the circulation, upon the respiration, or upon the secretions, save that of the skin. Some of his observations have been of interest with reference to the relative value of the external use of cold water and the internal use of antipyretics. In the sudden acute pneumonias of children with a temperature of 106° or 107°, with initial convulsions, where the prompt and repeated use of cold baths has been without gratifying results, full doses of either of these antipyretics have produced a remarkably successful effect. In a recent case in a child with double croupous pneumonia involving two-thirds of the left lung and one-third of the right lung, with a temperature in the rectum of 107°, and with repeated convulsions, cold baths failed to relieve the symptoms, although repeated at intervals of three hours. Antipyrin in repeated doses controlled the pyrexia at the beginning and on several occasions during the course of the disease, and after a severe struggle the child recovered. As to the ability of these agents to replace cold baths under all circumstances the evidence is not adequate. In the sudden hyperpyrexia occurring in the course of rheumatism he was not prepared to accept the view that these drugs are capable of replacing the cold bath. In these cases we have direct evidence that the high temperature is the direct cause of the symptoms, at least of the severe nervous symptoms. He was not one of those who consider high temperature in itself a dangerous symptom. There is no proof that high temperature, provided that it has not induced secondary changes, should be regarded other than as one symptom of the disease. He had had many patients with typhoid fever with a temperature of from 103° to 105°, who had done perfectly well without any measures directed to the reduction of the fever. We, however, meet with cases in which these temperatures are attended with certain symptoms for which there is apparently no other cause. In such cases we must consider that the hyperpyrexia calls for treatment. He had noticed the effect, to which attention has been called,

that is, the deep and tranquil sleep which follows the administration of these antipyretics.

DR. GEORGE C. SHATTUCK, of Boston, had used both antipyrin and antifebrin largely, and he thought that antifebrin offered all the advantages of antipyrin without its disadvantages. It has none of the disadvantages which belong to thallin. Three or four grains of antifebrin accomplish the same results as are produced by a larger dose of the other drugs. The disagreeable symptoms which some writers have referred to as following antipyrin are probably due to the fact that they follow the original recommendation and give 30 grains of the drug. The same benefit can often be obtained from 15 grains and often from 7 grains. With reference to the point suggested by Dr. Welch, he said that whether pyrexia is or is not a dangerous feature of the disease, we find clinically that where a patient has high fever, is irritable, impatient, and uncomfortable, the administration of one of these antipyretics, or the external use of cold water, produces a tranquil and refreshing sleep, and the patient awakes in a condition much better to continue the struggle with the disease.

DR. J. C. WILSON, of Philadelphia, agreed with other speakers that antifebrin has many advantages over thallin, particularly in its cheapness and in the smallness of the dose. A recent observation which he had made is interesting as bearing on the question of heat dissipation. He had been treating a case of typhoid fever in which, from time to time, antifebrin in five grain doses was given. These were repeated whenever the temperature reached 104° F. This caused copious sweating, with the usual reduction of temperature, amounting to three and a half or four degrees. On the last occasion one ninety-sixth of a grain of sulphate of atropia was given with the antifebrin. No sweating occurred and the temperature was reduced only one and one-half degrees.

DR. JAMES T. WHITTAKER, of Cincinnati, differed from the gentlemen who seem to accept the view that fever is a neurosis. He thought that there is no proof that the nerve centres are distinctly irritated, and we have no proof that the agents which reduce fever act directly on the nervous centres. Is it not more probable, he asked, that the antipyretic action is really an antimicrobic action? We have some observations which go to show that the disease is caused by bacteria, or if not directly by bacteria by some of their products, the ptomaines. Would it not be more rational to study the habits of these bacteria and address ourselves rather to the removal of the cause than to the counteracting of the effects?

DR. H. M. LYMAN, of Chicago, said that with regard to antifebrin and antipyrin his experience has been that of previous speakers, and his preference is for the former drug. He was disposed to regard their great value as proceeding not so much from their power to reduce temperature as from their general effect, especially upon the nervous system. He regards them as valuable adjuvants in the treatment of disease, largely from their hypnotic and tranquillizing effect upon the nervous system, to which allusion had already been made. He has observed that in many instances where, in abrupt febrile affections, relief has not been secured from antifebrin and antipyrin this failure is frequently due to the presence of the condition we call rheumatic, and there salicylic acid gives the relief that we fail to get with the antipyretics.

DR. JOHN GUITÉRAS, of Charleston, had some experience with these drugs in the treatment of the continued fevers of warm climates, but here the results have been rather negative and have showed the advantage of stopping their use after they have been continued for a certain length of time. He had been called in consultation where the drug had been continued for ten or fifteen days, each time that it was given producing a certain reduction of the temperature but having no permanent benefit, and the patients have begun to improve so soon as the drug was stopped. It has seemed that when given continuously in this way these antipyretics have an effect on the vasomotor system. The pulse is weak and dicrotic and he considers it advisable to give digitalis. The effect of cold-water baths in these continued fevers of the South seems more beneficial. If continued for two or three days they often favorably modify the course of the disease.

DR. PEABODY, of New York, said with reference to the point suggested by Dr. Whittaker, that there was no question in his mind that a considerable proportion of cases of typhoid fever can be aborted by antiseptic treatment of the intestinal ulcers with naphthaline or resorcine. For the past two years he has treated all cases coming under observation during the first ten days of the disease with a calomel purge (ten grains), followed by naphthaline in such doses that at least seventy or eighty grains are taken during the twenty-four hours. Under this treatment he had without doubt succeeded in aborting many cases in which the symptoms were quite pronounced. He has not succeeded in cases coming under observation at the end of the second week.

DR. H. C. WOOD, with regard to the dissipation of heat by sweating, stated that in the dog, on which the experiments were made, there are but few sweat glands; there are a few in the paws and about the mouth, so that there could be no heat dissipation from this cause. Sweating in man does undoubtedly cause a dissipation of heat. With reference to the possible influence of antipyrin on fever, through some action on the bacteria causing the fever, he said that in the experiments to which he had referred no microbes were concerned in the production of the fever, which was induced by the pyogenic principle of pepsin.

DR. JAMES TYSON, of Philadelphia, reported a recent case of rheumatism in which the temperature suddenly went up to 105°, with alarming brain symptoms. Antifebrin in five grain doses failed to produce any effect. The patient was then put into a cold bath, and the temperature of the water gradually reduced to 72°. The discomfort experienced by the patient then prompted his removal from the bath. The thermometer in the rectum showed a reduction of only one-half of a degree, but within the course of half an hour the temperature fell three degrees. He scarcely thought that this was a natural defervescence, but must attribute it to the effect of the bath. The fall in temperature was followed by a disappearance of all the symptoms, and the recovery of the patient. While he had never seen any serious results from the use of thallin and antipyrin, yet there have been symptoms which caused much alarm to the attendants. He had not seen such symptoms follow the use of antifebrin.

DR. R. P. HOWARD emphasized the fact that internal antipyretics and the cold bath are not equivalents, they are substitutes and important auxiliaries to the physician. These measures relieve special symptoms, but whether or not they shorten the duration of the disease, is a question not yet settled. Another important point is with reference to relapse in typhoid fever. This is a subject which requires investigation. He thought that every relapse, so-called, is due to the absorption of fresh poison. It is really a fresh attack, an initial attack which runs a severe course, and often proves fatal.

(To be continued.)

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Fourth Annual Meeting, held at Baltimore, May 31 and June 1, 1887.

TUESDAY, MAY 31ST—AFTERNOON SESSION.

The Society was called to order by THE PRESIDENT, DR. FRANK DONALDSON, SR., of Baltimore, who delivered an address on the

PROPHYLACTIC TREATMENT OF THOSE WHO INHERIT A PREDISPOSITION TO PHTHISIS.

DR. B. F. WESTBROOK, of Brooklyn, said that, according to the results of certain observations, the anatomical and physiological conditions which predispose to this trouble are a disproportion between the size of the heart and the lungs; the heart being smaller in proportion to the size of the lungs than in ordinary individuals, and a disproportionately small digestive apparatus. The former condition interferes with the circulation at the apices, while the latter condition causes a lack of nutrition.

DR. JAMES R. LEAMING, of New York, read a paper on

THE PHILOSOPHY OF CLIMATIC TREATMENT OF DISEASES OF THE CHEST.

It is observed that the greatest improvement takes place during the first three weeks of the patient's stay at a new place. He suggested that a line of resorts be established along the Atlantic seacoast. The patient could begin in the summer at the most northern, and gradually pass southward, making a stay of a few weeks at each place. Having completed the series, the patient may return, taking the stopping-places in a reverse order. This same plan might be applied to the Pacific coast and to the mountains. He also suggested the propriety of State and municipal authorities furnishing sanitariums for the benefit of those unable to avail themselves of the advantages of existing institutions.

DR. R. G. CURTIN, of Philadelphia, then read a paper on

THE INFLUENCE OF SEA AIR ON SYPHILITIC PHTHISIS.

The histories of five cases of what appeared to be syphilitic phthisis were given, in which improvement followed prolonged sea voyages, and in each case the symptoms returned when the patient again took up his residence on land. He was not prepared to say why it was that the sea air proved beneficial in these cases, while in most of the ordinary cases of phthisis residence on the sea-coast was not desirable.

DR. E. T. BRUEN, of Philadelphia, referred to the desirability of having correct views with regard to the influence of sea air on pulmonary affections. It is probable that in syphilitic phthisis the benefit of the sea air is due to its influence on the catarrhal processes. In catarrhal affections of the mucous membranes in general it seemed to him that residence at the seashore is useful. On the other hand, in tubercular phthisis, the influence of sea air has been disastrous. He was led to make these remarks from the fact that so many patients with phthisis are recommended to reside at the seashore or to take an ocean voyage. He had found that those cases benefited by prolonged sea voyages are those in which there is no inherited tendency to tubercle.

DR. V. Y. BOWDITCH, of Boston, would make a great distinction in speaking of sea-coast air and the pure sea air. Cases which could not stand the harsh cold and changeable air of the seacoast, may be benefited by a sea voyage or residence on an island some distance from the shore, where the conditions are similar to those which obtain in a sea voyage.

DR. F. I. KNIGHT, of Boston, said that while he agreed with the general feeling that the coast climate is not suitable for cases of phthisis, yet in several instances he had known patients to improve and gain in weight during a stay at some of the coldest resorts on the New England coast.

DR. J. C. WILSON, of Philadelphia, said that in his experience there are three classes of patients with consumption who cannot go to our exposed Atlantic seacoast without risk. These are, first, those in whom there is active febrile disturbance; secondly, those of a highly excitable and nervous organization; and thirdly, those who suffer from repeated attacks of spitting of blood. Such persons cannot safely reside for any length of time on the Atlantic seacoast.

DR. F. C. SHATTUCK, of Boston, said that the author had referred to syphilitic phthisis, that is to say, a destructive process in the lung not due to tubercle, but to the syphilitic virus. It seemed to him to be a difficult matter to determine whether or not there is such an affection. Tubercular phthisis varies so much in its symptoms that the points mentioned could not be relied on. It seemed to him that the criterion would be the presence or absence of the tubercle bacillus. The author referred to Dr. Porter as having examined the sputa from one hundred cases of supposed syphilitic phthisis without finding the bacillus. That number is so large for the short time this test has been available, that it should make us a little doubtful of the methods employed. The fact that the bacillus is not found, is no proof that it is not present. The German Committee on the Collective Investigation of Disease, studied this matter last year, and came to the conclusion that so-called syphilitic phthisis had no real existence. Both syphilis and tuberculosis are common diseases, and the one offers no immunity from the other, so that we should expect to find them frequently combined in the same individual.

DR. J. H. MUSSER, of Philadelphia, had never seen a case of phthisis which he considered of syphilitic origin. In his experience in the post-mortem room he had seen only one case in which the lesions bore any resemblance to what we should expect to find in syphilitic phthisis. This was the case of a young man with syphilis and cirrhosis of the liver, due to syphilitic interstitial hepatitis. There were also syphilitic gummata in the brain,

and the patient died of syphilitic meningitis. There were scattered through both lungs, innumerable miliary granules not at all resembling miliary tubercles. These were solid bodies made up of a yellow core, which was moderately firm, and surrounded by a ring which made up at least one-half of the nodule. The microscopical examination showed these bodies to consist of a ring of firm fibrous connective tissue, in the centre of which there were degenerating cells. He was unable to find the bacillus of phthisis, but, as had already been stated, the failure to find it, is no proof of its absence. He would not call this a case of syphilitic phthisis, but rather a case of syphilis of the lungs.

Dr. E. Fletcher Ingalls, of Chicago, had been much interested in the remarks of Dr. Shattuck, but he apprehended that most of the members had seen cases in which the syphilitic nature of the disease admitted of no question. Even if the bacilli were found, it would be no proof that the case had not originated as a syphilitic trouble, and that it had not subsequently become tubercular. He recalled one case in which the syphilitic manifestations were very prominent. There was consolidation of the lungs, particularly of the middle portion of one lung. There was a history of syphilis and distinct cutaneous lesion. The patient had been in Colorado, and returned much worse. On his return to a lower altitude, he was put on the use of iodide of potassium, and ultimately apparently recovered.

Dr. J. H. Musser, of Philadelphia, then presented a paper on

THE TREATMENT OF THE FINAL STAGE OF PHTHISIS.

He gave a detailed account of the symptoms met with in the last stages of phthisis, and referred to the various measures which he had found useful in these cases. To relieve the high temperature, he had resorted to antifebrin with advantage. Quinine was found to act unsatisfactorily.

The President announced as

THE NOMINATING COMMITTEE,

Drs. F. C. Shattuck, E. T. Bruen, Willis E. Ford, B. F. Westbrook, and W. H. Geddings.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, June 2, 1887.

The President, A. Jacobi, M.D., in the Chair.

Dr. F. Huber read a paper entitled

INTUBATION: A STUDY OF FORTY-SEVEN CASES.

As a result of his experience and observation he said that he would never advise tracheotomy only in cases in which intubation fails to afford the necessary relief. In his opinion, such a case would in the future be a rare exception. After stating that the dyspnœa is as effectively relieved by intubation as by tracheotomy, he proceeded to speak of the advantages of the former, and also referred to the origin of the procedure as proposed and practised by Bouchut in 1858. Then having referred to some practical points, derived from his personal experience, he stated that intubation had now passed through the experimental stage, and that its utility had been fully established by numerous operators in New York, Philadelphia, Chicago, and other places. Notwithstanding the gratifying results obtained, however, it had as yet received very little favor or even attention in Europe.

Of his 47 cases Dr. Huber said, 29 cases, with 11 recoveries, were in children under three years of age, and 18 cases, with 9 recoveries, in children of three years or over. Of the 11 children under three years, one was 9½ months old, one 10½ months, two 11 months, one 1 year, two 2 years, two 2½ years, and two 2 years and 8 months old. Of all the children that he had been called upon to treat who were suffering from laryngeal stenosis he had found it necessary to resort to intubation in only one out of every three or four; and he thought that it should not be employed until dangerous symptoms had supervened. He used it, in fact, in exactly the same class of cases in which he would have performed tracheotomy one year ago. Having spoken of the diagnosis of croup and the indications for surgical interference, he referred to the importance of making a careful examination of the neck and chest. He had known cases in which the dyspnœa caused by retro-pharyngeal abscess and by empyema had been supposed to be due to laryngeal stenosis. As confirmatory of the diagnosis of the latter, relative absence of pain, in uncomplicated cases, is of much value; and aphonia, with difficulty of both inspiration and expiration, is positively indicative of croup.

He then went on to speak of the various accidents and mishaps that had been met with in intubation, and the objections raised against the procedure. He referred first to the gag, and said that O'Dwyer's gag is liable to be displaced by the struggles of the child, but this is not the case with the one devised by Dr. Denhart, which he exhibited. The thread attached to the tube should be eighteen or twenty inches in length, and if not withdrawn at once, should be passed over the ear and secured. In order to avoid accidents in introducing the tube the efforts to place it in position should be short and repeated, rather than kept up uninterruptedly for any length of time. One of the most serious accidents that could occur is the pushing of dislodged membranes before the tube; and in a case of this kind Dr. Ferguson, of Troy, was obliged to resort to tracheotomy. Several deaths had been reported from this cause, and Dr. Waxham had recently devised a long tracheal forceps for the purpose of removing the membranes when this accident occurs. In a case of his own in which it happened, he gave the child brandy, with the effect of exciting a fit of coughing, which expelled both the tube and the membranes.

If at any time after the tube is introduced noisy breathing should come on, it is an indication for its temporary removal. The tube has been known to be coughed up and then swallowed. Instances have also been reported in which the tube has slipped through the larynx into the trachea; but this was when the earlier pattern of tube, with small head, was employed. The tube does not act as a foreign body when in the larynx, giving rise to choking sensations and coughing; but if it remains in position for a considerable length of time it may perhaps produce slight ulceration. This, however, does no harm.

Speaking of accidents in connection with the with-

drawal of the tube, he said that instances had been reported in which it was pushed down into the trachea, but this had only occurred when the older pattern of tube, with small head, was employed. As to the time for removing the tube, in favorable cases, this might be done as early as the fourth or fifth day, although it is often desirable to allow it to remain longer. As a rule, however, it can be dispensed with at a much earlier date than the tracheotomy tube. If the respiration continue free the tube should generally be allowed to remain until the fifth or sixth day. If the respiration becomes noisy, however, it should be promptly removed, and afterward introduced again, if this should prove necessary. When there are diphtheritic patches discernible in the nose or pharynx it is advisable, as a rule, to leave the tube in position until they have disappeared.

In intubation, as in tracheotomy, the prognosis is more favorable when there is simple local obstruction in the larynx than in cases where there is marked constitutional infection from diphtheritic poison. No age offers a contra-indication to intubation. No positive prognosis should ever be made, however, until forty-eight hours have passed from the time the tube was introduced.

As regards medicinal treatment, Dr. Huber said that it was his practice to keep up the use of bichloride of mercury throughout the course of the disease, whether intubation was resorted to or not. He employed it, in accordance with the views of Dr. Jacobi, in doses larger than those usually recommended; giving from one-sixth to half a grain, and in some cases as much as one grain, in divided doses, during the twenty-four hours, even in children a year old. Where there was much difficulty in swallowing he gave it in the form of tablet triturate, of one-fortieth of a grain each, mixed with sugar and placed dry upon the tongue. If there were extensive diphtheritic membranes in the fauces he also employed tincture of iron and chlorate of potassium. In threatened heart-failure, he resorted to brandy, caffeine, etc. If the temperature was very high he employed antipyretics, either by the mouth or rectum. Finally, he used the steam atomizer for producing a moist vapor.

Intubation, he went on to say, possesses every advantage afforded by tracheotomy. It would also save many cases in which tracheotomy would not be permitted, as well as many which would die if the latter were performed, especially in cases in children under three years of age. Out of twelve cases in which Dr. Huber had resorted to tracheotomy, ten had proved fatal. He had also seen many cases in the hands of others in which the results were no more favorable: so that he felt warranted in contending for the superior advantages of intubation.

DR. J. O'DWYER then read a paper on

FEEDING AFTER INTUBATION OF THE LARYNX,

and exhibited tubes modified to overcome difficulty in feeding. He also showed specimens with the tube in position, and a section of the cricoid cartilage filled up with membranes, except where the tube had left an opening, the form of which was just the shape of the latter. The difficulty in swallowing, he said, was recognized by all as the most important objection to intubation, and he had long been trying various modifications in the shape of the tube in order to diminish this as much as possible. At first he tried making the heads of the tubes quite small; but, while this rendered it possible for them to slip through into the trachea, it did not render deglutition any easier.

The next modification that he made was to increase the size of the head to some extent and give the tube a greater curvature in order to avoid ulceration at the base of the epiglottis. The third modification was to make the posterior surface of the tube larger than the anterior, so as to allow the epiglottis to pass over it more completely. Next he increased the size of the head still further, so that it should fill the cavity of the larynx and prevent fluid and other foreign substances from entering around it. The fifth modification was to make the upper surface of the tube concave, so that it would adapt itself more completely to the conformation of the parts; and this modification had the effect of rendering it very easy to remove the tube. Up to the present time extraction had always proved the most difficult part of the procedure.

The last modification which he had adopted was to give to the upper portion of the tube a double backward curve, with the hope of increasing the facility of swallowing, and this, at all events, had the effect of preventing ulceration of the anterior wall of the trachea, which hitherto had been sometimes quite extensive. Any one, however, who practised intubation at all largely would find it advisable to employ a variety of tubes according to the circumstances of particular cases, and he had devised a large, short tube for temporary use in certain instances. The string could be left attached to it, and he thought it probable, on account of the large calibre of the tube, that membranes might sometimes be coughed up through it.

Notwithstanding all his modifications, Dr. O'Dwyer said that he still found about the same difficulty in swallowing present. Solids and semi-solids, as a rule, are taken much better than fluids. Food will not enter the tube if the epiglottis is normal. In a number of instances he had removed the tube in order to give nourishment, but the results were no better than when it was in position. In some cases, particularly when nephritis was present, there were nausea and vomiting, as well as anorexia. Sometimes, however, swallowing was more readily accomplished than before the insertion of the tube, on account of the relief which it afforded to the urgent dyspnœa. As a rule, the longer the tube remained in position, the easier it became to swallow. When the patient was old enough to understand he always gave instructions that drinking should be done rapidly, and that as large a quantity of fluid as possible should be taken at one time. Then, by coughing the tube could be freed from any of it that might by chance have entered. Sometimes he employed rectal alimentation, but he very seldom had to resort to the stomach-tube.

Passing on to speak of pneumonia, Dr. O'Dwyer said that, in his opinion, this might arise (1) from the presence of secretions in the lower air-passages; (2) an excess of blood drawn out of the lungs; (3) atelectasis in the severe cases in which there was an extension of the membranes; (4) the presence of a tube either in the larynx or trachea. He did not believe that food is a cause of pneumonia, as there is no evidence that food

had ever been found in the minute bronchi. He had known a patient, an adult female, to wear a tube in the larynx for more than ten months, who not only did not take pneumonia, but who in the meanwhile recovered from bronchitis, which she had at the time the tube was put in.

He had lately devised two hard-rubber tubes for all kinds of acute stenosis of the larynx in adults; the smaller being for women and young males, and the larger for full-sized males. The principal difference between these and the metallic tubes was in regard to their weight and the size of the calibre. While a rubber tube weighed only one hundred grains, a metallic tube of the same size weighed one ounce and three-quarters, and the rubber tube was fully double the calibre of the metallic. As regards the comparative comfort of the two kinds of tubes, one patient found the metallic tube the most satisfactory, while another, who was a syphilitic and had a very sensitive larynx, preferred the rubber. In the latter case the metallic tube produced ulceration, which was not the case with the rubber one, while greater freedom of movement and facility of expectoration were also experienced with the latter.

Dr. Dillon Brown read a paper on

STATISTICAL RECORDS OF INTUBATION.

He said that there had been reported, so far as he had been able to collect them, 760 cases, by fifty-four different operators, and of these he had tabulated 502 cases, 211, or 27.07 per cent., had recovered. The average age of the children who died was 3 years and 2 months, and of those who recovered, 4 years and 1 month. In those who recovered intubation was resorted to at an average period of 2 days and 9 hours after symptoms of laryngeal stenosis had first appeared, and in those who died, at an average period of 1 day and 19 hours. In the fatal cases the average time after intubation at which death occurred was 2 days and 8 hours, and in those which recovered the average time during which the tube was worn was 5 days and 3½ hours. In 339 fatal cases the causes of death were given. Those who had performed intubation in the greatest number of cases were as follows: O'Dwyer, 78 cases; Waxham, 106 cases; Dillon Brown, 84 cases; and Huber, 47 cases.

Unavoidable accidents, Dr. Brown went on to say, were rare, and, with the exception of the one of pushing the membranes before the tube, were not important. From the use of too much force false passages had been made in two instances. The slipping of the tube down into the trachea, which had been reported in several cases, could never occur if a tube of proper size were employed. In two cases the tube had been passed into the œsophagus, instead of the larynx; but there is no reason why this mistake should happen if suitable care was taken. In order to avoid the possibility of pushing membranes before the tube, as far as practicable, it should be pressed well down and held firmly in position with the finger until the obturator had been removed. Coughing up of the tube is a source of danger, but this can, as a rule, be avoided if a tube with a sufficient retaining swell is used. If there is paralysis of the muscles, however, the accident is liable to occur, notwithstanding the sufficient retaining swell. As to the causes of death after intubation, the extension of the membranes to the bronchi is the most frequent, and he believed that pneumonia, when present, was secondary in character.

Dr. W. P. Northrup read a paper on the

PATHOLOGICAL ANATOMY OF THE RESPIRATORY TRACT AFTER DEATH FROM LARYNGEAL DIPHTHERIA AND INTUBATION.

In the paper on this subject, which he read before the Academy in December last, he said he had reported 87 fatal cases. Since that time 20 additional fatal cases had occurred at the Foundling Asylum; so that he had now altogether 107 cases on record. The cause for this large number during so short a period as four months was the occurrence of diphtheria in connection with a fatal epidemic of measles and scarlet fever. The severity of the outbreak was shown by the fact that all the fatal cases had pneumonia, and thirteen of them nephritis. In his former paper he stated that he had never met with ulcers of the trachea, but in the twenty cases, now reported for the first time, there were deep ulcers, laying bare the rings of the trachea, in no less than five instances. (The specimens from these cases were presented.) He had not as yet met with ulceration of any consequence caused by the head of the tube —nothing more, in fact, than necrosis of the epithelium. He had never seen any indication of aspiration-pneumonia, as it was called, due to the entrance of milk or other fluid into the finer bronchi.

Dr. Irwin H. Hance reported a

CASE OF LARYNGOTOMY AFTER INTUBATION

which occurred at the Nursery and Child's Hospital, and the patient, who was twenty months old, and suffering from scarlet fever and diphtheria, twice coughed up the tube. After it had been introduced the third time the tube became obstructed and had to be removed. At this time the child was so exhausted that artificial respiration was resorted to for a while. The tube was then inserted for the fourth time, and again it filled up with mucus and had to be removed. After being introduced a fifth time, it again became obstructed, and was finally coughed up. The stenosis still continuing, laryngotomy was performed, at the crico-thyroid membrane, and complete relief from the dyspnœa was at once afforded. The child died of the scarlatinous trouble the next day.

In this case, he said, the tubes were thoroughly tried, and were found to be utterly valueless. Their failure, he thought, was probably due either to the large quantity of tenacious mucus present or to the dislodgement of diphtheritic membrane. It was a question whether tracheotomy should not have been resorted to earlier, before the child had become so exhausted by the condition present and the repeated introduction of the tube.

In conclusion, Dr. Hance alluded to other cases in which laryngotomy or tracheotomy had to be performed after a trial of intubation. Nine of these cases had been reported, including his own, in which there were three deaths and five recoveries, while in one instance the child was still under treatment at the time the report was made. The operation had been performed or advised under the following circumstances:

1. Irritability of the larynx.

2. When membranes were pushed down before the tube.

3. In plugging up of the tube with dislodged membrane.

4. When there is a return of the dyspnœa with absence of the tube from the larynx.

5. When the tube becomes wedged in the larynx.

As to the laryngeal spasm, he had found that this could usually be combated with belladonna, nitre, and chloral. Practically, the only condition calling for tracheotomy was the obstruction of the tube by membranes, and this was a very rare occurrence. The attempt had been made to remove the membranes with the forceps. Finally, he said that he would advise resorting to tracheotomy only after intubation had failed.

DR. O'DWYER, in reply to a question by the President, stated that in his later cases he had resorted to tracheotomy in only one instance after intubation. He had met with such bad results in his own experience with this operation that he was not disposed to hope for much from it. As to removing membranes with the forceps, the subglottic division of the tube is of such narrow calibre that it is practically impossible to use this instrument in it, and he had, therefore, devised a flexible apparatus somewhat on the principle of the umbrella probang for this purpose. He knew of no wedging in the larynx that could occur except such as is sometimes met with when a tube with a small head is used. Like Dr. Northrup, he had never seen any evidence of the so-called aspiration-pneumonia arising from the entrance of food into the bronchi. The secretions, he believed, are the source of the pneumonia that is found after intubation, there being aspiration of these into the finer bronchial tubes. It is due primarily, however, to the presence of the tube, because the latter impairs the patient's power of expulsion; the secretions, under these circumstances, not being gotten rid of with the same ease as through the normal larynx.

THE PRESIDENT said that he was much pleased to hear from Drs. O'Dwyer and Northrup that they had never seen any reason to believe that pneumonia originates from the presence of food. He would like to inquire of Dr. Northrup whether lobar pneumonia is of frequent occurrence, and, if so, whether this is found especially in cases of sepsis.

DR. NORTHRUP replied that in the eighty-seven cases previously reported by him, twenty-seven were believed to have died from extension of the diphtheritic membrane. In a larger proportion of these there were found membranes extending from the tip of the nose to the finest bronchi of the lungs. Bronchial diphtheria, with œdema, was a marked feature at the autopsies. Pneumonia, when it did occur, was of late origin. It affected both lungs, and was lobular, not lobar, in character. In not more than one-fourth of the cases could it be said to have been the cause of death.

DR. CAILLE said that it was too early as yet to speak a final word as to the merits of intubation. Many of the cases published have been reported in such a way as to render them of no practical value. In comparing this procedure with tracheotomy in his own experience, he found that he had performed tracheotomy in twenty-one cases, with five recoveries, and intubation in sixteen cases, with six recoveries. In his cases of intubation diphtheritic membranes were observed on the nares and pharynx in nine instances. Most of them were seen in consultation, and, as a rule, intubation was undertaken rather late. He believed that all would have died without surgical interference, and that one which died would have recovered if intubation had been practised earlier. The cause of death after intubation he had found to be catarrhal pneumonia in a majority of his fatal cases. It was a fact that most of the children who died had taken liquids, and of late he had allowed only solids chopped fine, with ice to allay thirst. Since he had adopted this course his results had been better.

In general, he said, intubation is to be prefered to tracheotomy in the majority of cases. When the pharynx and nares are affected, intubation is, as a rule, preferable to tracheotomy, especially when the after-treatment of the latter cannot be carried out satisfactorily. Tracheotomy is preferable in some cases, hopeless without operation, provided the surgeon can operate and carry out the after-treatment under the most favorable conditions. These statements apply to intubation with the present style of tubes.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, May 25, 1887.

THE VICE-PRESIDENT, LEWIS A. STIMSON, M.D., IN THE CHAIR.

MOTOR AND SENSORY PARALYSIS FOLLOWING FRACTURE OF THE CLAVICLE.

DR. L. A. STIMSON presented a patient, a man, twenty-nine years old, with the following history: April 12, 1887, he fell from a height of about eight feet, striking upon the outer aspect of his left shoulder; he remained unconscious for an hour, and was then able to walk to the Presbyterian Hospital, a distance of about a mile. On examination there was found a simple fracture of the left clavicle at the junction of the outer and middle thirds without displacement, the symptoms being localized pain on pressure and crepitation when the fragments were moved.

But a more singular and striking phenomenon was the condition of the left arm, which hung powerless by the side, and which, on examination, showed extensive sensory and motor paralysis without recognizable injury to its skeleton or soft parts. There was loss or diminution of tactile sensibility over an area beginning a little above the lower margin of the deltoid muscle and covering the posterior surface and external half of the anterior surface of the arm and forearm, the radial half of the hand, the thumb, and index finger.

There was complete motor paralysis of the external scapular muscles, the deltoid, triceps, biceps, coracobrachialis, and brachialis anticus, and the supinator and extensor muscles of the right forearm. The extensors of the middle and terminal phalanges of the fingers (the interossei and lumbricales) were not involved.

The arm could not be actively raised, abducted, or rotated; the elbow could not be flexed or extended, the forearm could not be supinated, and the only movements of the parts below the forearm that were possible were flexion of the wrist and fingers, and extension of

the distal phalanges. The muscles reacted well to the faradic current.

During the six weeks that have elapsed since the accident the paralysis has persisted, and the limb has wasted notably, the wasting including the supra- and infra-spinatus muscles.

The only recorded cases of which I have knowledge in which a fracture of the clavicle has been immediately followed by paralysis of the arm, are those of Earle[1] and Gibson.[2] In the former, a sailor fell from the main yard, broke his left collar-bone and was rendered unconscious for some time; when first seen by Earle, two days later, the arm was found entirely useless and paralyzed. Three weeks later sharp pains were felt, especially at the finger-tips, whenever the limb was moved, and occasionally when it was at rest; there was complete loss of sensation throughout the limb. Improvement followed the use of electricity and blisters. He mentions the gradual recovery of power by the muscles of the scapula and by the pectoralis major.

In Gibson's case the falling branch of a tree caused a comminuted fracture of the collar-bone and bruised the soft parts so severely that violent inflammation followed. The fragments were depressed behind and below the line of the first rib, and the brachial plexus was compressed, in consequence of which complete paralysis and atrophy of the entire limb followed.

In two cases reported by Blassius,[3] in which the patients were first seen one or more years after the accident, fracture at or near the junction of the outer and middle thirds of the clavicle had united with marked angular displacement and approximation of the shoulder to the thorax, and in each the deltoid was atrophied.

A few other cases have been reported in which paralysis of the arm has been observed after an interval, and has been attributed to the pressure of the dressings, especially to that of an axillary pad.

In Gibson's case the attribution of the paralysis to pressure of the depressed fragments upon the brachial plexus may be accepted as probably correct, but in the report of Earle's case there is nothing to show that either fragment was exceptionally displaced, and in this, as also in mine, the implication in the paralysis of the suprascapular nerve, which is given off above the level of the clavicle from the cord formed by the fifth and sixth cervical nerves, seems to be almost a positive proof of some other cause. What that other cause may be is not indicated, so far as I can see, by any symptom that can guide to a choice among the several possible causes which suggest themselves, and a search through the works of a number of authors has not yielded any information. In Weir Mitchell's *Injuries of the Nerves* the only suggestion of the existence of such a class of cases is contained in the following portion of a sentence on p. 99: "Falls on the shoulder or on the hand being competent to cause palsies of the arm, we may expect to meet with the latter even in such cases of dislocation as put out of the question any possible compression of the nerves by the head of the humerus;" but he dismisses the question of pathology and etiology with the phrase that "in the whole it is more in accordance with modern views to see in the atrophy a consequence of nerve lesion, of which rheumatic or scrofulous inflammations of the joint are so apt to furnish examples."

The suggestion contained in the first of these quotations, that certain paralyses observed in connection with dislocation are not due to compression of nerves by the displaced bone, is one that deserves attention in connection with the prognosis and treatment. Nerves that are disabled by pressure promptly regain, as a rule, their power of conducting impulses after the removal of the cause, but those that are due to the unknown conditions assumed to exist in the present and similar cases are sometimes persistent.

DR. BRIDDON asked if there was any reason to think that the patient was unconscious *before* he fell. The reporter replied in the negative.

DR. GERSTER asked if the patient might not have struck the object upon which he fell in such a way as to cause traction on the nerves.

DR. STIMSON replied that the man struck directly upon his neck and shoulder, in the manner described.

DR. GERSTER cited the case of a boy whom he had presented to the Society two or three years before. The patient had been run over and sustained a fracture of the head of the humerus and the neck of the scapula with extensive effusion. There was almost complete paralysis of the limb, but recovery was subsequently perfect.

DR. A. G. GERSTER read a paper entitled

EXSECTION OF THE KNEE-JOINT FOR TUBERCULOSIS.

(See page 650).

After finishing his paper, the author added that he did not believe that any blood was saved in operations on the extremities by bandaging the limb previous to applying the constricting band. By elevating the limb for a few minutes, gravity assisted in depleting the vessels to some extent; then the constriction was applied. The blood left the arteries and collected in the veins. This was of great advantage to the surgeon, because he could, by making pressure on the part with both hands, always locate the vessels in order to apply the ligatures. Only a small amount of blood could escape, as the rest is kept back by atmospheric pressure. The reader objected to the use of Esmarch's bandage, for the following reasons: 1. Amputations and exsections are frequently performed in cases of acute or chronic infectious disease, where the application of the bandage tends to force the septic matter into the general circulation; 2. The avoidance of this danger more than compensates for the extra amount of blood that may be lost.

DR. STIMSON said that his experience in four or five cases had been similar to that of the reader. He had noted a recurrence of the disease in two cases, one that of an adult, the other that of a boy of fifteen; a complete excision was required later. The field of usefulness of the operation must be limited. A special objection to excision in young subjects arises from the consequent arrest of the growth of the limb, and it is important to remember that a cure may sometimes be obtained by immobilization and pressure, without resort to the knife. He cited the case of a child two years of age, whose left knee had presented marked evidences of tuberculous disease. A quantity of pus was aspirated,

[1] Earle: Med.-Chir. Trans., vol. 7, p. 175, 1816.
[2] Gibson: Princ. of Surg., 6th ed., vol. 1, p. 271.
[3] Blassius: Quoted by Gurlt, Knochenbrüche, vol. 2, pp. 602–.

the limb was fixed in a plaster-of-Paris splint, and three weeks later the symptoms were much relieved. A leather splint was then applied and was worn all winter. He saw the child six weeks before and all evidences of disease had disappeared, the joint being freely movable.

DR. GERSTER agreed with the speaker regarding the propriety of expectant treatment in the case of children, as the results are generally much better than when exsection is performed. He would only exsect in cases in which there had been prolonged suppuration, or where orthopædic treatment had been neglected. He had seen a number of cases that had been treated by orthopædic surgeons on the expectant plan, and was surprised at the good results obtained. We cannot be too radical in our treatment of tuberculous joints in adults, as hospital patients are too poor to submit to a long course of orthopædic treatment. By excision a cure is effected in six weeks instead of several months. All the cases reported had shown that it is better not to wait until fistulæ have formed and new complications have arisen.

NEWS ITEMS.

DISTILLED WATER IN EYE LOTIONS.—Physicians and pharmacists generally assume that distilled water is the best means of dissolving or diluting drugs, and in the great majority of cases this is undoubtedly the case. As a rule, the solvent should be absolutely pure and neutral in itself; but in some instances this very neutrality of the solvent may interfere with the intended action of the substance dissolved. A curious illustration of this exception to the rule was given some time ago by an eminent English oculist in a communication to a London journal. Our readers know that an aqueous solution of boracic acid is one of the most useful of eye lotions; but we remember that, as prescribed for the writer several years ago by one of the best oculists in this city, the order was for "ten grains in *distilled water*." Our English expert, however, says he has found that, when the lotion is made of distilled water, its use is attended with some discomfort and smarting; and, what is more singular, the irritation is even greater when there is no boracic acid in solution. "Anybody," he says, "can verify for himself that a drop of distilled water in the eye seems to be a most unpleasant and foreign element."

The simple explanation of this is, that well or spring water contains salts in solution which make it slightly alkaline, thus rendering it somewhat more neutral to the conjunctiva, a tissue ordinarily bathed in the lachrymal secretion, which contains about one per cent. of solids, chiefly chloride of sodium, or common salt. The addition of two grains and a half of this salt to the ounce of distilled water renders any lotion for the eye more soothing and more beneficial. This, our friend says, he has verified by experience; and we commend the fact to the attention of oculists and others interested. —*Popular Science News*, May, 1887.

OHIO STATE MEDICAL SOCIETY.—The forty-second annual meeting will be held at Toledo, Ohio, on June 15, 16, and 17, 1887. The officers of the Society are:

President.—Thomas McEbright, of Akron.

Secretary.—G. A. Collamore, of Toledo.

A TRAINING SCHOOL FOR COLORED NURSES.—The Atlanta University for colored people has established a training school for nurses, which is doing a good work.

NEW ORLEANS POLYCLINIC.—The New Orleans Polyclinic, a school for the special instruction of students and practitioners, has been thoroughly organized. The course will open the first Monday in April, 1888.

PROF. BILLROTH'S CONDITION.—The Vienna correspondent of the *Lancet*, writing on May 22, 1887, describes the distinguished surgeon's condition as follows:

The state of Prof. Billroth, who is suffering from bronchitis capillaris and pneumonia catarrhalis, was very serious on Friday last. There was considerable debility of the heart's action, and a catastrophe was feared; but after inhalations of pure oxygen the patient had rallied by the next day. The bulletin just published is confirming the hope of a speedy recovery of the illustrious surgeon. He felt himself greatly relieved, the appetite was good, and he slept soundly for some hours.

THE ILLNESS OF THE CROWN PRINCE OF GERMANY.—We obtain the following particulars of the Crown Prince's case from the *British Medical Journal* of May 28, 1887:

His Imperial Highness has been suffering from slight hoarseness since the beginning of the year; indeed, some people think that his voice has never been quite clear since his visit to Italy last autumn. He was treated in the ordinary way by Dr. Wegner, his Physician in Ordinary (who is also Surgeon-General of the Garde-du-Corps, and Inspector-General of the Hospitals of the Army), till the month of March, when Professor Gerhardt was consulted. Professor Gerhardt examined the Crown Prince's throat carefully, and found a small growth on the left vocal cord, and used the electro-cautery on several occasions with marked benefit and relief to His Imperial Highness. The growth had almost entirely disappeared toward the end of March; and, owing to the Crown Prince's constant occupation with the festivities connected with the birthday of the Emperor William, the treatment was then suspended. As some of the growth still remained, however, the Crown Prince was advised to go to Ems in April, where he took the waters most diligently for some weeks. During his residence there and on his return reports were carefully circulated in the newspapers that His Imperial Highness had benefited considerably, and had almost recovered the former use of his voice. Exactly the contrary was the truth. Some increase of the growth was found to have taken place, and the members of the Royal family in Berlin and London were beginning to feel really anxious. Professor Bergmann was then asked to see His Imperial Highness with Professor Gerhardt, and later on Professor Tobold, of Berlin, the well-known specialist in diseases of the throat, was also called in. These were subsequently joined by Dr. von Lauer, the Emperor's Physician in Ordinary and Chief of the Army Medical Department.

The tendency of the growth to enlarge was then fully established, and it became a question whether the new formation could be removed by the internal method, or whether a more extensive operation was necessary.

Under these circumstances it was thought desirable, before resorting to tracheotomy, to have the advantage of the unique experience of Dr. Morell Mackenzie, who was summoned from London, and arrived in Berlin on Friday afternoon, May 20th. The same evening a consultation was held, and Dr. Mackenzie was asked to remove a portion of the growth with the object of ascertaining its exact nature. The following morning Dr. Mackenzie succeeded, in the presence of Drs. Gerhardt, Tobold, and Wegner, in removing a small portion of the growth, which was immediately handed over to Prof. Virchow for microscopic examination. Prof. Virchow pronounced it not to be of malignant structure, all that was found being the inflammatory products of irritation.

This decided the diagnosis, and the treatment also. It is hoped that it may be possible to remove the base of the growth by forceps or destroy it by cautery.

BALTIMORE ACADEMY OF MEDICINE.—At the last meeting of the Baltimore Academy of Medicine, held May 31, 1887, the following officers were elected:

President.—W. C. Van Bibber, M.D.

Vice-President.—B. B. Browne, M.D.

Secretary.—C. C. Bombaugh, M.D.

A SUCCESSFUL SÄNGER'S OPERATION.—GUSSEROW reports, in the *Berliner klinische Wochenschrift* of May 16, 1887, a successful case of Sänger's operation in a rachitic pelvis, whose *conjugata vera* was 5.5 cm. (2¼ inches). The case was complicated by a mild intoxication from corrosive sublimate, but mother and child recovered perfectly from the operation. The child perished on the twenty-sixth day of its life, from gastro-intestinal catarrh.

SCHRÖDER'S MONUMENT.—The Committee appointed to secure a proper memorial to Schröder have decided to place his marble bust in the Frauen Klinik.

TRANSPORTATION OF PATIENTS TO HOSPITALS.—The Berlin authorities have investigated the dangers attending the ordinary methods of transporting the sick, and have ordered the establishment of four stations, to which telegraphic messages may be sent when such conveyance is needed. Penalties are laid upon the transportation of those ill with infectious diseases in open wagons, and a supervision of the transportation and disinfection of such patients and their baggage will be undertaken by the police.

COURSES FOR PRACTISING PHYSICIANS IN BERLIN.—The autumn courses will begin September 26, and last until the end of October. A summer course for practitioners is given at Jena.

LARYNGOLOGY IN BERLIN.—The Medical Faculty are about to create a new Extraordinary Professorship of Laryngology in connection with a Polyclinic for Throat and Nasal Affections, for which room has been taken in a private house in the Luisenstrasse. The first occupant of the chair will probably be Professor Bernhard Fränkel. A series of vacation courses intended for practitioners is being arranged. These are to begin on September 26th, and will continue till the end of October.—*Lancet*, May 21, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JUNE 4, 1887.

BLANSTORD, JOHN F. *Surgeon.*—Ordered to the Smithsonian Institution at Washington, D. C.

TRYON, J. RUFUS, *Surgeon.*—Detached from the U. S. S. "Quinnebaug," and ordered home.

SIEGFRIED, CHARLES A., *Surgeon.*—Ordered to the U. S. S. "Quinnebaug."

MARTIN, WM. *Assistant Surgeon.*—Detached from the U. S. S. "Pinta," and ordered home.

FITTS, HENRY B., *Passed Assistant Surgeon.*—Detached from the Receiving Ship "Vermont," and ordered to the U. S. S. "Pinta."

FIELD, JAMES G., *Assistant Surgeon.*—Ordered to the Receiving Ship "Vermont."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING JUNE 4, 1887.

GOLDSBOROUGH, C. B., *Surgeon.*—Detailed to represent the service at the meeting of the American Medical Association at Chicago, Ill., June 6, 1887. June 1, 1887.

BANES, C. E., *Passed Assistant Surgeon.*—When relieved, to rejoin station at Boston, Mass. May 23, 1887.

NORMAN, SEATON, *Assistant Surgeon.*—When relieved, to rejoin station at Cape Charles Quarantine. May 26, 1887.

OFFICIAL LIST OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM MAY 24 TO JUNE 6, 1887.

HUBBARD, V. B., *Major and Surgeon.*—Granted leave of absence for one month, to take effect on or about June 1, 1887.—*S. O. 119, A. G. O.*, May 24, 1887.

BURTON, H. G., *Captain and Assistant Surgeon.*—Granted two months' leave of absence on surgeon's certificate of disability. *S. O. 125, Department of the Atlantic*, May 27, 1887.

FRYER, B. E., *Major and Surgeon.*—Granted two months' leave on account of sickness; permission to apply for an extension. *S. O. 28, Department of the Pacific*, May 28, 1887.

BROWN, PAUL, *Captain and Assistant Surgeon.*—Granted leave of absence for four months.—*S. O. 126, A. G. O.*, June 2, 1887.

PERLY, H. O., *Captain and Assistant Surgeon.*—Relieved from duty at Fort Maginnis, Montana Territory, and ordered for temporary duty at Fort Snelling, Minnesota.—*S. O. 49, Department of Dakota*, May 23, 1887.

APPEL, A. H., *Captain and Assistant Surgeon.*—Granted leave of absence, on surgeon's certificate of disability, six months.—*S. O. 127, A. G. O.*, June 3, 1887.

WOOD, LEONARD, *First Lieutenant and Assistant Surgeon.*—Ordered for temporary duty at Fort Huachuco, Arizona Territory; relieved from duty at Headquarters Department of Arizona.—*S. O. 126, A. G. O.*, June 2, 1887.

SUTER, Wm. N., *First Lieutenant and Assistant Surgeon* (recently appointed).—Ordered for temporary duty at Washington Barracks, D. C.—*S. O. 122, A. G. O.*, May 27, 1887.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

ORIGINAL ARTICLES.

THE NATURE AND TREATMENT OF CHOLERA INFANTUM.[1]

BY VICTOR C. VAUGHAN, M.D., PH.D.,
PROFESSOR OF PHYSIOLOGICAL CHEMISTRY IN THE UNIVERSITY OF MICHIGAN.

PROBABLY a more correct title for this paper would be the nature and treatment of summer diarrhœa; for cholera infantum is now regarded by some of the best authorities as differing in degree only from the milder diarrhœa of infancy. The importance of this class of diseases is well understood by physicians generally. It is estimated that in the hospitals of New York City there are treated each summer not less than 25,000 cases of diarrhœal disease among children. Add to this those that are seen in private practice, and the number must be very large. It certainly would be safe to say that the average number of cases of summer diarrhœa in children coming under treatment annually in the United States is not less than a quarter of a million.

The causes usually enumerated by writers on these diseases are heat, atmospheric conditions, and changes in the food. Of these causes, great stress has been placed upon the first two. However, heat should affect young children more than older ones; but Holt states that, of 431 of his cases, only 12.8 per cent. were under six months, while 59.5 per cent. of the cases occurred between the ages of six months and two years. Holt says, "The explanation is obvious. Under six months the great majority of the children of the poorer classes receive breast milk either exclusively or principally, while from that time on they are accustomed to be fed from the table, or on articles totally unfitted for infantile digestion. It is a striking fact that Hope, of Liverpool, brings out in his statistics of 591 fatal cases of summer diarrhœa in children under two years of age, that only 28 had the breast exclusively; while Ballard states that, of 341 fatal cases occurring in Leicester, only 2 per cent. of the children had no food but the breast."[2]

Now there is no reason why heat and miasmatic influences should not affect those that feed at the breast as well as those that are brought up by artificial feeding, if the food has nothing to do with the production of the disease, as some few contend. That heat and atmospheric impurities have much to do with the causation of the diarrhœa I am ready to admit; but their chief evil effects are upon the food of the child. The demonstration of this now amounts almost or quite to a certainty. Three years ago the writer discovered in poisonous cheese a ptomaine which produced nausea, vomiting, and diarrhœa. Later the same poison was found in ice-cream, and in milk. The poison has now been isolated by as many as five chemists, and its chemistry and the conditions under which it develops, as well as its action, are fairly well understood. Chemically, the poison is diazobenzol,[3] which may be made artificially by the action of nitrous acid gas at a low temperature upon the nitrate, butyrate, or other salt of anilin. It is decomposed when heated with water to near the boiling-point. It is developed in milk by the growth of a germ, which multiplies very rapidly when the conditions are favorable. These favorable conditions consist principally of exclusion of air, or the presence of a limited supply of air, and a comparatively warm temperature, the germ developing most rapidly at about 98° F. If milk be placed in cans, and tightly closed as soon as it is drawn from the animal, and then be kept warm, the conditions for the development of the poison are favorable.

A nice illustration of this was furnished by a case occurring at Long Branch, N. J., and reported by Drs. Newton and Wallace.[2] A number of persons at the hotels was poisoned by milk. Investigation showed that the cows were healthy, their food good, and their pasture and stables all in good sanitary condition. The milking was done at the usual hours of midnight and noon. The milk drawn at midnight was cooled by being left in cans surrounded by water until morning, when it was sent to the hotels. This milk never produced any unpleasant effects. The noon milk was placed in closed cans as soon as drawn, with all the animal heat still in it, and carted a distance of eight miles during the very hot days of August. This milk was poisonous, and from it Drs. Newton and Wallace separated tyrotoxicon.

Of course, uncleanliness would increase the tendency of the milk to decompose, and it might afford the means of introducing the germ into the milk. Feeding the cow upon improper food, such as swill and refuse from breweries, would also render putrefactive changes more likely to occur.

Comparatively large doses of this poison, from one to one and a half grains, administered to cats, cause violent retching and purging, with death within from one-half to two hours. With these large doses vomiting is impossible, on account of the great constriction of the throat; but the retch-

[1] Read before the Michigan State Medical Society, May 13, 1887.

[3] Since the preliminary report on the chemistry of tyrotoxicon (THE MEDICAL NEWS, April 2, 1887), the writer has made an ultimate analysis of the salt obtained by the action of potassium hydrate on tyrotoxicon, and found it to be identical with the double hydrate of potassium and diazobenzol.

[4] THE MEDICAL NEWS, September 25, 1886.

ing is so violent that severe congestion of the lungs results. With smaller doses, about one-third of a grain, severe vomiting and purging are induced. The first stools are fecal; but the subsequent ones consist of clear serum, are rice-water like in appearance, and alkaline in reaction. The administration of small doses each day keeps up the vomiting and diarrhœa, leads to rapid emaciation and death from exhaustion. In other words, it establishes a cholera infantum condition. The similarity to cholera infantum does not cease with the symptoms induced and the death of the animal; but the post-mortem condition agrees exactly with that observed in children after death from cholera infantum. The mucous membrane of the stomach and small intestine is soft and blanched. We would expect, after so much vomiting and purging, to find this mucous membrane congested, or at least reddened; but that such is not the case I have demonstrated by repeated post-mortem examinations of cats, dogs, and guinea-pigs poisoned with tyrotoxicon.

Ebrenhaus says of the pathological anatomy of cholera infantum, "Generally the mucous membrane of the alimentary canal is pale and free from blood."[1]

Here we have the evidence for believing that this poison is an important factor in the causation of cholera infantum and similar diarrhœas of children, the violence of the attack varying with the amount of the poison present. When we remember that these diseases are most prevalent among the poor classes of our large cities, where fresh milk is almost unknown, we can readily understand their frequency. By such people milk is often not obtained until it has begun to sour; then it is kept at a high temperature, and often in a most foul atmosphere, and we all know something of the readiness with which milk takes up bad odors. This milk is then eaten by the little ones, who are weakened by poverty and everything that poverty means; insufficient food generally, and that of the poorest quality; insufficient clothing, insufficient and vitiated air. With these facts before us, it is not surprising that in all our large cities thousands of children die annually from the summer diarrhœas. Moreover, in our country places, how little attention is given to the food of children, we all know from actual observation. Cows stand and are milked in filthy barns and yards. The udders are generally, so far as my observation goes, not washed before the milking; the vessels for the milk are frequently found not as clean as they should be. Then there are the thousands of children that must draw their sustenance from bottles, the cleansing of which is in many cases not properly attended to. Crusts of decomposing milk form around the neck of the bottle, in the tube and nipple, and lead to the rapid decomposition of the entire contents of the bottle. I think that one of the most important advantages to be secured to breast-fed children arises from the lessened danger of infection of the milk with germs which may produce poisonous ptomaines.

I would not claim that decomposed milk is the sole cause of the summer diarrhœas of children; nor would I claim that tyrotoxicon is the only poison that may be developed in milk. It is *only one of a large class of bodies which are produced* by putrefaction, and many of these are cathartic in action.

But will this knowledge concerning the development of poisons in milk and other foods aid us in the prevention and treatment of these diseases?

Preventive measures will consist for the most part in attention to diet, and especially to milk. I have drawn up the following rules concerning the care of milk:

1. The cows should be healthy, and the milk of any animal which seems indisposed should not be mixed with that from the perfectly healthy animals.

2. Cows must not be fed upon swill, or the refuse of breweries, or glucose factories, or any other fermented food.

3. Cows must not be allowed to drink stagnant water; but must have free access to pure, fresh water.

4. Cows must not be heated or worried before being milked.

5. The pasture must be free from noxious weeds, and the barn and yard must be kept clean.

6. The udders should be washed, if at all dirty, before the milking.

7. The milk must be at once thoroughly cooled. This is best done by placing the milk can in a tank of cold spring water or ice water, the water being of the same depth as the milk in the can. It would be well if the water in the tank could be kept flowing; indeed, this will be necessary, unless ice-water is used. The tank should be thoroughly cleaned every day, to prevent bad odors. The can should remain uncovered during the cooling, and the milk should be gently stirred. The temperature should be reduced to 60° F. within an hour. The can should remain in the cold water until ready for delivery.

8. In summer, when ready for delivery, the top should be placed on the can and a cloth wet in cold water should be spread over the can, or refrigerator cans may be used. At no season should the milk be frozen; but no buyer should receive milk which has a temperature higher than 65° F.

9. After the milk has been received by the consumer, it should be kept in a perfectly clean place free from dust, at a temperature not exceeding 60° F. Milk should not be allowed to stand uncovered, even for a short time, in sleeping or living rooms. In many of the better houses in the country and villages, and occasionally in the cities, the drain from the refrigerator leads into a cesspool or kitchen-drain, this is highly dangerous; there should be no connection between the refrigerator and any receptacle of filth.

10. The only vessels in which milk should be kept are tin, glass, or porcelain. After using the vessel it should be scalded, and then, if possible, exposed to the air.

With the attention demanded by these rules given to milk, it will become more valuable as a food, and the development of poisons in it before its introduction into the body will certainly be prevented.

[1] Real-Encyclopædie der gesammten Heilkunde. [illegible]

But in the prevention of summer diarrhœas, attention to the food must not stop with its introduction into the body. The ferment which produces tyrotoxicon is widely distributed, and it only awaits conditions suitable for its development. We do not know exactly what germ it is that produces this poison; but it is either the butyric acid ferment, or some ferment which is frequently developed along with the bacillus butyricus; because I have found that if some butyric acid ferment be prepared according to the method usually followed in making butyric acid, and milk be inoculated with this and allowed to stand at the temperature of the body for a few hours or at the ordinary temperature of the room for several days, the poison will appear. Moreover, as is well known, the bacillus butyricus grows best in the absence of air—we have already seen that the exclusion of air favors the development of tyrotoxicon. We are aware of the fact that the butyric acid ferment frequently does develop in the stomach. Therefore, I think that the prevention of these diseases necessitates some attention to digestion. If the food lies in the stomach or intestine undigested, putrefactive changes will occur there.

During the hot months, children which are allowed to take food at will, often drink large quantities of milk simply for the purpose of quenching thirst. Especially is this true when the parent forgets that a child would sometimes relish a drink of good water. I feel that this overloading of the stomach with milk, caused by thirst, often is of no little detriment. It is hardly necessary to specify in regard to other ways in which attention should be given to the digestive organs of children. Those that partake of other foods with their milk should be allowed only the most wholesome articles, and these should be in perfect condition. Moreover, the depressing effects of extreme heat upon the nervous system, and its consequent injury to digestion, should always be borne in mind.

Now we come to the discussion of the curative treatment of these diseases. The first thing to do is to stop the administration of milk in any form. The ferment is present in the alimentary canal, and giving the best of milk would simply be supplying the germ with material for the manufacturing of the poison. This no-milk treatment is not by any means a new idea. It has been taught for some years by a few of the best authorities; but it has not been sufficiently insisted upon. Moreover, the reason for it has not been hitherto understood. It was believed in somewhat of a vague way, that the digestive organs lose their capability of digesting milk, and experience showed that the exclusion of milk led to improved results. But now that we know that a powerful poison is formed from the putrefaction of milk, the necessity of its exclusion must become apparent to all. I reported last year a case which is so applicable here that I must be pardoned for quoting it in full. If the child had been an animal upon which I wished to experiment, I could hardly have selected conditions more favorable.

"July 30, 1886, about 1 P.M., I was called to see the seven months' old babe of Mr. B. I found that the child had been vomiting quite constantly for some three hours. It had also passed watery stools some six or seven times. The eyes were sunken, skin cold and clammy, and pulse rapid and small. I diagnosticated cholera infantum. During the preceding night, the child had seemed as well as usual, and had taken nourishment freely from the mother's breast. Early in the morning it had been given a bottle of cow's milk, and soon thereafter the nausea and vomiting began. Later, as stated above, the child began to purge. The mother furnishing an insufficient supply of milk, it had been the habit to give the child cow's milk several times a day. I prohibited the further use of milk, both that from the mother and from the bottle, and substituted meat preparations and rice water as foods. I also prescribed pepsin, bismuth subnitrate, chalk mixture, and camphorated tincture of opium.

"The cow's milk which had been furnished the child was from an animal kept by one of the neighbors. On the evening of the same day that the child was taken sick, I obtained two quarts of the morning's milk of this animal. The milk had the appearance of very rich cream, being of a yellow tint throughout. This milk was allowed to stand through the night of the 30th in the ice-box of a refrigerator. On the morning of the 31st I began the analysis. After pouring the milk from the pitcher, there remained in the vessel about two ounces of a fluid the color of port wine. Microscopical examination of this fluid showed the presence of pus and blood corpuscles. The blood was also detected by obtaining the characteristic bands of oxyhæmoglobine with the spectroscope. The milk, which had already coagulated, was filtered. The strongly acid filtrate was rendered feebly alkaline with potassium hydrate, and then agitated with absolute ether. After separation, the ether was removed with a pipette, and allowed to evaporate spontaneously. This residue was dissolved in distilled water, and again agitated with ether. This ethereal solution left, after spontaneous evaporation, a residue which had a slightly brownish tint. I did not obtain the crystals of tyrotoxicon, doubtlessly owing to this trace of impurity; but the residue had the odor and taste of tyrotoxicon. This residue, dissolved in distilled water and given to a cat, produced retching and vomiting.

"That tyrotoxicon was present in the milk taken by the child shortly before the beginning of illness there now could be no doubt. It is true that the milk was abnormal in other respects also, inasmuch as it contained pus and blood.

"After the withdrawal of all milk and the use of the medicinal agents mentioned above, the child began to improve, and by the afternoon of August 1st it seemed so well that it was allowed a bottle of good cow's milk (from another animal); but soon after taking this milk it again began to vomit and purge. Milk was again withheld, and the same medicinal treatment resorted to. This attack was slight, and after it the child continued to improve until the night of August 4th, when the grandmother, who 'knew more about raising babies than the doctor,' fed the child bountifully upon milk. Again the vomiting and purging began, and it was more than a week before all symptoms of gastro-intestinal irritation had disappeared. About the 15th of August milk was again allowed, at first in small quantity, and this seeming to have no harmful effect, more liberal quantities were given. The child has continued well since."[1]

That my experience in this is not unique will be made evident by the following quotation from a

[1] Proceedings of the Michigan State Board of Health, October, 1886.

recent paper by Dr. L. Emmet Holt, physician to the New York Infant Asylum, who writes as follows:

"In children under two years of age, not fed at the breast, it is better to withhold milk entirely. This has been a subject of careful investigation during the past summer at the New York Infant Asylum, and both the resident physicians and myself have had this proved to our satisfaction by a large number of cases. Peptonized milk is very much less likely to disagree than either condensed milk or fresh cow's milk. But in many, even this caused an aggravation in the intestinal symptoms, particularly in severe and protracted cases. Again and again have I seen relapses brought on when milk was added to the diet in cases where the stools had been practically normal for two or three days."

The food used may consist of chicken and mutton broths, beef juice, and rice or barely water. With this list, no difficulty will be experienced in giving the child sufficient nourishment. In the medicinal treatment the first thing to do is to cleanse the alimentary tract as thoroughly as possible. In the first stages of the diseases there is no better agent for this purpose than castor oil. But if there have already been several serous discharges, copious enemata of water will be more suitable. These injections may contain either an astringent or a disinfectant, or both. For the latter, Holt recommends benzoate or salicylate of sodium, and for the former, nitrate of silver or tannic acid.

The next thing to be done is to arrest the growth of the germ. This germ has been found so far to develop only in acid media. Therefore, I think it wise to administer some antacid. Probably there is nothing better in this line than the old chalk mixture. In the preparation of the chalk mixture, the druggist should be requested to use glycerine, as many druggists still use syrup in this preparation. The presence of the sugar leads to rapid decomposition during hot weather. It has been said that the use of the antacid is irrational, because the discharges are often alkaline. Of course, the serous discharges are often alkaline, because they consist of blood serum and will be alkaline unless they have remained in the intestine long enough to ferment; but the reaction of such discharges does not prove that the contents of the stomach and small intestine are alkaline.

As to the use of germicides, much is yet doubtlessly to be learned. No doubt the chief effect of subnitrate of bismuth in this disease may be due to its effect upon the germ. Holt makes an excellent showing for the salicylate of sodium, but since he has been using this drug he has followed the no-milk diet and doubtlessly his lessened mortality has been due to the exclusion of milk quite as much as to the salicylate. He uses this drug in doses of from one to three grains every two hours.

I am now making some experiments with the object of ascertaining the effect of certain germicides on the development of this poison. The results I will give in some future paper, but I may state here what my success has been in a few experiments with mercuric chloride. The method of conducting the experiments was as follows: Four-ounce bottles were filled with milk, milk and ferment, and milk and ferment with mercuric chloride, closed with glass stoppers and kept in an air-bath at the temperature of the body for six hours. Then the milk was tested for tyrotoxicon with the following results:

No. 1. Bottle containing pure milk only. Result, no poison.

No. 2. Bottle containing pure milk only. Result, no poison.

No. 3. Bottle containing milk and ferment. Result, the poison present.

No. 4. Bottle containing milk and ferment. Result, the poison present.

No. 5. Bottle containing milk, ferment, and one-hundredth grain mercuric chloride. Result, the poison present.

No. 6. Bottle containing milk, ferment, and one-fiftieth grain mercuric chloride. Result, the poison present.

[illegible] Medical Journal, January 29, 1887.

NOTES ON SOME OBSCURE CASES OF POISONING BY LEAD CHROMATE, MANIFESTED CHIEFLY BY ENCEPHALOPATHY.

By DAVID DENISON STEWART, M.D.,

[illegible] in the Medical [illegible] Women's Medical College.

I desire to bring to the notice of the profession some cases of saturninism that recently came under my observation which are peculiarly interesting on account of the mode of entrance of the poison as well as of the somewhat unusual symptoms presented.

In a family of nine persons, all of whom had been in sound health up to January 1, 1887, and in whom no hereditary predisposition to affections of the nervous system was known to exist, six had, in a period of four months, eclampsia, which I am inclined to believe was in all of saturnine origin, or at least had a saturnine element in its causation. Four of this number succumbed to the eclampsia, two made good recoveries. The two cases that recovered and two of those that terminated fatally came under my immediate observation.

Beside these six cases, two other members of the same family presented symptoms which were of the nature of lead encephalopathy, although eclamptic attacks were absent. Of the two fatal cases under my care, in one there can be only the shadow of a doubt that the eclampsia was due to lead; in the other, the exclusion of other affections, the character of the symptoms, the presence of a blue line along the gums leave no room for question as to the nature of the case. The discovery that all had, for a continuous period from the above-named date, probably daily, ingested more or less lead, and in a highly toxic form, contributes greatly to the support of my assumption as to the probable nature of the other cases.

In presenting concise histories of these cases, I purposely refrain from enlarging upon points connected with the manifestations of the eclamptic attacks, and the treatment pursued not necessary to the establishing of a diagnosis, believing that a prolonged history, however interesting, would render the sketch too discursive, and contribute but little to

its value in directing the attention of the profession to the possible greater frequency of saturnine encephalopathy in our midst than we are aware. It is likewise hoped that it will aid, at least in a slight way, toward bringing about some stringent action on the part of the authorities, making the use of lead chromate as an adulterant of food articles a misdemeanor punishable by the severest penalties.

CASE I.—Mary D., æt. five and one-quarter years, had never been ill until December last, when she contracted a mild attack of pertussis. There had been a slight whoop in her cough for two or three weeks before death, but the spasmodic element was said to have been so slight that the parents were in doubt whether the affection deserved the name of whooping-cough; the accessions were few in number and the cough of very moderate severity. She had been about from the first and partook of her meals with the family. For two or three days prior to the onset of the eclampsia, she had complained of anorexia and nausea and had frequently vomited. The vomited matter was said to have consisted of a greenish-yellow fluid. It was thought the fits of vomiting were not particularly provoked by cough. The symptoms were thought to indicate a digestive disorder by the parents, and medical aid was not sought. She was seized with a violent, general convulsion on January 8th, and died on the following morning, eight hours after the first seizure, having had in the neighborhood of thirty-five convulsions. On account of not having seen the case twenty-four hours prior to death, the physician who was called reported it to the coroner. No post-mortem examination was made.

CASE II.—Louisa D., æt. three and one-quarter years, had never been ill until a slight attack of pertussis appeared early in January. There had been a slight whoop in her cough since January 10th, but the cough was not thought by the parents sufficiently troublesome to require treatment. She was constantly about the house, and was permitted to eat of whatever food was upon the table. She complained of not feeling well on January 23d, and had several attacks of vomiting. She was about on the 24th, but vomited during the day, not particularly, however, after a paroxysm of cough. The vomited matter was said to consist of a greenish-yellow fluid, biliary in character, similar to that ejected by Case I. On the afternoon of January 24th, shortly subsequent to an exacerbation of cough, she complained of nausea and asked for a basin that she might vomit. During the act of vomiting convulsions appeared, which, I am informed, continued, with brief intervals of stupor, until death occurred within twelve hours after the first seizure. Her bowels were said to have been open on that day, and there was thought to have been neither constipation nor diarrhœa.

I did not attend either of the preceding cases, but believe the clinical histories as given to be entirely reliable. I have been informed, since my attention was directed to lead as the possible cause of these deaths, that both of the preceding cases complained occasionally, for a few days anterior to the attacks, of pains in the abdomen, but I could not discover if they were of a colicky nature.

CASE III.—Wm. D., æt. fifteen months, also had pertussis when convulsions appeared. The first spasm occurred on the day Case II. died, January 25th. The whoop had appeared in the cough ten days before. The attack of pertussis was of average severity, and the number of accessions moderate. His cough was loose and attended by profuse secretion, most of which was swallowed when coughed into the pharynx. There was not a great deal of vomiting. He had been allowed for several months to partake of ordinary "table food," but he was not known to have eaten at that time anything particularly indigestible and his bowels had been open twice on the preceding day. The first convulsion lasted fifteen minutes and was very severe; it was succeeded by stupor in which I first saw him. The temperature was but slightly elevated; the head not very hot; anterior fontanelle moderately tense; gums nowhere sufficiently swollen to account for the spasms; the tongue was furred. There were a few moist râles in the chest but unaccompanied by any alteration in resonance. The urine was free from albumen. Five severe convulsions occurred on the following day, each being succeeded by insensibility lasting an hour or more. On the next day there was but one, which, however, was exceedingly severe and continued for nearly two hours, during which there were constant tonic and clonic spasms, general and local. On January 28th there was a mild one, after which no more occurred until February 3d, when he had a severe one, which terminated the eclamptic attacks, and he then made a rapid recovery from both eclampsia and pertussis.

On the day preceding the last convulsion, February 2d, the gums covering the lower canines seemed to be rather tense; they were freely incised at the time of the last convulsion. There was only a moderate amount of bronchial catarrh accompanying the pertussis and no inflammatory complications occurred. The convulsions did not occur during or immediately succeeding paroxysms of cough.

CASE IV.—Lewis D., æt. seven and a half years, had an eclamptic attack for the first time on March 18th. He had had an attack of pertussis in December, 1886, from which he made a good recovery. No complications were supposed to have occurred during it, and there had been no whoop in his cough for two months. He was supposed to have coughed rarely, if at all, for several weeks preceding the above date. His health had always been most excellent, and he was of a strong though nervous constitution. It was remarked that, for a day or two preceding the outbreak of the eclampsia, his breath had been offensive and his tongue furred. The bowels had been inclined toward constipation for several weeks before this time. On the evening of March 17th, after having fallen asleep on a chair, before retiring, on awaking his face wore a startled expression accompanied by some oscillation of the eyes. No complaint was made of headache or pains elsewhere, as far as could be remembered. I gleaned from an outsider that he had had a fall, while at play in the street, a day or so before. His parents were not aware of it, as he had uttered no complaint.

At noon on March 18th, without known premonitory symptoms, while playing with a sister, he suddenly fell to the floor in a general tonic convulsion, which rapidly gave place to a severe general clonic one, lasting upward of a half hour, leaving him in a stupor from which, in a few minutes, he emerged to be again seized with tonic and clonic spasms. He continued in this state, almost constantly convulsed, with short intervals of remission in which great restlessness, stupor, or coma was present until 4 o'clock on the following afternoon, when death ensued, about twenty-eight hours after the first seizure.

Œdema of the lungs, bronchi, and trachea occurred in the preceding evening, and from this time on, at short intervals, frothy mucus, sometimes blood-streaked from the bitten tongue, appeared at the mouth and nose. The respirations changed from stertor to well-marked Cheyne-Stokes two hours before death, and so continued until dissolution. His temperature, which a few hours after the onset had been only slightly above normal, rose to 107° F. before death.

I did not see him until some hours after the first seizure, and could then get no further information as to the origin of the attacks than has been given. The physical examination revealed very little. The heart was normal; moist râles were present in the chest, due, I thought, to a beginning œdema; and there was some alteration in the resonance at the bases posteriorly, but it was difficult to determine satisfactorily to what this was due. An examination of the urine showed neither albumen nor sugar. He had had no symptoms indicating the onset of any of the acute diseases which are, in children, frequently accompanied by sympathetic convulsions.

The result of the necropsy, briefly stated, was as follows: Externally, on the forehead of the right side, in the upper part of the middle frontal region, there was a small ecchymosis, and the external periosteum beneath was the seat of a very small punctiform extravasation. There was no bruise in the internal periosteum. The brain weighed fifty-six ounces avoirdupois; was healthy and rather anæmic. There was a very small quantity of fluid contained in the lateral ventricles. The pericardium and heart were normal. An old adhesion existed in the left pleura, at the apex of the lung. The lungs were congested, œdematous, and, posteriorly, part of the lowest and middle lobes on the right, together with a small part of the lower lobe on the left, in the same situation, were apparently the seat of a bronchopneumonitis, which had been altogether "latent" during life. This condition was only evident posteriorly in small portions of the lobes. Dr. Rively, Demonstrator of Histology in the Jefferson Medical College, very kindly made sections of these portions for microscopic examination, and assured me they were the seat of a pneumonia. In the abdomen the organs were all apparently in a healthy condition. A thorough examination was not made here, it being the wish of the parents that as little as possible should be disturbed.

CASE V.—Mrs. V., æt. thirty-seven, mother of seven children. At the date her eclamptic attack occurred she was at the end of the eighth month of gestation. She had always been healthy, but had noticed during the past three or four pregnancies some œdema of both legs; not sufficient, however, to affect her general health, or interfere with locomotion. She had never had a convulsion, puerperal or otherwise, until April 24th of this year. For the space of a week or two previous to this date she had suffered with supraorbital neuralgia and slight pains and anæsthesia in the inferior extremities. Her bowels were inclined toward constipation, but she thought she had a free passage four times a week. Her urine was normal as to the quantity passed, but there was a small amount of albumen present, estimated by the method of Hoffman and Ultzmann to be one-sixth per cent. The quantity of her urine underwent no diminution prior or subsequent to the attack, and by the specific gravity alone it was thought the nitrogenous elements were being excreted in fair amounts. No examination for casts was made.

On the morning of April 24th, while occupied with her household duties, feeling quite well and entirely free from any cloudiness of mind, headache, disorders of vision, or vertiginous sensations, she was suddenly seized with a severe epileptiform convulsion, lasting ten minutes. After an hour's interval, during the greater part of which she lay in a semi-unconscious state, and had an attack of vomiting, the matter vomited containing a great deal of bile, a second convulsion occurred, which continued, with very slight intermissions, a half hour, followed by an attack of acute mania lasting three hours. The tongue was severely bitten during the convulsions. Very prompt treatment brought her about, and the convulsions were not repeated. As they were believed to be of puerperal origin, and closely related to the albuminuria, she was put upon an absolutely milk diet, appropriate remedies were prescribed for her condition, and complete rest in the recumbent posture was enjoined.

CASE VI.—Amelia D., æt. twelve years, was well-made physically; her temperament was a combination of the lymphatic and nervous, and she was considered a bright and promising child. Her health had always been remarkably good prior to the beginning of the present year. Since then it was noticed she had fallen off in flesh and color, but this was attributed by her parents to her grief on account of the loss of her brother and sisters, as she made no complaints of feeling ill. For several days preceding the eclamptic attacks, she seemed listless and unable to exert herself; spoke of having headache and "feeling bad all over." There was complete anorexia and a very fetid breath. The day before the onset of the convulsions she suffered with nausea, accompanied by vomiting of a greenish fluid resembling bile, and a racking headache, located in the frontal and occipital regions.

I was called to see her for the first time on May 12th. Her temperature was 99° F., pulse 130; the tongue was heavily furred, particularly the posterior portion, while along the left lateral edge, on a line between the dorsum and under surface, the fusiform papillæ were prominent and of a deep black color. There was no cough, and the lungs and heart were normal. No abdominal tenderness was present, and no pain on pressure about the head, neck, or spine, and there was no retraction of the neck or spots on the skin. An examination of the urine revealed nothing. In the evening the headache had greatly increased in severity, great restlessness had developed, and two severe general convulsions occurred. These were apparently checked by the treatment begun, and she passed a moderately comfortable night. The headache, however, became again more severe toward morning and continued so through the day; the tongue remained coated and the breath offensive, notwithstanding she had been well purged on the preceding day. At five o'clock in the afternoon the convulsions recurred and continued from that time on, with slight intermissions, during which there was restlessness, stupor, or coma, until four o'clock on the following afternoon, when death occurred—about forty-two hours after the first seizure. Œdema of the lungs, bronchi, and trachea developed some hours preceding the fatal issue, and well-marked Cheyne-Stokes breathing appeared. Her temperature during the convulsions was never found to rise to a greater height than 102½° F. The restlessness during a few hours preceding death was intense. The convulsions continued up to death, but were confined, toward the end, to the upper extremities and facial muscles.

A necropsy was made shortly after death, for the purpose of removing the viscera that a chemical examination might be made of them for the presence of lead. The body was well nourished and well developed for a girl of twelve years. There was a distinct blue line below the lower central and lateral incisors at their junction with the gum. The stomach and contents, part of the liver, the large and small bowel, the spleen, and a kidney were removed and placed in Dr. Leffmann's hands for chemical examination. The abdominal organs appeared to be in a healthy condition. The thorax, on account of the wishes of the parents, was undisturbed. Dr. Longstreth very kindly made an examination of the brain, and informed me that the fibrous tissue about the base, particularly in the neighborhood of the straight sinus, was thickened; the lateral and fifth ventricles were somewhat dilated and contained more than the average quantity of fluid. Microscopically, many of the arterioles showed irregular dilatations. In the cerebellum the corpus dentatum was

exceedingly ill-defined, and in small parts seemed thickened. The brain and meninges were congested, and there was an ante-mortem clot in the longitudinal sinus. The brain weighed fifty-three and three-quarters ounces, avoirdupois.

The sudden illness of this child in whom there had existed no previous disease, in so short a time after the eclamptic seizures in the others, and with some points of similarity in the symptoms preceding the onset of the eclamptic attack, caused me to look carefully for something apart from a mere neurotic element as the cause, underlying the supposed digestive disorder, which could give rise to the eclampsia. I felt a doubt if any of the convulsive seizures in these cases had been directly excited by the affections under which they were known to have been laboring. The symptoms presented by Case VII., who was now brought to me, assisted materially in throwing light upon all the preceding cases.

Case VII.—Kate D., æt. thirteen and three-quarter years, was noticed to have failed in health and strength for several months past; her skin had, from a rosy tint, become of rather an earthy hue; her appetite had failed, and she suffered with frequent headache and slight pains in the legs, back, and abdomen, with occasional attacks of nausea and vomiting.

No particular notice was taken of her condition, her parents supposing that grief because of the loss of her playmates, together with the fact that she was approaching puberty, would account for her condition. About the time Case VI. was taken ill she grew rapidly worse and was brought to me for examination. She was then very anæmic, the conjunctivæ and gums were very pale. Her skin had not the hue of chlorosis, it was rather of an earthy-yellow color. Her heart was over-acting, with a markedly accentuated second sound at the apex. The temperature was 99° F. She suffered with constant severe headache, which she located in the temples and occiput; there was pain in the posterior part of the neck as well. There were no painful points. The back of the neck was tender on pressure, but no cutaneous hyperæsthesia or retraction of the neck existed. She had slight photophobia, and the pupils were irregular. Slight pains in the knees and ankles were also present, without swelling or tenderness on pressure. There were occasional colicky pains about the umbilicus, but of no severity. Her bowels, which previous to her falling off in health had been quite regular, now became constipated. She had irregularly, though about once daily, attacks of nausea, and vomited a good deal of bile. The night previous to the day I saw her she had been quite delirious and continued so, with lucid intervals, into the day. During this attack of mental wandering she complained of numbness in the upper and lower extremities, passed a large quantity of limpid urine, and vomited freely, the vomited matter being bilious in character. Lead poisoning being suspected, the gums were examined carefully for a blue line. A moderately well-marked one was noticed at the junction of the left lower canine and the adjoining first bicuspid and the gum. Her urine was free from albumen.

Case VIII.—Edward D., æt. nine years, who up to this time had exhibited no symptoms of illness, now began to ail in much the same manner as Case VII. He was seized with severe headache and some pains in the knees and ankles. He had slight colicky pains in the belly associated with vomiting; the vomited matter consisted of a greenish-yellow fluid resembling that ejected by the others. His bowels were inclined toward constipation. He was anæmic and there was fine tremor in both hands and twitching in the muscles about the mouth on protruding the tongue and in speaking. The tongue was thrust out tremulously and was quite heavily furred. There was a suspicion of a blue line along the gum in the neighborhood of one of the lower incisor teeth. His urine contained no albumen.

Seven of these cases exhibited several similar and notable symptoms in common, though in a varying degree. All the eclamptic cases, save Case III., had preceding symptoms referable to the stomach or bowels, and vomiting of a greenish fluid resembling bile[1] was present in seven out of the eight cases. In Case VI. the gastric symptoms were very marked, and it was not until Case VII. was taken ill that it was mentioned to me as having occurred in some of these cases, by the parents, who fancied the bilious vomiting and slight colicky pains present in Cases I. and II. to have been a simple gastric disorder unworthy of remark.

Convulsions occur in pertussis with a moderate degree of frequency, and from such a variety of causes that it would be difficult to assert that none of them were in operation in the first three cases of my series. They are, however, very rare in uncomplicated cases, unless the child is of very tender age, or the attack severe, with the spasmodic element marked, and the accessions frequent. In the latter case deficient aëration of the blood or, in highly sensitive children, an exaggeration of the nervous excitement which is an ordinary symptom of the disease, is the probable cause.[2] Convulsions in pertussis may, too, be due only indirectly to that disease.[3]

In early childhood a tendency to eclamptic attacks, which is more or less common, is aggravated by the state of nervous tension in which the system is maintained by the pertussis, so that often very slight gastric or intestinal irritation, or an attack of dentition, will provoke a seizure. But convulsions from such a cause are rarely followed by serious consequences, and are readily checked. A frequent cause of eclampsia in pertussis is the presence of an inflammatory affection of the lung, such as bronchitis of the smaller tubes, or broncho-pneumonia. In twelve cases of eclampsia in pertussis, observed by Meigs and Pepper,[4] all of which occurred under the age of three years, six had severe bronchitis preceding the eclampsia, and one a pneumonia. Five of the twelve died; of these five, four were bronchitic cases.

I have previously remarked in the recital of the histories as to the mild character of the whooping-cough in the first three cases, none of them having had a lung complication, and Cases I. and II. were beyond the age at which any of Meigs' and Pepper's cases occurred. As all were of a nervous organization and presented symptoms of gastric disorder, the eclampsia might be attributed to the latter as a complication if the attacks had not been so severe, frequent, long-continued, and, in two, ending in

[1] Tanquerel laid stress on the great frequency of nausea and vomiting as accompaniments of colic seated about the epigastrium, due to lead. He also stated that vomiting most frequently exists at the commencement of lead colic, as soon as the pains are felt, and that the matter vomited has a greenish hue.

[4] Diseases of Children.

death. But as the digestive trouble was probably produced by the cakes containing the chromate of lead, of which all the cases, even the baby, ate freely, and as this salt acts as an irritant poison,[1] even in small quantities setting up gastric trouble, I may be permitted to say that lead probably was the source of the trouble, even if the eclampsia were not what is technically called saturnine—that is, due to the direct action of the metal on the nervous system. But, in Cases II. and III., colicky pains, nausea, and vomiting of a greenish-hued fluid, would rather indicate the systemic action of this substance.

The latent broncho-pneumonitis found *post-mortem* in Case IV., in a boy aged seven and a half, with a brain weighing fifty-six ounces, seemed at that time sufficient to account for the eclamptic attacks, though I thought scarcely sufficient to account for their continuance and mode of termination. Looking at the case now, in the light of later developments, it would seem reasonable to suppose that since the slight broncho-pneumonitis present was probably secondary to a lobular collapse, occurring at the period of his attack of pertussis in December last, it is unlikely that, having escaped eclampsia then, at a period most favorable to its development in one predisposed, he should have succumbed to it now. It is difficult to decide what influence the fall of a day or two before had upon the development of the eclampsia. As he made no complaint of his head and presented no symptoms of cerebral irritation, it is fair to conclude the trouble did not arise from it. The knowledge of the ingestion of lead, the colicky pains in the abdomen, with the fetid breath and constipation, point strongly to that mineral as the agent at work.

It is more difficult to form an idea as to the influence of lead in the production of the eclampsia in Case V., occurring as it did toward the end of pregnancy, with albuminous urine and œdema of the legs. There was, however, no diminution from the normal quantity of urine excreted preceding the onset of the eclampsia, and though no examinations were made to determine the quantity of urea excreted, it was thought from the specific gravity of that passed, that the kidneys were doing their work fairly well. The amount of albumen was at no time large. Lusk[2] calls attention to the fact that it is the renal insufficiency causing the retention in the blood of the excrementitious matters, and not the mere presence of albumen which gives rise to uræmia and convulsions. Although this woman had œdema of the legs and, probably, albuminuria in former pregnancies, no convulsions had occurred. She presented no symptoms of uræmia at the time of the attack. The headache and slight loss of sensation in the legs complained of, unaccompanied by such symptoms as drowsiness, vertigo, disorders of vision, were scarcely of this nature. The fact that she had been consuming more or less lead in no small quantities for several months, and that the convulsions occurred at a time when others were likewise affected, after having been exposed to the same agent, favors the assumption that the eclampsia was of saturnine rather than renal origin.

When searching for evidences of lead poisoning in the others, her gums were examined, and it was noticed that the upper part of the gum near the teeth in the neighborhood of the lower central and lateral incisors, was very distinctly blue. The removal of the cause in the cases surviving, and proper remedies directed against the lead in the system, soon produced a marked improvement in all.

Case VII.'s headache, colicky pains in the abdomen, anorexia, nausea, vomiting, and pains in the legs, all disappeared, and she is rapidly regaining her strength and color. She complains yet of a persistent pain in the right hip-joint, which does not cause any serious annoyance.

Case VIII. made a still more rapid improvement, not having been so much affected as his sister.

In searching for the origin of the trouble, it was learned that the family had occupied the dwelling they were then in for the past five years, and that no case of illness of any sort had occurred during that time, until about the beginning of the present year. I made a careful examination of the house, its contents, and the plumbing, but was unable to discover anything to cause suspicion, save, perhaps, an iron kettle, glazed on its interior, which had been in use for several months. Knowing that litharge was formerly used in making glazed earthenware and iron vessels, and that accidental cases of poisoning have occurred from the use of such utensils in cooking acid fruits and vegetables,[1] I had some of the glaze removed for a chemical examination. Scarcely supposing the lead could have come from this, as they had eaten very few acid fruits and vegetables during the winter and spring, I thought it probably came from a source external to the house.

Learning from the family that they had made a change in their baker a short time preceding the date their illness began, and learning, accidentally, that the baker, who had been in the neighborhood scarcely a year, had himself lost a number of his family in convulsions a year or so previous, I visited him for the purpose of making inquiries. I found his wife suffering with pains in her ankles and stomach, which had been worrying her intermittently for some months, and which she attributed to overwork. A brief examination disclosed the fact that she was intensely poisoned by lead. Her bowels were constipated, she had dry colic, a metallic taste in her mouth, loss of appetite, occasional attacks of nausea and vomiting, headache, and arthritic pains in the limbs, her tongue was coated, the breath fetid, and the gums in the upper and lower jaws were of a deep blue color.

I at once informed the baker of her trouble. He assured me he was unable to enlighten me as to its source, as he had no lead about his establishment. He denied using any artificial coloring agent in his trade. A visit to his cellar, however, into which I had him take me, disproved his assertion, for after making an inspection of his plumbing and the bake-

[illegible]

[illegible] Acts of Medicine.

[1] Woodman and Tidy: Forens. Medicine and Toxicology.

oven, and procuring some samples of his flour and chemicals used for raising dough, he permitted me, after some demurring, to see a pitcher, which contained a quantity of yellowish substance, partly in solution, which I recognized as chrome yellow.

Further inquiry elicited from him the information that he used it solely to give color to his tea- and cinnamon-buns, employing about a tablespoonful of the powder and water to a forty pound mass of dough. He assured me he was unaware of its poisonous nature, and did not introduce it into his more expensive cakes, using eggs for them. I took a sample of this substance to Dr. Leffmann for examination; he at once pronounced it chromate of lead.

I further learned from the baker that he had lost, between May, 1884, and January, 1886, a wife and six children in convulsions, and that lead poisoning was suspected to be the cause of death in most of the cases. During this time a journeyman baker in his employ also was seized with lead colic, and was forced to leave him.

On making inquiry of one of the physicians who had attended this family at the time some of the deaths took place, I learned that these cases had caused a great deal of talk when they occurred, as the circumstances surrounding the deaths were so peculiar. They seemed to be all cases of saturnine eclampsia, but the source whence the lead was derived had not been discovered. It now seems most likely that it was the chrome yellow used by the baker to color his cakes.

I ascertained from Mr. D. that his family, since dealing with this baker, had been in the habit of purchasing daily from twelve to eighteen of the tea and cinnamon-buns from the baker and, usually, double this quantity on Sunday. He stated that they were greatly liked on account of their yellow color and good taste by all in the house but himself, who had no liking for sweet cakes, and that it was a rare thing for any of them, scarcely excepting the baby, to partake of anything at breakfast save these buns, and coffee or milk.

The use of chrome yellow as a coloring agent by bakers is not recent. In the *Medical Times and Gazette* of December 24, 1859, p. 635, are recounted six cases of acute poisoning caused by eating Bath buns, colored by this agent. Some of the buns which had not been consumed were subjected to analysis, and it was found that each contained seven grains of chromate of lead. Marshall, of the University of Pennsylvania, has recently[1] published the result of some work he has done in this direction. He found lead in the buns and pound-cake of four out of twenty-six shops. Dr. Leffmann made for me analyses of some bright-yellow sponge-cake and tea-buns obtained from the baker I found using the chrome yellow. The result is subjoined. He suggests that while the naphthol yellow, which he is inclined to believe is the agent used to impart color to the sponge, may in itself be harmless, it is possible that it may, from its chemical nature, promote somewhat the absorption of the lead chromate when these agents come together in the stomach.

The only cases hitherto on record of death by chrome yellow are those[1] reported by Dr. von Linstow, of Ratzeburg, who described the cases of two children under four years of age. They ate some substances made to look like bees, consisting of gum tragacanth, colored with this agent. They were seized, in two or three hours, with violent vomiting, great thirst, restlessness, and prostration. The matter at first vomited had a yellowish color. There was no diarrhœa, or complaint of pain. On the following day the younger had slight purging, with convulsions, and died on the second day. The other was listless, almost unconscious, with irregular pulse, great thirst, and dysphagia. He died on the fifth day.

It is stated by Wormley[2] that the amount of chrome yellow taken by each of these children did not exceed the one-fifth of a grain. That seems barely possible, as it could scarcely, in that quantity, cause death on account of its insolubility.

Encephalopathy is the rarest of all diseases caused by lead. Tanquerel met with but seventy cases. It is usually found only in those profoundly saturated with the poison and rarely occurs as a primary affection, commonly being preceded by colic, arthalgia, or paralysis. Tanquerel has found the most important of the prodromes to be violent headache, either general or partial, and often limited to the forehead and accompanied by vertigo. He found, of all trades producing it, that it was least rare among manufacturers of white lead, and after them least rare in painters of buildings. I can find records of only a few cases in the past three decades, after a prolonged search in the library of the College of Physicians, and records of cases of the eclampsic form of encephalopathy seem especially rare, though Tanquerel pronounced them the most frequent cerebral accidents caused by lead.

Dr. Leffmann reports the result of his analyses as follows: "The examination of the bun shows lead in a small amount, approximately two grains of lead chromate to each bun; but as the material was irregularly distributed, and the portion most distinctly colored was selected for analysis, this estimate is doubtless too high.

"The sponge cake is colored with an organic color soluble in alcohol. This is possibly naphthol yellow, but it has not been definitely identified.

"The samples of urine from Mrs. D. and Katie D. respectively, and various parts of the viscera, give slight precipitates, indicating the presence of some metal of the lead group, but the quantity is too minute to permit of identification, and it cannot, therefore, be affirmed that lead was found in any of these.

"The glaze, very finely powdered, and treated with strong boiling hydrochloric acid, yields a solution which gives with hydrogen sulphide a precipitate which indicates the presence of tin, but this has not yet been fully examined."

NEPHROLITHOTOMY.

By D. HAYES AGNEW, M.D.,
OF PHILADELPHIA, PENNSYLVANIA

W. S., æt. thirty-seven years, married, a grocer by occupation, and living in Western Pennsylvania, consulted me in the autumn of 1885 on account of a dull pain, deeply seated in the left lumbar region, and radiating in the direction of the groin, and across the front of the abdomen. The pain was always worse at night, and was accompanied by considerable vesical irritation, causing frequent urination, with occasional rigors. On examining the left lumbar region, there could be felt, as well as seen by the eye, a well-defined swelling. The urine, about normal in quantity, contained considerable mucopus, phosphates, and albumen, the latter not, perhaps, greater in quantity than might be accounted for by the pus corpuscles present.

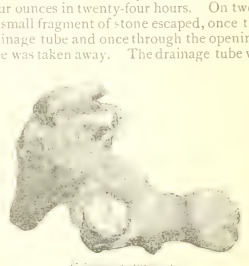
The diagnosis lay between renal calculus, perinephritic abscess, or cystic disease. Inasmuch as there had been no renal elements discovered in the urine, no colic at any time present, and no concretions passed, together with the fact that a tumor existed in the left lumbar region, I was induced to conclude that the disease was either cystic or perinephritic. The patient did not remain in the city, and consequently passed out of my observation without having an opportunity of further investigating his case.

In February, 1887, I was again called to see Mr. S. with Professor Pepper, under whose care he was at that time. His lumbar pain had never been relieved; on the contrary, had increased in severity; the urine still contained pus corpuscles, blood corpuscles, and a small amount of albumen. The preceding November he thought he had, after an attack of colic, passed a small stone, and the swelling, first observed in the loin, was no longer detectable. His suffering had now become so constant and severe that he was no longer able to follow his business. It was the opinion of Dr. Pepper, as well as myself, that the only cause sufficient to account for his symptoms was the presence of nephritic calculus, and in view of this conclusion, an exploratory operation was proposed, and readily assented to by the patient. With this object Mr. S. was kindly turned over to my professional care by Dr. Pepper.

Operation.—On the 7th of March, after a brief preliminary treatment, the patient was placed on the operating-table, after etherization, and laid on the right side, over a pillow rolled into a firm cylinder. An incision about four inches in length was made on the left side, beginning at the edge of the erector spinæ muscles, and carried obliquely forward and downward half an inch below and parallel with the last rib. The different strata of tissues were divided down to the lumbar aponeuroses. The latter being opened, the renal fat immediately projected into the wound. On breaking up the mass of adipose matter a quantity of purulent matter escaped, which had evidently been confined for some time around the kidney. After the latter had been sufficiently denuded of its fatty covering, a careful exploration of the organ was made by the finger, in search of the suspected stone, and at first without success, but on repeating the examination a hard point was discovered, which, on scratching away the renal tissue with the finger-nail, proved to be a calculus. As the process of denudation, partly by the nail, and partly by the point of a steel director, progressed, it was found that the stone was one of much greater magnitude than at first anticipated, filling up the entire pelvis of the kidney, and sending its prolongations into the infundibula. After following the different branches of the concretion separately, the calculus was lifted out of its bed by a scoop, and carried sufficiently near the surface of the wound to admit of being seized by a pair of fenestrated forceps and removed. A careful digital examination was now made, to ascertain if any fragments had been left behind. A single piece was discovered and removed.

During the enucleation the bleeding was quite free, but soon subsided on the application, for a short time, of a pledget of antiseptic lint. A drainage-tube was next introduced through the wound into the pelvis of the kidney, and the cavity well washed out with a solution of bichloride of mercury (1 to 2000). The wound was closed by two rows of sutures, the deep ones (catgut) bringing together the aponeurosis and muscles, and the superficial ones (silver) approximating the skin and subcutaneous tissue. The wound was next dusted with iodoform, covered with a strip of protective, over which were placed deep and superficial compresses of carbolated gauze with mackintosh, reinforced with a layer of salicylized cotton, and the whole secured in place with an antiseptic roller. The whole operation was done antiseptically.

The patient was placed in bed somewhat, but not seriously, shocked by the operation, but in a few hours reacted satisfactorily. From this time forward he had no symptoms giving rise to any anxiety whatever. His temperature ranged from 98⅘° to 99°, and only on two occasions reaching over 100°. Urine passed freely through the drainage tube, requiring the dressing to be renewed twice in the twenty-four hours. The lowest quantity passed by the natural routes was twenty-five ounces, the largest fifty-four ounces in twenty-four hours. On two occasions a small fragment of stone escaped, once through the drainage tube and once through the opening after the tube was taken away. The drainage tube was not



disturbed for two weeks, after which time it was removed by instalments, the last portion being taken

away at the end of the third week, at which time the patient was sitting up, and on April 3d was discharged from the hospital. A narrow tract in the loin was still open, but scarcely any urine escaping.

The stone (see figure) weighed 275 grains, and was composed chiefly of phosphate of lime and uric acid.

MEDICAL PROGRESS.

A Case of Successful Extirpation of a Laryngeal Cancroid by Intralaryngeal Procedure.—As this case is referred to in our editorial comments upon the case of the Crown Prince of Prussia, we transcribe the reference in the May number of the *Internationales Centralblatt für Laryngologie, Rhinologie, und verwandte Wissenschaften*, to Frankel's article in Langenbeck's *Archiv*, Bd. xxxiv. H. 2, 1886.

On September 17, 1881, Dr. Fränkel removed, with the snare, a tumor larger than a French bean from the right vocal band of J. W., of Rostock. The tumor was without doubt a cancroid, as demonstrated by the author in several microscopic sections. Recurrence ensued despite the apparently thorough removal. In September, 1882, a similar growth the size of a pea, and in May, 1883, another the size of a French bean, were removed from the same spot and in the same manner. In 1884, a lymphatic tumor the size of a hen's egg had developed on the right side of the neck. In February, 1884, the larynx was again cleared, and extirpated portions were examined by Virchow and found to be cancroid. On April 1st, Professor Magdeburg, of Rostock, successfully extirpated the diseased glands from the neck despite extensive adhesions with the jugular vein, and found that the extirpated glands were undoubtedly carcinomatous. In June, 1884, intralaryngeal interference became requisite for the fifth time, in consequence of recurrence, and the tumor was torn out with the snare in two sittings.

This time the operator omitted the subsequent electrocauterization which had followed the previous extirpations. No recurrence ensued, and since the summer of 1884 the seventy-five year old patient has been completely well. His voice has been thoroughly preserved, and he can be regarded as cured. The author is of opinion that this case justifies the institution of intralaryngeal measures, even in cases of laryngeal cancroid, although such procedure has its limits. Thus he recently transferred a patient to Dr. von Bergmann for unilateral extirpation of the larynx, because the partially subglottic seat of the cancroid at the anterior commissure of the vocal bands indicated danger of extension to the other side of the larynx. This patient has thus far remained cured, and speaks with an audible voice.

Fränkel recommends the following rules in the management of laryngeal carcinoma: In all instances justified by the location of the tumor, a tolerably large piece should be removed with snare or forceps under the topical influence of cocaine. Should microscopic examination show that it is carcinoma, and should there be no immediate danger that the tumor is extending to the other side of the larynx, then the indication exists to attempt to tear the growth out with snare or with forceps under local anæsthesia. The patient is to be kept under frequent laryngoscopic observation, and every recurrent formation is to be removed as soon as practicable by the same methods. If the desired end cannot be accomplished by intralaryngeal procedures, then partial resection of the larynx becomes justifiable. Even should both sides of the larynx be implicated, it becomes a question for consideration whether extirpation is not possible by intralaryngeal procedure before the question of total extirpation is to be entertained.

Sänger's Description of the Object and Result of his Studies in Cæsarean Section.—In the *American Journal of Obstetrics* for June, 1887, Sänger, of Leipzig, describes his researches and their results as follows:

"To study the behavior of the uterine wound in the Cæsarean operation: this formed the basis for the correct principles governing its surgical treatment by a suture adapted to the physiological peculiarities of the uterus. Briefly defined, it (the suture) consists in the exact closure of the entire uterine wound by a two-rowed suture, the lower tier of which is to comprise the whole uterine wall without passing free through the cavity of the organ; while the superficial tier, placed between the deeper stitches, merely unites the surfaces of the serous edges; both tiers of sutures to be so close and so numerous as to insure an absolutely perfect reunion of the uterine wound, and its covering with peritoneum. The suture material to consist of a substance the knots of which do not loosen, and which will not dissolve (silk, silver, or chrome catgut). Since the uterus does not present a movable subserous layer of tissue, the undermining of the peritoneum and resection of the muscularis are intended for cases in which the parallel union of the wound and the lymperitoneal plane suture could be effected only with difficulty. The uterus after the suture must be like an uninjured organ; the uterine wound must heal by first intention without adhering to the abdominal wall."

A Formula for the Administration of Creasote and Iodoform for Phthisis.—Huchard gives the following prescription in *Les Nouveaux Remèdes*, of May 24, 1887.

℞.—Creasote,
Iodoform,
Benzoin pulv. . . . . aa gr. ¾.
Balsam tolu . . . . . ℥ ¾.
for 1 sugar-coated pill.

Sig.—From 2 to 4 pills may be taken daily.

A New Operation for Nasal Deformities.—Dr. Roe, of Rochester, thus describes an operation which he has employed successfully for nasal deformities.

The operation is performed as follows: We first deaden the sensibility of the interior of the end of the nose by cocaine (general anæsthesia being unnecessary) and then brightly illuminate this part.

If the tissue is to be removed from that portion where the mucous membrane is not too firmly adherent, the membrane should be dissected back, to be replaced after the operation.

The end of the nose is turned upward and backward, and held with a retractor by an assistant; then sufficient of the superfluous tissue is removed or dissected out to

allow the nose to conform to the shape that we desire. Great care must, however, be exercised not to remove too much tissue, and also not to cut through into the skin, lest we may have afterward a scar or a dent in the external surface of the nose.

In some cases no after-treatment is required, but in others it is advisable to mould a saddle or splint, as it were, to the top of the nose, so as to make it, while healing, assume the shape we wish to obtain.

In some instances the large and unsightly end of the nose is not due to an excessive tissue but to a malformation of the cartilages of the alæ, bulging outward with a corresponding concavity on the inside.

These noses can be very readily moulded into a handsome shape by cutting, with a small tenotomy knife, through these cartilages, in different places, sufficiently to destroy their elasticity. Then by inserting a silver or hard-rubber tube, of the proper size and shape, into the nostril, and conforming the saddle to the outside of the nose, we have it encased in an outside and inside splint that compels it to conform to the exact shape we desire.

While performing this operation and moulding the nose into shape, we must not neglect to preserve the nasal passages free and unobstructed.—*Medical Record*, June 4, 1887.

THE DISINFECTION OF SHIPS.—KOCH and GAFFKY have made experiments upon vessels in the German navy, from which they draw the following conclusions:

1. The keelroom of a vessel can be thoroughly disinfected, and also its contents, by corrosive sublimate.

2. Sufficient mercurial sublimate solution should be added to the bilge water to give a reaction when the copper test is made.

3. Bilge water and solution must be thoroughly mixed, which can best be done when the vessel is in harbor; a pump is requisite to accomplish this.

4. Such disinfection is complete in eighteen hours.

5. After the keelroom has been washed out with this mixture four times there is no danger of mercurial poisoning for the occupants of the vessel.

6. The material composing the vessel will not be impaired.

7. The pump used becomes so impregnated with mercury that it should not be used for other purposes; six months after such experiments neither the ship nor the pump used was found to be injured.—*Deutsche medicinische Wochenschrift*, May 5, 1887.

ANTISEPTIC FLUID USED IN THE PREPARATION OF GAUZE FOR THE AUSTRIAN ARMY.—The following formula is official in the preparation of dressings for the army:

R.—Hydrarg. bichlorat.	. . .	1 part.
Spirit. vini	. . . .	100 "
Aquæ destillat.	. . .	125 "
Glycerin.	. . . .	50 "
Indigo	. . . .	1 "

The coloring matter is to render the material easy of recognition.—*Wiener medizinische Presse*, No. 7.

THE HEREDITY OF TUBERCULOSIS.—RÜHLE, of Bonn, at the recent German Congress for Internal Medicine, read a paper of which the following is an abstract:

Koch's discovery of the bacillus has aided our diagnostic knowledge much more than our knowledge of the etiology of tubercle.

He raises the question, How by heredity is the tubercular nidus formed in the body?

The theory has been advanced that the tubercle bacillus in semen may affect the ovule, and that the germ, having lain dormant for some time, finally develops; or that the germ existing in the mother's blood may pass into the blood of the fœtus.

The facts supporting this theory are very few.

The influence of contagion by the presence of dried sputum in the atmosphere is also overestimated, as is shown by the comparative immunity enjoyed by nurses in the wards of the phthisical. The communication of tubercular matter by direct contagion in the use of drinking cups, eating utensils, in kisses and handkerchiefs is, the writer thinks, much more potent in producing tuberculosis than any other mode of infection.

He would suggest, in view of these reasons, the term *family tuberculosis*, in its widest sense, as more accurate than hereditary tuberculosis.—*Deutsche medicinische Wochenschrift*, April 28, 1887.

ANÆSTHETIC EFFECTS OF POMADES.—TOPOROFF reports good results from the following methods: One drachm is used by inunction for 10 minutes over a surface 1½ inches in diameter; at the expiration of this time the sensibility is tested by an electric current of known strength. A pomade of belladonna, 1 to 8, diminishes sensibility in a proportion represented by 0.6 after 10 minutes, and 1.1 after 30 minutes.

When lanoline was substituted for lard the effect was 0.55 to 0.99.

Chloroform pomade, 1 to 8, gave analogous effects; 0.66 and 0.62 with lanoline.

Pomades prepared with powdered drugs, as morphine hydrochlorate and potassium bromide, used for 30 minutes, increase sensibility for a certain time, which is less with lanoline than with lard. This, however, was observed in friction with simple fats.

The conclusion reached in these observations is that pomades made with lard are more active than those made with lanoline in lessening sensibility.—*Les Nouveaux Remèdes*, April 24, 1887.

SYRUP OF SUPERPHOSPHATE OF IRON AND OXYGEN.—DR. RICHARDSON, in *Asclepiad*, No. 14, gives the following formula:

Syrup of superphosphate of iron, solution of peroxide of hydrogen (ten-volume strength), pure glycerine—of each a fluidounce. Mix. To make a mixture of three ounces. Dose for an adult, from one to two fluidrachms two or three times a day in three ounces of water.

It can be made to combine with tincture of nux vomica, with strychnine, and morphine, codeine, quinine, salicine, or any other agent which does not by its presence disturb and liberate the oxygen from the peroxide.

The syrup, as it is, is a most useful remedy in cases of a neurasthenic type, and especially when anæmia is also present. In an instance of pure anæmia treated with the syrup in combination with an occasional saline purgative, I have seen more rapid results toward recovery than from any ferruginous remedy I have hitherto employed under similar circumstances.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JUNE 18, 1887.

THE CASE OF THE CROWN PRINCE.

WE are in receipt of the following special cablegram from London, giving a concise clinical report of the case of the Crown Prince of Germany. It comes from a source which justifies absolute confidence in the accuracy of its statements.

"The Crown Prince began to suffer from catarrh and hoarseness last January, and was treated at that time by his physician-in-ordinary, Dr. Wegner, Director-general of Hospitals. A morbid growth on the left vocal cord was discovered by Professor Gerhardt in the beginning of March, and he applied the electro-cautery with but slight improvement resulting.

"On the occasion of the Emperor's birthday at the end of March, the Crown Prince was obliged to use his voice much. In the middle of April he was ordered to Ems, where he took the waters for a month and then returned to Berlin no better. The growth was at this time found to have increased in size; Professor von Bergmann was called in consultation, and subsequently Professor Tobold, of Berlin, and Dr. von Lauer, the Emperor's Physician-in-Ordinary and Chief of the Army Medical Department. They all agreed that the growth was cancer, but before doing an external operation they advised that Dr. Morell Mackenzie, of London, be summoned. Accordingly the Crown Prince telegraphed Queen Victoria requesting that Dr. Mackenzie be immediately dispatched to Berlin, and he arrived there on the afternoon of May 19th. He found that all the necessary arrangements had been made to do an external operation at 7.30 o'clock of the next morning.

"Dr. Mackenzie, upon examination, found a small sessile growth of the size of a split bean, and he recommended that a portion of the tumor be removed by intralaryngeal operation for microscopic examination. Professor Gerhardt and Professor Tobold thought that this was impossible, but agreed that Dr. Mackenzie should attempt the operation the next morning. With the aid of forceps, Dr. Mackenzie succeeded in removing a portion of the growth, which, after microscopic examination, Professor Virchow reported consisted of inflammatory products.

"Dr. Mackenzie then left Berlin, but returned on June 7th, and performed a second intralaryngeal operation. Professor Virchow, after making an immense number of sections of the tissue removed, reported that the growth was a pachydermia verrucosa; that there were enlarged papillæ and epithelial cells, but no morbid elements in the areolar tissue.

"The Crown Prince arrived in England on Monday, and will stay at Norwood, under the entire charge of Dr. Mackenzie, until the middle of July, when he will go to Norreys Castle, the seat of the Duke of Bedford in the Isle of Wight."

The case of the Crown Prince of Germany cannot fail to interest citizens of the United States, as they recall some of the features of the history of the last illness of General Grant.

As we learn from our special cablegram, the Prince's disease manifested itself in catarrh and hoarseness in January; and two months later a warty growth was detected on the left vocal band. Treatment with electric cauterization was then instituted, and was attended with slight improvement; but excessive use of the voice in the festivities attending the Emperor's ninetieth birthday, in the latter part of March, made matters worse. A month's sojourn at Ems failed to be beneficial, and the Crown Prince returned in the middle of April with the growth larger than before. This clinical history of inflammatory hoarseness, probably augmenting dyspnœa, and the presence of a morbid growth which resisted the radical attack of the electric cautery, and increased rapidly in volume, despite rest of the part and other appropriate treatment for inflammatory conditions, naturally led the attendants, some of whom are men spècially skilled in the diagnosis and treatment of intralaryngeal growths, to the opinion that the tumor was malignant, and to the conclusion that radical measures should be instituted for its extirpation. But it was felt that such an operation ought

not to be undertaken unless absolutely unavoidable, on account of the accompanying risk to life, and the probable great impairment of voice, even if successful.

Dr. Mackenzie was then summoned from London to the case, and reached Berlin in time for a consultation on May 20th. Upon examination, he found a small sessile growth, of the size of a split bean, attached to the posterior portion of the left vocal cord, on its inner and upper surface. He urged that the proposed operation should not be performed before a portion of the growth had been removed for microscopical examination, which had not been previously done, because its small size and sessile character was believed to render it impossible. Dr. Mackenzie, however, on the following morning succeeded in removing a small piece of the growth, which, upon microscopic examination by Professor Virchow, was found to be composed of inflammatory products; the epithelial cells were increased in size and number, and the growth was pronounced benign in character. We learn that Professor Virchow also stated that, as the portion removed included a complete section of the growth and the surface of the vocal cord beneath, as clearly demonstrated by the presence of some of the longitudinal elastic fibres of the latter structure, he considered that there was no reason to suppose that any remaining portion of the growth was of a cancerous nature.

Three weeks later Dr. Mackenzie performed a second operation, removing more of the morbid growth, which, after microscopic examination of many sections, has been pronounced by Professor Virchow a pachydermia verrucosa, a term usually applied to a certain variety of elephantiasis of the cutaneous integument, subcutaneous and deeper connective tissue; and, in this instance, to the condition of the mucous membrane. The sections showed enlarged papillæ and epithelial cells, but gave no evidence of morbid elements in the connective tissue.

The Crown Prince is now in England under the care of Dr. Mackenzie, whose experience in intralaryngeal procedures for the removal of growths is probably unequalled, and his manipulatory skill unexcelled. We understand that attempts will be made to get rid of this troublesome growth by intralaryngeal procedures to the exclusion of external operations. But this does not preclude the resort to severer measures if it should be proven that less serious procedures will not suffice. That the latter do succeed at times, even in malignant cases, there is sufficient evidence. Only lately, Fränkel, of Berlin, has reported an instance of undoubted malignant growth eradicated by repeated intralaryngeal attack. Other practitioners believe that they have been equally successful in occasional instances; and, therefore, there is a fair hope for a favorable result in the present case, even if the growth were malignant.

CARDIAC EPILEPSY.

THE possibility of epileptiform convulsions coming on, due to lesions of the heart, has been recognized for a number of years, and interesting contributions have been made on the subject by such writers as Stokes, Thornton, and Blondeau, although the literature of the subject has not by any means been confined to the pen of these writers.

It will be remembered that the symptoms of cardiac epilepsy are chiefly characterized by a remarkable slowing of the pulse, so that the pulse-rate has been known to drop from the normal to not more than five beats a minute, and in a case reported by THORNTON (*Trans. Clin. Soc.*, London, vol. vii. p. 95) it was proved by the stethoscope that in the first stage of the attack the heart ceased to beat for many seconds. In some cases the heart's beat can be heard over the apex, but the patient becomes pulseless at the wrist. The respiratory movements are generally quickened at first and then become labored, and, perhaps, stertorous. The temperature of the body falls very decidedly, not only during, but before the attack, so that the complaint of feeling cold may be the only warning given of an approaching seizure, and this sensation of extreme cold occurring previous to an epileptic convulsion is, in the opinion of several writers, almost pathognomonic of cardiac epilepsy. The color of the face resembles the coloring of an ordinary idiopathic attack, being at the first pale, then red and cyanotic. The convulsive movements do not generally assert themselves during the period of unconsciousness, but they may do so, and biting of the tongue has been reported. In some instances the heart has been found after death in a state of fatty degeneration, and this, of course, points to a lack of sufficient blood-supply as being the cause of the attack. That the disease is not in every case due to organic failure of the heart, is proved by the fact that Charcot has seen such cases occur, in which after death no cardiac lesions were discoverable.

The question as to whether the nerve storm originates in the brain centres or is only secondarily produced by cardiac failure, is one which is solved with great difficulty; since it is perfectly possible to imagine that disordered nervous centres might produce not only an epileptic seizure, but also exert an influence over the heart, as, for example, by sending a powerful impulse along the pneumogastric nerves. Every physiologist knows, too, that cutting off the supply of blood from the brain by the partial ligation of the principal bloodvessels in the neck will

produce violent epileptiform convulsions, and it has also been proved that the convulsions arising in poisonings from the cardiac depressants, which are epileptiform in character, are due to this cause, namely, starvation of nervous centres, whereby their functions are perverted or set aside. The true cause of the epilepsies supposably due to cardiac failure, cannot be considered as decided in every case, but it would seem probable that such cases may arise from both the causes mentioned.

The theory of the production of attacks, owing to deficient blood-supply, has been greatly strengthened by the recent reports of several observers, notably the very recent one of Lemoine in the *Revue de Médecine*, of May 10, 1887, in which he reports five cases of cardiac epilepsy in which valvular disease of the heart existed, and where great amelioration of the symptoms or recovery occurred upon the use either singly or together of such cardiac stimulants as digitalis and caffeine.

While the cardiac muscle was under the influence of these drugs the epileptic seizures became much less frequent, and in some cases entirely disappeared, the only symptoms remaining being vertigo on certain movements, which, however, decreased as the condition of the heart improved. Such evidence as this is of considerable weight, as it strengthens very materially the belief that in many instances the convulsion is due to the cardiac failure.

TYROTOXICON AND CHOLERA INFANTUM.

THE advance of medicine from empiricism to scientific accuracy is very largely dependent upon a painstaking investigation of the causes of disease; and the study of foods and the diseases occasioned by their decompositions, is one of the most important fields for scientific work.

While many of the recent discoveries in medicine have been made by bacteriological research, PROF. VAUGHAN has by chemical analysis isolated a poisonous ptomaine in decomposed milk, and his writings upon this subject are among the most valuable recent contributions to practical medicine.

In his interesting paper in the present number of THE NEWS, Professor Vaughan describes the conditions under which this poisonous body is formed; cites clinical cases of infection produced by it, and demonstrates its causation of cholera infantum. The rules which he lays down for the care of milk, should receive the widest publicity, and their observance will go far toward the improvement of the character of our milk supply and the eradication of that scourge of infancy—cholera infantum. His deductions regarding the treatment of this disease are of great value, and especially timely at the approach of summer, and the results of his experiments, now in progress, upon the value of different germicides which destroy tyrotoxicon, when completed, cannot fail to prove of the greatest interest.

THE Rhode Island Medical Society held its seventy-sixth annual meeting in Providence, June 9th. Officers were elected as follows:

President.—Horace G. Miller, M.D.

Vice-Presidents.—Albert Potter, M.D., and John W. Mitchell, M.D.

Recording Secretary.—William R. White, M.D.

Corresponding Secretary.—Geo. D. Hersey, M.D.

Treasurer.—Charles H. Leonard, M.D.

The Trustees of the Fiske Prize Fund reported that the prize for the current year, of $200 for the best essay on "Membranous Enteritis," was awarded to Dr. James B. Field, of Lowell, Mass. There was no award on the second subject. The subjects for the coming year are:

(1) "What Changes has Acceptance of the Germ Theory made in Measures for the Prevention and Treatment of Consumption."

(2) "Antiseptics in Medicine and Surgery; with original observations and experiments."

For the best essay on either of these themes a prize of $200 is offered under the usual conditions.

The President, Dr. Horace G. Miller, delivered the annual address on the "Bacteriology of the Eye."

THE President of the Key West Board of Health, Dr. J. Y. Porter, reported by telegraph, under date of June 5th, that "Yellow fever had ceased to be sporadic, and absolute segregation of patients in hospital impossible, as friends conceal cases, and violently oppose removing sick; therefore, for these reasons, the board will declare the disease to be fast assuming an epidemic character." Twenty-two cases and eight deaths from yellow fever have been reported up to June 10th.

THE Kings County Medical Association held its third stated meeting at Brooklyn, June 7th. The paper of the evening, by Dr. J. D. Rushmore, treated of veratrum viride as a therapeutic agent. The use of large doses of veratrum in puerperal convulsions, sometimes spoken of as "the Brooklyn treatment," came up prominently in the discussion, a circular calling for the experience of the profession having been previously sent to every registered physician of the city, from which it appeared that by very many this drug is regarded as a "sheet-anchor" in ante-partum and post-partum convulsions.

DR. CARL FRIEDLANDER.—This well-known pathologist died at Meran on May 13th, after a long illness, aged forty. Although a victim of progressive

pulmonary tuberculosis, he did not abandon his scientific work to secure those climatic advantages whose value he strongly urged upon the profession. He was an early champion of the curability of phthisis, but in his enthusiasm for science devoted himself assiduously to his work. His researches upon the "Uterine Decidua," upon "Local Tuberculosis," and upon the "Proliferation of Epithelium in its Relations to Cancer," are well known.

His name is coupled, however, with the pneumococcus, whose discoverer he was; and his theory of the causation of pneumonia has received universal attention.

The *Fortschritte der Medicin*, published at Berlin twice monthly, was established by Dr. Friedländer, and is a monument to his memory. His last writing was in the discussion of the antiseptic properties of iodoform.

WE are happy to learn from the Austrian press that PROFESSOR BILLROTH'S convalescence is almost assured; it is confidently expected that after a summer of careful recuperation this distinguished surgeon will be able to resume his duties at his clinic in the autumn.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Thirty-eighth Annual Meeting, held at Chicago,

(Specially reported for THE MEDICAL NEWS.)

TUESDAY, JUNE 7TH.—FIRST DAY.

The Thirty-eighth Annual Session of the American Medical Association was opened in Central Music Hall, at 11 A.M., by the Chairman of the Committee of Arrangements, Charles Gilman Smith, M.D., who called the assemblage to order, and invited the Rev. S. J. McPherson to offer prayer. Dr. Smith, with an allusion to the kind feelings of the citizens of Chicago toward physicians, because, although they took a great and active part in "labor" troubles, they never struck for eight hours work or higher wages, introduced Mayor John A. Roche, who, as the official representative of the city, delivered an address of welcome.

A call for the ex-Presidents of the Association to sit upon the platform was responded to by Drs. William Brodie, T. G. Richardson, J. M. Toner, and N. S. Davis.

The Chairman of the Committee of Arrangements announced the programme of the session and the various entertainments, and called the First Vice-President, P. H. Millard, M.D., of Stillwater, Minn., to the chair.

The PRESIDENT, E. H. GREGORY, M.D., of St. Louis, then delivered the annual

ADDRESS ON [illegible]-ANTAGONISM.

(See THE MEDICAL NEWS, June 11th, page 645.)

DR. A. N. BELL, of Brooklyn, stated that he had a report to present to the Association.

DR. WILLIAM B. ATKINSON, of Philadelphia, moved its reference to the Section on State Medicine.

DR. I. N. QUIMBY, of Jersey City, moved that the report be read to the Association, as it had appointed the committee. The latter motion was put and declared carried.

DR. BELL then read a report on

THE SANITATION OF EMIGRANT SHIPS.

The report discussed the United States laws bearing upon the subject, which require that every vessel carrying immigrant passengers exceeding fifty in number, shall be provided with a duly qualified and competent surgeon or medical practitioner; and dwelt on the common inefficiency of the service thus required, especially in preventing the importation of disease, and of the mentally unsound or imbecile who would be added to the defective and criminal classes of the country. Unsuccessful attempts to secure the amendment of these laws had been made through the Hon. John H. Reagan, Chairman of the House Committee of Commerce. Attention was called to the low status of the medical officers, and the exemption of cabin passengers from the obligations of the law. It was urged that on all vessels carrying more than six hundred passengers and crew, other than first-cabin and saloon passengers, should be provided also with a junior or assistant surgeon. These should not only give prompt medical attendance to passengers and seamen, but should also perform the duties of sanitary officers, making suggestions to the master of the vessel, when needful; seeing that all parts are kept in good sanitary condition, and making full report to the sanitary authorities of the port of the arrival of all cases of disease, insanity, or imbecility occurring during the voyage. The medical officers should have at command a competent apothecary or medical steward, and a sufficient supply of medicines.

On motion, the report was adopted, and copies thereof directed to be sent to the Secretary of the Treasury, and to both branches of the next Congress.

CRITICISING THE NEWSPAPERS.

DR. D. J. ROBERTS, of Nashville, Tenn., referring to an editorial in the morning issue of the Chicago *Times*, offered a series of resolutions repudiating the statements made as an unwarranted, uncalled-for, and unjust attack upon the regular medical profession of the United States and its representatives here assembled, and expressing deep regret at the insult that had been offered to the regular medical profession of Chicago, and, through the American Medical Association, to the regular medical profession throughout the world.

DR. EUGENE GRISSOM, of Raleigh, N. C., urged that the Association could not afford to prostitute its high mission by controversy; and moved to lay the resolutions on the table.

Several members attempted to get the floor to discuss the motion, but it was put and carried by a vote of 133 to 89.

DR. WILLIAM BRODIE, of Detroit, Mich., moved the adoption of the proposed amendment creating

A SECTION ON DERMATOLOGY AND SYPHILOGRAPHY,

Carried.

DR. J. MCF. GASTON, of Atlanta, Ga., Chairman of the Committee to memorialize Congress on the investigation of inoculation for the prevention of yellow fever,

asked that the report of his committee be referred to the proper Section.

Referred to the Section on State Medicine.

WEDNESDAY, JUNE 8TH—SECOND DAY.

REPORT ON THE JOURNAL.

DR. J. M. TONER, of Washington, D. C., read the report of the Board of Trustees for the publication of the *Journal of the Association;* and, as part of that report, the Editor, Dr. N. S. Davis, read his annual report to the Board of Trustees. The weekly circulation is 4,387, of which 3,478 go to members of the Association, and the remainder to subscribers, exchanges, etc. During the year the membership of the Association has increased by 104, and the weekly circulation by 116. The total expense of publishing the *Journal* was $15,920.96, of which $2,758.95 were expended for editorial work. The amount received for subscriptions (from non-members), for advertising, and for reprints, was $7,580.63; the remainder having been drawn from the treasury. It was further stated that Dr. Davis had consented to continue as editor of the *Journal* for another year.

On motion, the report was accepted and adopted.

DR. D. J. ROBERTS stated that the *Chicago Times* had made satisfactory acknowldgments as regards its assertions reflecting on the regular medical profession of Chicago and elsewhere; and begged leave to withdraw the resolutions he had introduced the previous day.

On motion, he was granted the desired permission.

DR. A. VON MANSFIELD, of Ashland, Neb., inquired how many members of the Association were receiving the *Journal* without paying for it.

DR. DAVIS could not tell, as the Treasurer received all dues for membership.

DR. N. S. DAVIS, Chairman, then read the

REPORT OF THE SPECIAL COMMITTEE ON CHANGES IN THE PLAN OF ORGANIZATION AND BY-LAWS OF THE ASSOCIATION.

This committee had been appointed under the following resolution, adopted at the last annual meeting: "*Resolved*, That a committee of nine members, including the President, President elect, and four Vice-Presidents elect, be appointed by the Chair to consider the various propositions looking to the amendment of the organic law of the Association, by the establishment of branches, or in any other way; said committee to report at the next annual meeting what measures of organization, if any, may be desirable."

The report had been drawn up by the chairman, and signed by all the members of the committee (seven) present at this meeting. The above resolution had been inspired by two considerations: *First*, the desirability of a more permanent and representative body to perform the duties now devolving upon the Committee on Nominations, and to consider other questions of importance referred to it by vote of the Association. *Second*, the desirability of increasing the paying permanent membership of the Association. The usually hasty, and often informal selection of members of the Nominating Committee, who are charged with the important duty of selecting the general officers of the Association, members of the Judicial Council, and of the Board of Trustees, besides determining upon the next place of meeting, has given rise to much adverse criticism. A committee thus hastily appointed, compelled to discharge duties of the greatest importance with equal haste, and then ceasing to exist, could not fail to commit some errors and make some injudicious recommendations.

To secure a properly organized council, or standing business committee, and an increase of paying membership, it had been proposed to remodel our organization after the plan of the British Medical Association. But the conditions here are different. The 25,000 British practitioners are included in an area scarcely as great as that of our New England States. The British Medical Association has been in existence fifty-five years, and as yet includes but half of those who are eligible to its membership. And if some of its branches become so indifferent as to neglect the election of delegates to the Council to which they are entitled, as shown by reports at the last annual meeting, how would it be if the attempt should be made to require a select Council of this Association to meet four times a year, composed of delegates from branches in California, Maine, Minnesota, Texas, and Florida, at some central place as Washington Philadelphia, or Chicago, for the satisfactory consideration of all its important interests?

If the practical result of the experiment of the British Association, where all the circumstances have been most favorable, has been to put the entire control of the affairs of the Association in the hands of those members of the Council in London and in the few important cities affording most ready access thereto, it requires but a moment of serious reflection to see that the evils actually developed in the progress of the British Association, would be produced with far greater rapidity and intensity, if the same machinery and methods were adopted here.

It is believed that to accomplish the promotion of personal interest between neighboring members of the profession, the general development and diffusion of medical knowledge, both scientific and practical, and unity or concert of action on questions of education, medical legislation, and the sanitary surroundings of the people, the most desirable form of organization conceivable is but an ideal representation of the actual organization of the profession in this country as it now exists. After a careful study of the development of medical organizations at home and abroad, the Committee recommend no radical changes in the existing plan of organization; but urge the preservation of its essential principles and their present accurate adjustment to the needs of the situation, the correction of minor defects in practical application, and such changes in the by-laws as will facilitate the business and scientific interests of the body.

Under existing regulations "members by application" "simply have the right to receive the *Journal* on the same terms as the members." This affords no adequate motive for seeking such membership, since any one, whether a member or not, can obtain the *Journal* by the payment of five dollars a year. Therefore the following was recommended as an

AMENDMENT TO THE CONSTITUTION, SECTION SECOND.

"Members by application shall consist of such members of the State, County, and District Medical Societies

entitled to representation in the Association as shall make application in writing to the Treasurer, and accompany said application with a certificate of good standing, signed by the President and Secretary of the Society of which they are members, and the amount of the annual membership fee, five dollars. They shall have their names upon the roll and have all the rights and privileges accorded to permanent members, and shall retain their membership on the same terms."

This would enable one or all the members of recognized State and local Societies to become *de facto* permanent members of the Association without the expense of attending a meeting.

From the fifth section of the Constitution it is proposed to strike out the first paragraph relating to the Nominating Committee, and in its place insert the following:

CREATING A GENERAL COMMITTEE OR COUNCIL.

"The General Committee or Council shall be composed of two members from each State and Territorial Medical Society entitled to representation by delegates in this Association, and from the Medical Departments of the United States Army, Navy, and Marine-Hospital Service. They shall be chosen by the members registered and present at each annual meeting, from each State, Territory, and from the Medical Corps of the U. S. Army, Navy, and Marine Hospital Service, acting separately on the third day of each annual meeting, each delegation reporting the names of the members chosen, to the permanent Secretary of the Association on the same day, that they may be announced by him at the opening of the morning session of the fourth day. At the first election each delegation shall choose two members of the General Committee, one of whom shall serve one year and the other two years; and at each annual election thereafter one member shall be chosen to serve for two years; thus making the term of office of members of the General Committee, two years. It shall be the duty of the General Committee, thus constituted, to organize by choosing annually, a Chairman and Secretary, and such sub-committees as may be found necessary to facilitate the work that may be assigned to it; to meet annually at the place and on the day preceding each annual meeting of this Association, and as often during that week as may be necessary; to nominate on the third day of each annual meeting all the general officers of the Association (none of whom shall be members of its own body), the members of the Committee of Arrangements, the Committee on Necrology, seven members of the Judicial Council, and three members of the Board of Trustees for Publication, for election by the Association; to recommend the place and time of holding the next annual meeting, and to consider and report upon all subjects that may be referred to it by vote of the Association, and particularly on all propositions involving the appropriation of money. The presence of one-third of the whole number of members elected to the General Committee shall constitute a quorum for the transaction of business. If at any annual meeting of the Association it shall be found at the close of the general meeting of the first day that a quorum of the General Committee is not present, it shall be the duty of the President and Permanent Secretary to fill vacancies in the Committee temporarily, by selections from the lists of delegates registered as present from the States to which vacancies belong."

At the annual meeting of 1883, the duties of the Committee of Publication were transferred, by resolution, to the Board of Trustees for journalizing the transactions. It is proposed so to amend paragraph three of section five of the Constitution, as to make it conform to the practice of the last four years in this matter; and to define clearly the powers and duties of the Trustees.

In addition to the above, the Committee proposes certain

AMENDMENTS TO THE BY-LAWS.

Change Section II. of the By-Laws relating to the Duties of Chairmen of Sections, to read thus:

"The Chairman of each Section shall prepare an address on the recent advances in the branches belonging to his Section, including such suggestions in regard to improvements in methods of work as he may regard important, and present, on the first day of its annual meeting, the same to the Section over which he presides. The reading of such address not to occupy more than forty minutes."

Hitherto these addresses have been made before the general meetings of the Association, but the pressure of business and the multiplication of Sections render this no longer practicable. To take the place of these addresses in the general meeting, another By-Law, to be numbered XIV., is proposed as follows:

"The Association shall annually elect, on the nomination of the Nominating Committee (or the Standing General Committee), three members of the profession, eminent in some of its departments, to deliver addresses in the general session of the next ensuing annual meeting, one on some topic or topics relating to general medicine, another relating to general surgery, and the third relating to public medicine, including under that head, hygiene, sanitation, prophylaxis, education, and medical legislation; each of such addresses not to exceed one hour in its delivery."

DR. R. REYBURN, of Washington, D. C., moved that the report be received and the Committee discharged.

DR. R. G. JENNINGS, of Little Rock, Ark., moved that the report be received and adopted.

THE PRESIDENT then put the motion to accept and adopt the report, and declared it carried.

DR. A. W. ALVORD, of Michigan, asked in what shape did this leave the amendments to the Constitution.

The PRESIDENT could not answer; but the Permanent Secretary said that Dr. Davis understood that they were adopted.

DR. I. N. QUIMBY, of Jersey City, thought that they must lie over for one year.

DR. E. GRISSOM, of North Carolina, held that they had been adopted.

The Chair decided the adoption of the report carried with it the adoption of the amendments.

DR. DAVIS said he would be glad if the amendments could now be adopted. It could legally be done by construing the resolution under which the committee was appointed, as a proposed amendment to the Constitution. In this way it had been before the Association for a year.

DR. A. B. PALMER, of Michigan, disagreed with the

construction put upon the resolution by Dr. Davis. It should lie over.

DR. J. B. GREEN, of Indiana, said that this committee was one of consideration. Its recommendations were not before this body until this morning.

Amid great confusion, Dr. A. N. Bell, of Brooklyn, got the floor, and moved that it was the sense of the Association that these amendments had been before the Association one year and duly considered. This motion was put and declared lost. Division was called for; and the Permanent Secretary counted the votes as the members stood up in their places, and announced 272 affirmative, 232 negative. It was decided that the motion was carried. This surprised the meeting and great confusion ensued. A delegate asked if all questions were to be decided that way. The yeas and nays were called for, but the call was ignored.

DR. GREEN moved to reconsider.

DR. GRISSOM moved to table the reconsideration, and this was declared carried.

The Permanent Secretary then announced the

NOMINATING COMMITTEE.

Alabama, W. C. Cross; Arkansas, D. E. Ewing; California, J. W. Robertson; Colorado, P. Drummond; Connecticut, W. H. Whittimore; District of Columbia, J. M. Toner; Florida, M. B. Phillips; Georgia, A. G. Whitehead; Illinois, E. P. Cook; Indiana, T. B. Harvey; Iowa, W. Watson; Kansas, W. L. Schenck; Kentucky, D. S. Reynolds; Louisiana, T. G. Richardson; Maine, D. E. Marston; Maryland, T. B. Evans; Massachusetts, E. W. Cushing; Michigan, W. Brodie; Minnesota, J. E. McGaughey; Mississippi, T. R. Trotter; Missouri, J. M. Allen; Nebraska, W. M. Knapp; North Carolina, Eugene Grissom; New Hampshire, J. W. Parsons; New Jersey, Lott Southard; New York, Darwin Colvin; Ohio, X. C. Scott; Pennsylvania, E. A. Wood; Rhode Island, Wm. J. Burge; South Carolina, T. Legare; Tennessee, J. B. Murfree; Texas, R. W. Park; Vermont, S. H. Griswold; Virginia, H. M. Nash; Wisconsin, J. K. Bartlett; U. S. Navy, D. Bloodgood; U. S. Marine Hospital Service, H. M. Goldsborough; Dakota, E. M. Dow; New Mexico, Russel Baily.

A Committee of the American Pharmaceutical Association presented the following resolution which the Pharmaceutical Association had adopted at its last annual meeting.

"*Resolved*, That this Association solicits the aid and coöperation of the American Medical Association in promoting the prescribing by physicians, of official medicines only, or such preparations as have published formulas, in preference to others."

On motion the communication was received.

The Chairman of the Section on Surgery and Anatomy, Dr. H. H. Mudd, of St. Louis, being absent, his address was read by title.

DR. J. S. LYNCH then delivered his address as Chairman of the Section on Practice of Medicine.

The meeting then adjourned.

THURSDAY, JUNE 9TH.—THIRD DAY.

Dr. William Brodie, Chairman, presented the report of the Nominating Committee, recommending the following for

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. A. Y. P. Garnett, of Washington.

Vice-Presidents.—Drs. Duncan Eve, of Tennessee; Darwin Colvin, of New York; Charles J. O'Hagan, of North Carolina; A. Stedman, of Colorado.

Librarian.—Dr. C. H. Kleinschmidt, of Washington.

Treasurer.—Dr. R. J. Dunglison, of Philadelphia.

Assistant Secretary.—Dr. J. S. Ransohoff, of Cincinnati, Ohio.

Trustees of Journal.—Drs. L. Connor, of Detroit, Mich.; E. O. Shakespeare, of Philadelphia; W. T. Briggs, of Nashville, Tenn.

Members of the Judicial Council.—Drs. J. Murphy, of Minnesota; J. M. Toner, of District of Columbia; J. K. Bartlett, of Wisconsin; A. B. Sloan, of Missouri; X. C. Scott, of Ohio; A. W. McClure, of Iowa; J. W. Stormont, of Kansas; and J. F. Hibberd, of Indiana.

Place of meeting, Cincinnati, Ohio; *Time*, the third Tuesday in May.

Chairman of the Committee of Arrangements.—Dr. W. W. Dawson, of Cincinnati.

DR. MILLARD moved that the report as read be received and adopted; and the Committee directed to report the names of three members to deliver the addresses before the general meetings of the next annual session, in accordance with the newly adopted by-laws. Carried.

The choice of the various Sections for officers for the ensuing year was then announced. The list of

CHAIRMEN OF SECTIONS:

Anatomy and Surgery.—Donald McLean, of Michigan.

Practice of Medicine.—A. B. Palmer, of Michigan.

State Medicine.—H. B. Baker, of Michigan.

Obstetrics and Diseases of Women.—Ely Van de Warker, of New York.

Oral and Dental Surgery.—J. Taft, of Ohio.

Ophthalmology, Otology, and Laryngology.—F. C. Hotz, of Illinois.

Diseases of Children.—F. E. Waxham, of Illinois.

Medical Jurisprudence.—E. Miller Reed, of Maryland.

Dermatology and Syphilography.—L. Duncan Bulkley, of New York.

DR. N. S. DAVIS called attention to the need for the members from each State getting together and selecting two members of the General Standing Committee, in accordance with the amendments to the Constitution adopted yesterday.

DR. W. T. BISHOP, of Pennsylvania, asked how this confusion had arisen as to whether the amendments affected the Constitution or the By-laws?

THE PRESIDENT said there appeared to be some dissatisfaction regarding this matter [A member—"A great great deal of it"], and that he felt that he was the head and front of the offending. Now he desired, above all things, to do right, and wished to offer this written statement: "It is the opinion of the Chair that some mistakes were made in the decisions yesterday. Those portions relating to the adoption of the amendments to the Constitution clearly should lie over for one year, while the amendments to the By-laws may be adopted at once."

On motion, it was decided that the proposed amend-

ments to the Constitution be not adopted, but lie on the table, subject to ratification at the next annual meeting.

THE RUSH MONUMENT COMMITTEE,

through its Secretary, DR. George H. Rohé, of Baltimore, read a report of progress. $389 had been collected, of which $140.08 had been expended for printing, etc. Referred to a committee of three: Drs. Grissom, Garcelon, and Palmer, to audit.

DR. ROHÉ read a letter from Dr. D. Hack Tuke, of London, inquiring if foreign contributions would be received.

DR. RANNEY, of Michigan, stated that at the recent meeting of the Michigan State Medical Society, $100 had been appropriated for the monument fund.

In the absence of the Chairman, DR. JOHN MORRIS, of Baltimore, read the report of the special committee on

CREMATION,

closing with the following resolution:

Resolved That it is the judgment of the American Medical Association that the burial of all persons dying of zymotic diseases should be placed by law under the control of the health authorities, and in all such cases of disease chemical agents should be used by such authorities to bring about a rapid disintegration of the dead body.

This was referred to the Section on State Medicine for discussion.

DR. J. MCF. GASTON, of Georgia, offered a series of resolutions calling on the President of the United States to appoint two additional members of the Commission for the

INVESTIGATION OF YELLOW FEVER;

one to have a practical clinical acquaintance with the fever; the other qualified to communicate with the population of the localities in which it occurs.

DR. GEO. H. ROHÉ moved to lay the resolutions on the table. This was lost, and the resolutions adopted.

DR. F. M. JOHNSON, of Kansas City, Mo., Chairman of the Section on Obstetrics and Diseases of Women, delivered his address.

DR. GEO. H. ROHÉ, of Baltimore, Chairman of the Section, delivered an address on State Medicine.

DR. J. S. KNOX, of Chicago, Chairman of the Section on Diseases of Children, read an abstract of an address on [illegible]

THE REPORT OF THE TREASURER

was read. It showed for last year, total receipts, $21,723.22; total disbursements, $20,319.43; leaving balance in the treasury of $1403.79.

THE REPORT OF THE LIBRARIAN

was read, showing the addition of 158 new titles to the Library during the year.

On motion of Dr. J. F. Hibberd, of Indiana, the report was received and $10 appropriated for a copy of the *Index Medicus*.

A communication was received asking for an

APPROPRIATION FOR THE INTERNATIONAL MEDICAL CONGRESS.

DR. DAVIS moved the appropriation of $500 for the purpose.

An amendment was offered making the sum $1000.

It was stated that but few understood the need for additional funds; but $12,000, including the appropriation made by Congress, were yet available; and unless at least $40,000 or $50,000 could be raised the Committee on Organization of the Congress would be most seriously hampered in its work. The amended motion was carried.

FRIDAY, JUNE 10TH.—FOURTH DAY.

The Nominating Committee appointed the following to deliver

THE ADDRESSES

in the general meetings next year:

On Medicine, R. Beverley Cole, of California.
Surgery, E. M. Moore, of New York.
State Medicine, J. S. Cabell, of Virginia.

It was recommended that a committee of three be appointed to notify these appointees, and to fill any vacancies that might occur in this list prior to the next annual meeting.

On motion, the report was adopted, and Drs. Toner, Grissom, and Colvin appointed as such committee.

DR. J. B. HAMILTON, of Washington, D. C., offered resolutions requesting the Senate and House of Representatives to cause such number of copies of the report of Dr. Sternberg, the Commissioner to investigate the

PREVENTION OF YELLOW FEVER BY INOCULATION,

printed as should be required by the medical profession of the country; and rescinding the resolutions adopted the day before asking for the appointment of additional Commissioners.

DR. ROHÉ believed that the members did not understand yesterday the true state of the case. The President had fully complied with the law as passed by Congress and could do no more. Dr. Sternberg was already in Brazil engaged in the investigation.

The previous question was then moved on Dr. Hamilton's resolutions, which were put and carried.

DR. J. S. MARSHALL, of Illinois, Chairman of the Section, delivered the Address on Oral and Dental Surgery.

DR. I. N. QUIMBY, of Jersey City, N. J., delivered the Address on Medical Jurisprudence.

DR. ALONZO GARCELON, of Maine, on behalf of the Auditing Committee reported the accounts of the Treasurer correct and properly vouched.

DR. N. S. DAVIS, as Chairman of the Standing Committee on Meteorological Conditions and their Relations to Disease, and on the Collective Investigation of Disease, reported that he had not been able to arrange the material in hand so as to form from it a report of value, but hoped to be able to attend to it in the future.

Accepted as a report of progress and the Committee continued.

DR. N. S. DAVIS then offered the following:

Resolved, That the regular graduates of such dental and oral schools and colleges as require of their students a standard of preliminary or general education and a term of professional study equal to the best class of the medical colleges of the country, and embrace in their curriculum all the fundamental branches of medicine, differing chiefly by substituting practical and clinical instruction in dental and oral medicine and surgery in place of practical and clinical instruction in general

medicine and surgery, be recognized as members of the regular profession of medicine, and eligible to membership in this Association on the same conditions and subject to the same regulations as other members.

He said a Section on Oral and Dental Surgery had been established in the Association, also in the proposed Ninth International Medical Congress, and some such action was required to draw the line indicating who could be properly admitted to these Sections. Of yet greater importance is the influence it will exert toward raising the standard in the schools of dentistry. The resolution was adopted.

DR. DAVIS offered the following also:

Resolved, That the Committee of Arrangements are hereby directed at each annual meeting of the Association so to arrange the programmes regarding entertainments and receptions that the evening of the third day be reserved for a regular annual dinner, under the following general regulations: The chief registration officer shall provide for each registration table a paper headed, "Annual Dinners of the American Medical Association," with two columns for names, one headed tickets without wines or liquors at a specified sum; the other, tickets with wines, etc., at a specified sum; that each member when registering can have the opportunity to take a ticket for the dinner if he desires it, and can be entirely free to enjoy the dinner, not only without using wines, but, also, without being required to assist in paying for that drunk by others; while those who desire the addition of wines will enjoy the same liberty. It shall be the duty of the Committee of Arrangements to select a proper place for the dinner, to ascertain the cost per plate on the plan already indicated, that the price paid for the tickets will pay the entire cost of the dinner, leaving no part to be paid either by the local profession or by the Treasurer of the Association. Each man having to pay for his dinner would effectually limit the expense. The plan had proven satisfactory in the British Medical Association.

DR. WILSON, of Boston, moved that an honorarium of $300 be granted the Permanent Secretary.

DR. DAVIS stated that the money was needed for the *Journal*, and that the Permanent Secretary already had his expenses paid, including all expense connected with attendance on the meetings. He moved, as a substitute, that all such propositions to appropriate money be referred to the Trustees of the *Journal*. This substitute was carried.

On motion of Dr. A. B. Palmer, the Committee on Sanitary Police, Dr. A. N. Bell, Chairman, was continued.

DR. D. J. ROBERTS, of Tennessee, moved that a committee of five be appointed to report on the legal regulation of medical practice. As such a committee had already been appointed in the Section on State Medicine, the resolution was referred to that Section.

DR. J. M. TONER offered the following:

Resolved, That the Presidents of all State and Territorial Societies entitled to representation in this Association shall be *ex-officio* honorary Vice-Presidents of the Association, and entitled to seats upon the platform.

DR. JENNINGS, of Arkansas, thought there were enough on the platform now, that most of the business was transacted there already.

The resolution was laid upon the table.

On motion of Dr. E. A. Wood, of Pittsburg, Pa., a committee of three was appointed to investigate the subject of dietetics, and report at the next meeting. Dr. E. A. Wood, of Pittsburg; J. T. Whittaker, of Cincinnati; and F. Woodbury, of Philadelphia, were appointed.

A telegram was received from the President-elect, Dr. A. Y. P. Garnett, expressing his sense of the honor shown him, and regret at his inability to be present.

On motion of Dr. Wm. Brodie, the thanks of the Association were tendered the citizens of Chicago, the medical and secular press, and the railroads from which courtesies had been received.

DR. GREGORY, in a few appropriate remarks, closed the session.

In the afternoon many of the members took part in an excursion to the town of Pullman.

THE ASSOCIATION OF AMERICAN PHYSICIANS.

Second Annual Meeting, held at Washington, June 2 and 3, 1887.

THURSDAY, JUNE 2D.—AFTERNOON SESSION.

DR. HENRY HUN, of Albany, reported some

CASES OF SEWER-GAS POISONING.

He thought it probable that the following diseases may result from sewer-gas poisoning: vomiting and purging, separately or combined; general debility; fever; sore throat of a diphtheritic type; neuralgia; and perhaps, also, myelitis of the anterior horns. These conditions are frequently combined. Fever is frequently associated with the other symptoms. There is one group of symptoms which is almost always present, and that is, loss of appetite, extreme prostration, and pain in the head. When this occurs as a chronic condition we are justified in suspecting that the patient is suffering from sewer-gas poisoning. He reported in detail twenty-nine cases.

DR. W. W. JOHNSTON, of Washington, said that the theory of sewer-gas poisoning has gradually taken the place of malaria as the supposed cause of many obscure conditions, just as malaria superseded the hepatic origin of disease. The theory which attributes many of these conditions to the presence of sewer gas has not been proven. In an examination of a number of men working in the sewers of this city, it was found that they were more healthy than those who worked above ground, and the same observation has been made in other places.

DR. ISRAEL T. DANA, of Portland, Me., reported

A CASE OF ANEURISM OF THE ABDOMINAL AORTA

in a man of thirty. The most prominent symptom was a constant sensation of throbbing and pulsation centring in the epigastrium. Exacerbations occurred on slight exertion or on excitement, and also often on waking in the morning. More or less tenderness existed in same region, varying at times both in intensity and area. He was also subject to sensations of faintness and sinking, referable to the same region. There was a history of an accident in August, 1884, to the small of the back.

Exploration of the abdomen anteriorly revealed the existence of a small, equally expansile tumor just above the level of the umbilicus. There was a single impulse related to cardiac systole, with no backstroke. A distinct blowing sound was heard. On examination posteriorly, there was found a distinct independent centre of motion and sound. The sound was doubly sharper and more intense than that heard in the precordial region, and possessed of a well-marked "booming" quality. It was as if a miniature heart were there. Between this centre of sound and the lower left interscapular region where the normal heart sounds could be faintly heard, there intervened an area of silence.

The diagnosis was a small traumatic aneurism of the abdominal aorta just after its passage through the diaphragm; also some inflammation of the aortic coats, higher up.

The treatment consisted of: (1) absolute rest in bed for two months; (2) restricted diet of bread, meat, milk, and cocoa, the amount of which was limited; (3) iodide of potassium, twenty grains four times a day. Immediate improvement ensued within the first week, and he continued to gain in power till by the middle of November he could walk and ride about carefully.

On May 9, 1887, he began light work at the paper-mill. He had regained the twenty-five pounds of lost weight, ate well, slept well, and had but little palpitation, though excitement, physical or emotional, readily induced a slight return of some of the old sensations.

Physical examination at this date revealed anteriorly the existence of the aneurismal mass, perhaps a little diminished in size, while the blowing sound was scarcely audible. The impulse and expansion were markedly reduced. On examination posteriorly the independent centre of pulsation and double sound was found, but both motion and sound were greatly reduced in amount and the booming quality was gone.

The conclusion was that a practical cure had taken place, the sac having become largely filled with concentric layers of fibrine; and that reduction of the existing inflammation of aortic coats higher up had been effected.

The estimate of chances of final complete recovery was not considered encouraging. The circumstances of the patient were not favorable to such rest, recreation, and tranquillity of mind as might be desirable; and even with all external conditions at the best, there would yet be too many dangerous liabilities remaining, such as embolism, pyæmia, atheromatous degeneration, etc. The quick improvement under treatment is noticeable. The patient himself attached great value to the iodide of potassium, which he still takes; he feels so much better while taking it, that he is unwilling to leave it off.

Evening Session.

Dr. W. H. Welch, of Baltimore, opened the discussion

Hemorrhagic Infarction.

He referred to the different theories which had been advanced to explain the occurrence of hemorrhagic infarctions. These are: 1, the changes in the walls of the artery obstructed; 2, the increased pressure with which the blood is sent in from the collateral circulation; and 3, a regurgitant flow of blood from the veins. Numerous experiments had been performed by the author, with the assistance of Dr. Mall, of Johns Hopkins University, to determine which of these theories was the correct one. Hemorrhagic infarctions were produced in the intestines of dogs, and the method of experimentation was given in detail. He presented, as the result of his studies, the following conclusions:

1. The blood which produces hemorrhagic infarctions comes chiefly, if not exclusively from the collateral vessels.

2. Hemorrhagic infarctions in the intestine cannot take place merely from a reflux of blood from the veins.

3. The blood-pressure is very low in the region where hemorrhagic infarction occurs, in consequence of occlusion of the main artery.

4. A certain degree of force of the collateral circulation is required to produce a hemorrhagic infarction.

5. No positive proof exists that a change in the vascular walls is essential to the production of a hemorrhagic infarction.

6. The hemorrhage occurs by diapedesis.

Where hemorrhagic infarction has taken place, the large and small veins are widely dilated with blood, and the arteries contain a smaller quantity of blood than normal. There is stasis in many of the veins and capillaries.

Dr. William Osler, of Philadelphia, the conferee, referred to the *clinical aspects of the subject*. Among other cases coming under his observation, he reported the following: J. M., aged twenty, admitted to the Philadelphia Hospital, October 10, 1886. He had never had syphilis, and was a healthy-looking man. He presented a clear history of typhoid fever, with a sickness of six weeks, two years previously. His present illness began with diarrhœa one week before admission. For two days he had attacks of bleeding at the nose. There was temperature of 102°, with pain in the abdomen. There was no cardiac murmur, and examination of the lungs gave negative results. The splenic dulness was increased. By October 15th the temperature had reached 103°. There was almost constant delirium. There was some diarrhœa. Coldness of the feet appeared, and continued to increase in degree, and extended up the leg. The legs became livid, and no pulsation could be detected in the femoral and popliteal vessels. The patient died on the 17th. It was supposed that there was thrombosis of the iliac veins, with gangrene of the legs, which is one of the rare sequences of typhoid fever. At the autopsy it was found that the lower portion of the abdominal aorta and also the two iliac arteries were plugged with thrombi. There was general peritonitis. The right kidney presented a red-brown infarction. There were no ulcerations in the bowel; no endocarditis. The lungs were normal; there was an infarction in the spleen. During life the blood was examined for microbes, but none was found. After death microbes were found in the spleen.

Hemorrhagic infarction of the liver, under ordinary circumstances, is impossible. A. B., a hard drinker was admitted to the hospital September 27th. His illness began in the previous June with vomiting and swelling of the abdomen. The dropsy steadily increased. He died two days after admission. At the autopsy a large amount of fluid was found in the peritoneal cavity. There was nothing special found in the heart or lungs. The

liver was remarkably cirrhotic; through the right half of the right lobe there were scattered numerous reddish-brown areas. The walls of the portal vein were thickened, and a large brown thrombus occupied the upper portion of its trunk; the branches passing to the right lobe were filled with clots. The hepatic artery and vein were normal. In this case the hemorrhagic infarctions were in all probability due to the cirrhosis of the liver, which had caused more or less obstruction of the branches of the hepatic artery. The only other case of infarction of the liver which the speaker had been able to find was one reported by Recklinghausen.

In the intestine hemorrhagic infarctions are met with in two forms, one involving the mucosa, the other affecting the entire gut. The former not infrequently ends in ulcerative necrosis. The latter form of hemorrhagic infarction is not common in man. In the horse it is frequently seen resulting from thrombi formed from verminous aneurisms of the mesenteric and its branches. This is a common cause of the severe and fatal colic so frequently seen in these animals. In conclusion, the speaker referred to the fact that in the lung it is not uncommon to have a vessel blocked without the production of an infarction. An occasional cause of thrombotic infarction is local disease of the pulmonary artery. It sometimes results from the endarteritis induced by beginning tubercular processes.

DR. R. H. FITZ, of Boston, reported a case which, in his experience, is quite unique. It was that of an elderly man with globular thrombi in the left ventricle. Emboli were transferred to the splenic artery, but at first were not sufficient to occlude the vessel completely. The spleen became enlarged, and thrombi formed in the splenic veins, and from this point the thrombus extended into the superior mesenteric vein. As a consequence hemorrhagic infarction occurred in the intestine.

(To be continued.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Fourth Annual Meeting, held at Baltimore, May 31 and June 1, 1887.

EVENING SESSION.

DR. FRANK DONALDSON, JR., of Baltimore, read a paper on

THE CAUSES OF CARDIAC FAILURE IN HIGH ALTITUDES.

The important fact that there is often great dyspnœa and sudden cardiac failure in going from low to high altitudes has not been sufficiently emphasized. Many patients are sent for general or special reasons to high altitudes, and are thereby done great injury, especially if they suffer from any form of functional or organic heart disease. From some experiments with the pneumatic cabinet, he had come to the conclusion that this treatment should not be employed in cases in which there is any valvular disease of the heart or fatty degeneration of its walls. Before being subjected to treatment in the cabinet, an examination of the heart should always be made. It has been asserted that the cause of the cardiac failure in ascending to high altitudes is want of oxygen. The speaker had performed certain experiments with reference to this point. At altitudes within ten thousand feet there is still sufficient oxygen to supply the hæmoglobin. In ascending to high altitudes the pressure of the air within and without the lungs is the same, but on the heart the action is different. The pressure is removed from the outer surface of the heart while the internal blood pressure remains the same. There, consequently, must be dilatation of the heart walls. This, in the author's opinion, was the cause of the heart failure under these circumstances.

DR. F. C. SHATTUCK, of Boston, then reported

SOME HOSPITAL CASES OF PHTHISIS; MARKED IMPROVEMENT UNDER GENERAL TREATMENT, WITH SPECIAL REFERENCE TO ALIMENTATION.

The cases had been treated in the Good Samaritan Hospital, of Boston, which is devoted to the care of chronic disease. Many of the patients had been exposed to unfavorable hygienic surroundings. The treatment employed was devoted largely to improvement of the general condition. Search had been made for a specific treatment, and if the disease is of a parasitic nature, it is natural to suppose that such a treatment would be of avail. At present no such method of treatment is known. There are few individuals to whose lungs, at one time or another, the bacillus does not gain access. The fact that certain individuals are affected while others escape, forces us to believe that there is a predisposition to the disease. The treatment employed by the author had consisted in relieving symptoms, improving the digestion, and in the administration of as much food as the patient could take in the natural way. Artificial feeding had not been resorted to, but the patient was fed six or seven times a day. From two to ten raw eggs with milk were given daily to each patient. Alcoholic stimulants were not administered as a routine treatment, but were used only temporarily for special purposes. He had for several years been systematically cutting down the quantity of alcohol used in chronic cases, and had seen no reason to regret it. His experience had been that alcohol was not used with sufficient discrimination in chronic cases of disease. Beef, milk, eggs, and other nourishing articles are more expensive than alcohol, but if they can be consumed in sufficient quantity, they are more useful. In 1883, the amount expended per patient for alcoholic liquors had been $2.70, while in 1886 it had been only 34 cents. The patients received no injury even if they were not benefited by this reduction. Eight cases of well-marked phthisis were reported in which a decided gain in weight and general improvement resulted from the employment of the plan of treatment above described. About sixty cases had been under treatment.

DR. BRUEN said that diet, climate, and suitable hygiene are the most important of the therapeutic measures under the control of the profession. It is possible by climatic and dietetic treatment so to change the nature of the tissues that they shall not be suitable culture media for the growth of the bacillus of tuberculosis. He referred more particularly to the use of the Bergeon method by the injection of sulphuretted hydrogen. To antagonize the specific cause of the disease, this method has been a failure, so far as his experience goes. Since February last he had had under treatment sixty-one cases by this method. Systematic examinations of the sputa have been made by Dr. E.

O. Shakespeare. There has been no apparent reduction in the number or change in the character of the bacillus. This method should be classed among the methods at our disposal for the treatment of this disease. The good effects in his hands had been reduction of temperature, reduction of expectoration, very often a complete suppression of bronchial catarrh, and relief of cough. This leads to improved digestion and enables the dietetic treatment to be carried out with great thoroughness. Forty-four of these cases showed improvement to a certain extent, the average gain in flesh being about five pounds. In one-half of the cases the temperature has been brought to the normal, while in the remainder, although the temperature has not been brought to normal, it has been reduced two or three degrees. In fifteen cases the results have been negative, but in no case did any harm follow the use of this plan of treatment. The improvement has been most marked where there was considerable catarrhal element. Those cases in which there has been more or less thickening of the lung, with the general symptoms well marked, wasting, loss of flesh and weight, without much rise of temperature, were not specially benefited by the injection of gas. He had the opportunity of making a post-mortem in one case which had been subjected to this treatment. Although the cavities in the lungs were unusually clean, he did not observe any evidences of cicatrization. With reference to the strength of the solution, he had not found strong solutions at all satisfactory. The best results have been obtained from a solution of five grains of sulphide of sodium with five grains of chloride of sodium in one and a half pints of water. He had never found it desirable to administer more than a gallon and a half of gas at one time, and insisted that the injection be made slowly and that one-half to three-quarters of an hour should be occupied in its administration. He had not derived as much satisfaction in the treatment of the various forms of phthisis referred to, from any method as from the injection of sulphuretted hydrogen. He had always tested the breath for the presence of sulphuretted hydrogen. He had negative results in at least eight out of every ten cases.

DR. S. S. COHEN, of Philadelphia, remarked that the experience of Dr. J. Solis Cohen and himself differed in some respects from that of Dr. Bruen. They have obtained the most decided benefit from strongly impregnated waters. The best results were obtained in those cases in which the patient had a decided taste of sulphuretted hydrogen which continued for two or three hours after injection. The best effect has been obtained in those cases in which suppuration is about beginning. Bergeon states that the treatment is directed especially to the suppurative process. In employing this measure, great attention must be paid to detail. In about fifty per cent. of the cases, the condition has been greatly ameliorated; in twenty-five per cent. there was slighter amelioration; while in the remaining twenty-five per cent. there was more or less benefit to certain symptoms. He had not seen a case in which no results were obtained.

DR. JAMES T. WHITTAKER, of Cincinnati, had for a month used sulphuretted hydrogen by inhalation, having previously employed it for a month by injection. He began the use of inhalation carefully, and finding it well borne, had pursued the method more boldly. He puts the patients in the cabinet and allows them to have all the gas they will take. It has produced no unpleasant results in any case. The effects obtained have been about the same as those resulting from injection. In about one-third of the cases there were no results. He had searched the literature for records of bad results following the use of sulphuretted hydrogen, and had found only two in which a fatal result followed. It has been asserted that the good effect is due to the carbonic acid, but he was entirely incredulous as to the effect of this agent.

DR. CURTIN had followed the recommendation of Dr. H. C. Wood, that the sulphuretted hydrogen be taken by the stomach, using a saturated solution through which carbonic acid has been passed. He had tried this in four or five cases, and had had the same effects as from injection.

DR. MUSSER had used the gaseous injections to a certain extent, but his results have not been as marked as some which have been reported. His best results have been in two cases. One was a case of incipient phthisis in which the patient gained thirteen and a half pounds in four weeks. The second case had gained eight pounds in four weeks and had much improved in general condition. He attributed his want of good results in part to the want of enthusiasm on the part of those whose duty it was to carry out the details of the treatment.

DR. SHATTUCK had used the sulphuretted hydrogen gas, and in several patients it produced collapse in varying degrees, with weak pulse, nausea, vomiting, and headache. In several other cases, although the treatment was well tolerated, it produced no good effect. In one case of asthma with chronic bronchitis and emphysema, thirty four injections of the gas were given. While the treatment did not disturb the patient, it did no good. With the use of the gas was combined the administration of iodide of potassium and other remedies, and the patient recovered in about the same time as on a previous occasion when the latter remedies were given and no gas used.

DR. B. F. WESTBROOK, of Brooklyn, then read a paper on

THE LOCAL TREATMENT OF DISEASES OF THE RESPIRATORY ORGANS.

The methods of treatment which had been employed were the direct introduction of coarse sprays, the use of the Evans' inhaler, and the use of the pneumatic cabinet.

In cases of chronic bronchitis where the cough is severe, a spray of a solution of carbolic acid, fluid extract of hyoscyamus, or other sedative remedies, is employed. Where there is copious secretion astringents are called for, and of these tannic acid, iron salts, and fluid extract of pinus canadensis have been employed. The pneumatic cabinet has been used with marked success in the treatment of chronic bronchitis. The patient is confined in the cabinet under a diminished pressure, the sitting lasting from ten to fifteen minutes. This may be combined with the inhalation of the spray. If there is much emphysema the cabinet is not indicated. In using the cabinet in the treatment of chronic interstitial pneumonia and bronchiectasis, there is danger if the pressure is great of producing emphysema of those

portions of the lung still accessible to the air. The pressure should not exceed one-half an inch of mercury.

In the treatment of phthisis the best results are obtained in the early stages of the disease, or where the disease, although further advanced, is limited to a small portion of the lung. The use of sprays is beneficial only in so far as we desire to treat the coexistent bronchitis or cavities connected with bronchi of the second or third order. In incipient phthisis with very little bronchial catarrh, local treatment is probably of little service. These cases are best treated with compressed air. In a large proportion of the cases we may hope to render the disease latent. The expansion of the lung favors the expectoration of the contents of the smaller tubes and modifies the intrathoracic circulation. The sittings should be frequent—every day or every second day. Ten minutes is usually sufficiently long for the patient to remain in the cabinet. The pressure should gradually be increased up to one-half or three-fourths of an inch. If used cautiously, this is the best method for the local treatment of incipient phthisis. With the Evans' inhaler his results had also been satisfactory.

In the treatment of advanced cases of phthisis, the first effort must be to cure or diminish the bronchitis. The pneumatic treatment then comes into play. This gives better expansion, improves the circulation, and alters the action of the trophic nerves. In all cases internal medication has been combined with the local treatment. The more acute the disease the higher the fever, and the more sudden the onset the less can we expect to accomplish by treatment. In no case diagnosticated as acute phthisis did treatment have the slightest effect.

THE AMERICAN LARYNGOLOGICAL ASSOCIATION.

Ninth Annual Congress,
held in New York, May 26, 27, and 28, 1887.

(Specially reported for THE MEDICAL NEWS.)

DR. J. SOLIS COHEN opened the discussion on

THE TREATMENT OF LARYNGITIS IN PROFESSIONALS WHO ARE UNABLE TO REST.

He did not know that he was any better able to treat these cases without rest than are others. Sometimes a professional will consult him with hoarseness the result of acute laryngitis, and want to use his voice in a few hours. The best method to accomplish this that he had found has been the administration of a sharp emetic, and then let the patient rest until the time of the performance, sucking pieces of ice and keeping a cold compress to the neck. In chronic laryngitis he had found nothing of the same service as the use of a weak solution of sulphate of zinc, two grains to the ounce, used in a spray apparatus. In the intervals of the play the patient may inhale a little compound tincture of benzoin, if he finds that he is hoarse. Another remedy of considerable service is the use of a respiratory with turpentine, terebene, or eucalyptol, or something of that kind. He sometimes directs the patient to sprinkle a little turpentine on the floor of the bedroom. He was, however, not aware of any special method which is adapted to this class of individuals.

DR. T. A. DEBLOIS had had some experience with these cases, and had endeavored to keep up the systematic use of sulphate of zinc, but had found that the hoarseness continued unless the voice is rested. He had occasionally to treat vocalists who could spare a few hours, and had found excellent results from the use of nitrate of silver, and the most disastrous results from the use of cocaine. There seems to be a certain amount of relaxation following the use of muriate of cocaine. He thought that it may be said that, in these cases, unless there is rest there is no cure.

DR. BEVERLY ROBINSON, of New York, stated that his experience with the class of cases under discussion would lead him to believe that, so far as the acute cases are concerned, there are milder measures than an emetic. He had found that under these circumstances the use of tablet triturates of chloride of ammonium repeated as often as once every fifteen minutes, is one of the most efficient methods of overcoming the difficulty. For local application he did not think that there is anything better than the carbolized spray. In the chronic form of laryngitis in vocalists he believes that we cannot obtain much information from the appearance of the mucous membrane. In these cases he has often found the membranes red, and this may continue after the trouble with the voice has disappeared. He believes that here the trouble is chiefly in the nervo-muscular apparatus. He has found the internal use of a good wine of cocoa, with the application of a faradic current to the neck, very useful. The faradism should be repeated once or twice a day.

DR. BOSWORTH remarked that he believed that there is no such disease as laryngitis, as that term is used to mean an inflammatory process. The seat of the disease is not in the larynx, but in the nasal passages. If cocaine is applied to the nasal mucous membrane, causing contraction of the bloodvessels, and followed by the use of chromic acid, thus eliminating the cold in the head, it will usually be found that the laryngitis has disappeared. Relaxation has been spoken of as following the application of cocaine. Although he has used the drug in many cases, he has seen this result in only two, and they were cases of hay-fever. His method of using cocaine is to suspend it in fluid cosmoline, and direct the patient to spray the nose and inhale it.

DR. SAJOUS had treated many cases of this trouble. The action of cocaine in laryngitis is pernicious. He has used it in a four and in a ten per cent. solution, and every time that he has done so, has had occasion to regret it. In cold in the head cocaine is useful, but it should not be used within four hours of the time when it is desired to use the voice. In the majority of the cases of chronic laryngitis the condition is due largely to fatigue. He has found that the use of cocaine and nux vomica internally, and the external use of a weak faradic current, are the best measures to employ.

DR. GLASGOW, in this class of cases, had devoted himself entirely to the larynx, and had not treated the nose. He employed applications of carbolized iodine to the larynx. This is a soothing application, and relieves congestion. It also acts as a stimulant, and enables the person to keep at his work, but it does not cure the condition.

DR. MORRIS J. ASCH, of New York, thought that the best way to treat the acute cases is that which we pursue

in other acute cases. The treatment suggested by Dr. Cohen, with the omission of the emetic, is useful. The employment of muriate of ammonium is useful. He gives it in solution in compound liquorice mixture which contains a little tartar emetic. The chronic cases are more difficult to treat, because the patients cannot quit work. He had found nothing equal the application of astringents. He used the spray in some cases, but more good is done by the use of the brush. The solution which he most frequently uses is one of the perchloride of iron, thirty to sixty grains to the ounce. Where a person has to use the voice in a few hours, a single application will put them in a good condition temporarily. Another point to be considered is that these individuals usually live irregular lives, drinking wine and eating heartily. There is, therefore, nearly always some hepatic trouble which requires attention. He did not believe that it is possible to put the larynx of a singer in perfect order as long as he has to work.

DR. HOOPER said that in these professionals there is sometimes an alteration in the quality of the voice, the result of over-exertion. Here there seems to be want of tension in one vocal cord. To relieve this he used electricity outside, with the internal use of aromatic spirits of ammonia, thirty to forty drops in half a glass of soda water.

DR. MACKENZIE thought that Dr. Bosworth was to a great extent right with reference to the dependence of laryngeal disease on nasal trouble. He thought that the vast majority of cases of laryngitis are associated with disease of the nasal passages, and upon the recognition of this fact depends the successful treatment of many cases of chronic laryngitis. While he admitted the existence of chronic primary laryngitis, he considered that the majority of cases are due to disease higher in the respiratory passages. He cautioned against the indiscriminate use of cocaine in diseases of the nose and throat. He would never use it just before a person was going to use the throat. The sensation which it produces in the larynx is only next to that of hanging. In the nose the effect is very pleasant, provided some of the solution does not trickle into the nose or larynx.

DR. WESTBROOK thought that while it is true that many of these singers and elocutionists suffer from strain and overwork, it is probable that in the majority of cases the seat of the whole trouble is in some derangement of the digestive apparatus, which predisposes to these affections. He thought, therefore, that an emetic or active purgative is indicated in many of these cases. After the emetic he gives small does of the mineral acids frequently repeated, say one or two drops of dilute muriatic or nitric acid repeated every hour.

DR. CHARLES H. KNIGHT, of New York, then read a paper on

THE GALVANO CAUTERY IN THE TREATMENT OF HYPERTROPHIED TONSILS.

He first referred to the objections to the cutting operation. The principal of these is the danger of hemorrhage. At times the tonsil is so deeply situated that it is not possible to get the tonsillotome over it. In other cases the patients positively object to the cutting operation. There are two methods of using the galvano-cautery; one is by puncture, and the other by the snare. The former is much the slower. Not more than three punctures should be made at each sitting. The number of sittings required varies from five to ten. The latter method with the snare is much the quicker. The current should be used intermittingly, and contraction should only be made during the passage of the current. He did not recommend this as a universal operation. In the majority of cases the cutting operation is easier and better. It should be used where there is danger of hemorrhage, and he was almost disposed to say that the galvano-cautery should be used in all cases in adults.

DR. SAJOUS had tried galvano-puncture, but it is quite tedious. He had modified the method by making a puncture, and then introducing chromic acid. He thought that the use of the snare is an excellent method.

DR. A. W. MACCOY, of Philadelphia, in the treatment of these cases, made a distinction in the methods employed. In the glandular enlargements he uses puncture, while in the interstitial hypertrophies he does not, for in these cases one is apt to get cicatrices which give considerable trouble. He was not satisfied that the puncture is any better than chromic acid fused on a probe and passed into a crypt.

DR. ROBINSON had long held that we know of no simple operation in surgery. There is nothing that is so unpleasant to him as to have to remove large tonsils from a small child. Although, as a rule, the hemorrhage is readily controlled, yet he always undertakes the operation with a good deal of reluctance. He was disposed to think that galvano-cautery is one of the best methods. We can thus remove many tonsils that give us a good deal of apprehension.

DR. RICE said that very little can be accomplished with the cautery in the large white hypertrophies in children. The cutting operation is what must be done in these cases. In adults, however, galvano-cautery is the most useful measure.

DR. INGALLS had used the cautery, but a certain amount of soreness had always followed its use. In children, in order to avoid the pain and nervous shock attending the cutting operation, he is in the habit of etherizing the patient and removing the tonsil with the snare.

DR. ALLEN said that while it may be proper to do the cutting operation in certain cases of hypertrophied tonsils which have been selected with great care, he thought that we err in making broad statements in regard to this operation. He believed that the number of cases in which serious hemorrhage occurs, is much larger than is supposed. All the disastrous cases are not reported. He was not willing to perform the operation until he had studied the case very carefully. Other measures should be first used, and the knife resorted to at the last.

DR. DELAVAN thought that where the operation of tonsillotomy is done with proper care, with suitable styptics at hand, there is not much danger from hemorrhage. At first there is a gush of blood, but in a few seconds this stops. He had found it very difficult to get authentic reports of cases in which serious hemorrhage followed this operation.

DR. ASCH said, with reference to this question of hemorrhage, that some time ago one of his assistants removed a small section of the tonsil. The next day there was serious bleeding, and it was found necessary

to keep up pressure on the tonsil for six hours before it was controlled. In another case that he knew of, it was found necessary to tie the common carotid artery.

DR. COHEN thought that a great deal of the trouble in tonsillotomy is due to the adhesion of the anterior fold of the palate to the tonsil. It has been his custom first to free the tonsil from the palate. In many cases the tonsil will then go down without any treatment whatever. He thought that the hemorrhage comes from the cutting of this fold, for as the vessels run in a vertical direction they are cut obliquely. He had never been able to use the cautery with the success of the reader of the paper. In his cases it has required from twenty to fifty sittings. One plan that he had followed is, after having penetrated the tonsil transversely, to try to cut his way out. Then to cut in the other way, and thus remove a portion of the tonsil. In this way, by making the application every day, or every other day, the tonsil is removed in the course of a month or six weeks.

DR. BEVERLY ROBINSON then presented a

NOTE ON A FREQUENT CAUSE OF NASAL HEMORRHAGE.

In his experience the ulcerations in atrophic rhinitis had been a most frequent cause of hemorrhage. He had found himself unable to detach the crusts from these ulcerations, either by the use of douches or sprays, so well as by the employment of ointments. In the course of two or three days the patient is able to blow out the crusts. He had found no ointment act so well in imbibing the crusts and producing changes in the ulcerations, as the ammoniated mercury ointment of the Pharmacopœia, of one-half or full strength, made up with vaseline. In applying plugs in the case of hemorrhage, he had found nothing so useful, especially in children, as Steele's flexible probe, recommended by Dr. J. Solis Cohen; he had found the so-called sheet sponge very useful as a plug. This may be cut in long strips, and pushed through the nose until the bleeding is controlled.

To be concluded.

CORRESPONDENCE.

A VISIT TO NAPLES.

The Public Hospital—Vesico-vaginal fistula—Symphyseotomy—Gynecological practice.

A correspondent writes us from Italy:

Circumstances have not been favorable for the investigation of medical matters here. I was very kindly received at Naples by Professor Ottavio Morisani, thanks to a letter of introduction from Philadelphia. I accompanied him once to the only public hospital of the city in which clinical instruction is given. It is an immense building, containing all departments, but I can write no particulars, as printed statistics were not furnished me as promised. The gynecological wards were contiguous on one side to the obstetrical, and on the other to the pathological department. The evils of this state of affairs are fully recognized; strenuous efforts are being made to effect a change, and hopes were expressed of early success.

I saw several cases of severe vesico-vaginal fistula which were being operated upon by Prof. Morisani, and judging from the appearance of the population of Naples, as seen in the streets, it is a lesion likely to be met with here very frequently. There were also some fine specimens of fibroids removed by enucleation. When laparotomy is resorted to for these, hysterectomy is performed, the pedicle being secured by clamp, and I could not hear of the *étage* suture and closure of the abdomen.

Prof. Morisani was kind enough to show me the knife which he uses in performing symphyseotomy, and to describe the operation. The knife is short, strong, sharply sickle-curved, with probe-point and very blunt back. An incision about two inches long is made over the symphysis, the joint recognized, and the knife then being passed behind the bone, it is divided from within outward. The pains being efficient, nothing more is done; if they are not so the forceps are applied. Prof. Morisani has performed this operation ten times with two deaths. In such an operation the facts of each case are to be considered, and without them a mere enumeration of the operations with the results remains of no value whatever. Nor can I give you the pelvic diameters under which he would resort to this procedure, as his papers upon the subject, although promised, have not came to hand.

Prof. Morisani was about leaving town to go to an operation in Calabria, and he turned me over to his assistants, who were conducting the out-door gynecological clinic. There was a great similarity in applications to the cases. The position of the patient was on the back, and a bivalve speculum, with lateral blades, was used. I could not learn that Emmett's operation for laceration of the cervix was ever performed in Naples. I saw some cases of so pronounced "ectropion," as to lead me to inquire about it. I had difficulty, and I think other than that appertaining to language, in making myself understood about the operation. R.

NEWS ITEMS.

CONNECTICUT MEDICAL SOCIETY.—The sixty-ninth annual convention of the Connecticut Medical Society was held at the County Court House, Hartford, on Wednesday, and Thursday, May 25th and 26th. The following officers were elected for the ensuing year:

President.—Dr. Francis Bacon, of New Haven.

Vice President.—Dr. George L. Porter, of Bridgeport.

Secretary.—Dr. S. B. St. John, of Hartford.

Treasurer.—Dr. E. P. Swasey, of New Britain.

LEPROSY AT ST. MARTINSVILLE, LA.—The *New Orleans Medical and Surgical Journal* for June, 1887, gives the following account of the results of an investigation of cases rumored to be leprosy, ordered by the State Board of Health of Louisiana:

After examining a number of persons who were more or less healthy, the physicians visited in a body the residences of eight sick persons about whom rumor murmured loudest. One of these was a gentleman suffering with a number of rodent ulcers in the face, associated with a large epithelioma on the neck, and a second case was an aggravated form of acne indurata.

Upon the remaining six cases opinions differed somewhat, but it was the unanimous verdict that three should

be called *undoubted leprosy*, and a majority of the physicians considered the remaining three cases as *doubtful*.

Two other cases of leprosy (of the tubercular form), a son and a brother of two of these doubtful cases, are now under care at the Charity Hospital; thus making eight persons from St. Martinsville about whom suspicion is cast.

MUST AN OFFICER OBEY THE ORDERS OF THE SECRETARY OF WAR.—The case of Surgeon John S. Billings, which was a bone of contention between Secretary Endicott and Assistant Secretary Maynard while the latter was Second Controller, has been carried into the Court of Claims. This matter involves the power of the Secretary of War to issue an order requiring foreign travel except on purely military business. Dr. Billings was ordered to England in 1881 to attend the International Medical Convention in London. Before going to London Dr. Billings visited many of the important European cities in quest of information for the medical corps of the army. On his return home he claimed mileage for the entire distance travelled. The accounting officers disallowed the claim upon the ground that the Secretary of War had no authority to issue the order under which Dr. Billings travelled. The Secretary differed from the accounting officers, and asked that the case be reopened. The then Second Controller refused, and concluded his letter with a paragraph which gave some offence to Secretary Endicott, suggesting that if the Secretary was not sufficiently posted on the laws governing such cases it would be well for him to refer the matter to the courts for decision. The Secretary has concluded to follow this advice and has laid the papers in the case before the Court of Claims. There are several similar cases now on hand, and others are continually arising. The Secretary wishes the court to decide how far his authority over the movements of army officers extends.

MONEY VALUE OF LIFE.—The calculation of the money value of human life and the consideration of the money saved to a nation by sanitary science are a favorite line of study with Edwin Chadwick, the veteran English sanitarian. He is President of the Association of Public Sanitary Inspectors and, as such, recently read a paper on the financial value of sanitary science. He calculates upon evidence, which it is not necessary to reproduce, that the money charges upon the community arising from excessive sickness and mortality which is prevented by sound sanitation, amount to about 62,000,000 pounds.

He likens money expended for sanitary work to money voted by parliament for the maintenance of the army and navy and for the repair of defences, and says that we have an annual invasion of an enemy in the form of preventable disease, which every year fights and wins a battle against the community, and slays upward of 100,000 people beyond the present reduced death-rate, all of whom we know and have proved might have been saved by more efficient sanitation, and at a saving of double the annual cost of naval and military defences.

All this excessive loss of life and money is due to wastefulness and ignorance in legislation and administration. The only effective preventive will be the superior economy of tested and corrected sanitary science. Executive functions are generally confided to persons inadequately furnished with the qualifications required, and incapable to fill the offices. Adequate salaries with a system of promotion and retirements, as may be found in the army, will keep the hospitals empty. All these officers should be centralized under one Minister of Health.—*Sanitary News*, June 4, 1887.

A RUSSIAN MEDICAL COMMISSION has recently been sent from St. Petersburg to investigate a disease called "Pendel's tumor," which has for several years attacked Russian soldiers near the Caspian Sea. It is believed to be caused by microbes.

DR. MORITZ SCHUPPERT, a well known and highly honored physician of New Orleans, died in that city on May 2, 1887.

PROFESSOR HYRTL.—The illustrious Vienna anatomist, Hyrtl, who has for some time been suffering from cataract, has had the right eye operated on by Prof. Fuchs, apparently with great success. The left eye is also affected, and will shortly have to be operated on. Prof. Hyrtl is seventy-five years of age.

HONORS TO PROFESSOR ESMARCH.—Emperor William has conferred upon Prof. Esmarch, the great surgeon, the rank of nobility. Prof. Esmarch, who married Princess Henrietta, of Schleswig-Holstein, has been ignored by the royal family. It is surmised that he owes his ennoblement to his skill as a surgeon.

GERMAN ASSOCIATION OF PUBLIC HEALTH.—The German Association of Public Health will convene in Vienna September 26th to October 28th, to meet with the International Hygienic and Demographic Congress. The latter will meet in the University building. All governments are requested to send delegates.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JUNE 11, 1887.

VAN REYPEN, W. K., *Surgeon*.—Ordered, June 8, for examination preliminary to promotion as Medical Inspector.

ROBINSON, SOLOMON, *Medical Inspector*.—Ordered, June 20, before a Retiring Board convened at Mare Island, Cal.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERSSERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM JUNE 7 TO JUNE 13, 1887.

BAXTER, COL. J. H., *Chief Military Purveyor*.—To proceed to New York City for the purpose of inspecting the Medical Purveying Depot at that place.—*S. O. 133, A. G. O.*, June 10, 1887.

Par. 15, S. O. 52, A. G. O., March 5, 1887, is so amended by Par. 9, S. O. 133, A. G. O., June 10, 1887, as to direct that Major CHARLES H. ALDEN, *Surgeon*, be relieved from duty in Department of Dakota, about June 20, 1887, and he is granted leave of absence f.om the date when so relieved to include August 27, 1887.

FRYER, MAJOR B. E., *Surgeon*.—Granted sick leave for one month.—*S. O. 28*, current series, Div. Pacific, amended by *S. O. 29*, Div. Pacific, June 2, 1887.

FRYER, MAJOR B. E., *Surgeon*.—Found incapacitated for active service by an Army Retiring Board, and granted leave of absence until further orders on account of disability.—*S. O. 133, A. G. O.*, June 10, 1887.

TREMAINE, MAJOR W. S., *Surgeon*.—Sick leave still further extended two months on account of sickness.—*S. O. 129, A. G. O.*, June 6, 1887.

ORIGINAL ARTICLES.

LUPUS AND THE BACILLUS TUBERCULOSIS.

BY JAMES E. REEVES, M.D.,
OF WHEELING, W. VA.

THE question concerning the identity of lupus and tuberculosis, since the discovery of Koch's tubercle bacillus, has received much attention, and, notwithstanding the studies of the pathological anatomy of lupus by Virchow, Wedel, Auspitz, Kaposi, and Neumann, in Germany, and by Malassez, Grancher, J. Renaut, Chandelux, Vidal, and Leloir, in France, it is still a matter of discussion and difference of opinion.

The observations of Koch, Doutrelepont, Neisser, Lassar, Leumiski, Lewin, and other distinguished pathologists, which led them to regard lupus as nothing more nor less than a local tuberculosis of the skin, have been ably discussed and opposed by several careful authorities: notably by Schwimmer, of Budapesth, and Kaposi, of Vienna, both of whom base their declarations, opposing the view establishing the identity of lupus and tuberculosis, mainly on clinical grounds.

At the recent Berlin Congress, Schwimmer said that "the affection known as tuberculosis of the skin is a very rare one, while lupus occurs frequently." He found among 2,400 patients, 90 cases of lupus, but only 5 cases of pronounced tuberculosis of the skin. The clinical diagnosis in the latter affection is based on the bacterial proofs. Among the 90 lupus patients, he found 68 per cent. constitutionally untainted; in 15 per cent. only he found a hereditary element. These facts, he held, speak against any etiological relation between the two diseases.

In the latest edition, 1886, of *Les Bacteries*, by Cornil and Babes, in which is presented a summary of all the knowledge on the subject, these authors say:

"We have searched with Lewin for the bacillus of tuberculosis in a dozen cases of lupus, in material taken during life, and although we have examined several sections of each fragment taken, we have found but a single time a bacillus. Malassez, on the other hand, has looked in vain in several cases of lupus for the bacillus of tuberculosis. Pfeiffer, Doutrelepont, and Demme have been more fortunate, and have found it constantly. . . . .

"When Friedländer, Köster, and others had described the tubercular follicle with its giant-cells, and when it was well demonstrated that lupus gave the type, the most perfect, the identity of tuberculosis was proclaimed —lupus being considered a local tuberculosis of the skin. Such has been for some time the fixed opinion of Besnier.

"Leloir, had in 1882[1] commenced the inoculation of lupus. In these experiments made with one of us, Leloir has obtained in half of the experiments[1] positive results, that is to say, a generalized tuberculosis in which the tubercles contained bacilli and gave rise to tuberculosis in successive inoculations. We have nevertheless remarked that the result was more slowly produced than when one employed the pulmonary tubercle as inoculating material.

"The most recent researches of Koch[2] demonstrate quite clearly the identity of tuberculosis and lupus. Koch has found four times the bacillus of tuberculosis in small numbers. In one case, for example, he was obliged to examine twenty-seven sections, and at another time forty-three sections, before finding a single one. But upon a series of successive sections, he found at one time one or two in each section. He has never seen more than a single bacillus in a giant-cell. Further, Koch has obtained in a pure state, cultures of the bacillus upon blood serum following the inoculation with material from hypertrophic lupus. One can then say, to-day, that tubercular lupus and lupus scléreux belong to tuberculosis."

By the light of the foregoing references, the following case, from the practice of Dr. J. F. Baldwin, of Columbus, Ohio, to whom I am greatly indebted for the report, may be of interest to those who have been engaged in the study and discussion of the question—Are lupus and tuberculosis identical? At least, the record is given for what it is worth.

January 9, 1887. Miss M., aged twenty-two. One sister died of consumption. Rest of family healthy. Has been failing rapidly for six months; cough, emaciation, anorexia, night sweats, etc. Examination of lungs by Dr. Baldwin revealed the usual evidences of advanced phthisis. Three years ago, she fell from a swing and caught her left index finger over a wire in such a way as (she says) to lacerate the flexor tendons. The skin was not broken. The finger became enlarged, but was not so painful as to keep her from working as a domestic. A few weeks ago, it became more tender and enlarged, and when Dr. Baldwin saw it, it presented a typical picture of specific dactylitis. On examination, he found it contained pus and was about ready to burst. He lanced it, and gave exit to quite an amount of sanious pus, though not as much as he had expected. The usual after-treatment directed. He saw her again on the 13th of January. A peculiar looking mass was presenting at the opening. The finger was nearly as large as before—about as it had been previously to the recent inflammation, she said—and hard: there were also two hard masses to be seen and felt along the flexor sheath in the palm of the hand. The protruding mass led him to fear sarcoma, from its appearance and feel, and he removed at once a considerable portion of it. To remove it all, would have required removal of the finger and a part of

[1] Société de Biologie Dec. 1882.

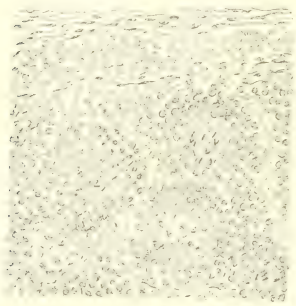
[2] Mittheilungen aus dem Kaiserlichen Gesundheitsamte von Dr. Struck, 2 vol., Berlin, 1884.

the hand, an operation which would not have been justifiable in her condition.

A portion of the removed mass was sent to me for microscopic examination. The wound did nicely, but the patient died of phthisis within the next three weeks.

The specimen sent me for microscopical study was passed through weak and absolute alcohols, cleared in spirits of turpentine, and then cast in paraffin. Twenty-eight sections were made, and stained so as to show bacilli if present, every one of which demonstrated typical giant-cells of tuberculosis, and countless numbers of tubercle-bacilli. Indeed, in all of my microscopical studies I have not found, even in lung-tissue, greater colonies of bacilli, neither sharper nor better definition, than in this specimen of lupus tissue. In proof that there was no mistake in the diagnosis—lupus—I have the honor to mention that sections were submitted to Prof. Wm. H. Welch, of Johns Hopkins University, who unhesitatingly pronounced the specimen lupus.

The accompanying illustration shows the microscopic appearance of the section.



Prof. Welch's report is as follows:

"The microscopical appearances in the sections sent for examination are those of tuberculosis. The sections, which have been well prepared, are devoid of epithelium. The tissue is composed of typical miliary tubercles, of diffuse tuberculous tissue, and of a small amount of ordinary fibrillated connective tissue moderaely rich in leucocytes. The miliary tubercles present a cental part composed chiefly of large endothelioid cells, and a peripheral part in which small round cells predominate. In a few tubercles giant-cells are present. Central areas of coagulation-necrosis are to be found in only a small number of tubercles, and, when present, are of small size. The tubercles lie in diffuse tuberculous tissue composed mainly of endothelioid cells and of leucocytes.

In the sections stained for tubercle-bacilli, these bacilli are present in very large number, both within the tuberculous nodules and in the diffuse tuberculous tissue. The bacilli lie, for the most part, scattered irregularly throughout the tissue, but here and there they are accumulated in clumps. The bacilli are both intracellular and extracellular; in the former case being found within the giant-cells and the endothelioid cells."

Since the foregoing was written Prof. George H. Rohé, of Baltimore, has kindly sent me a specimen of *lupus vulgaris*—an entire ear. The neoplasmic cellular structure was found on microscopical examination to be precisely the same as in the specimen sent me by Dr. Baldwin; but showing fewer tubercle bacilli, which, possibly, may be accounted for by too long soaking and hardening of the specimen in strong alcohol, and the use of a stain not freshly made.

The following is the clinical history of the case furnished by Dr. Rohé:

"Mr. N., white, American, aged sixty-two, and by occupation a shoemaker, first noticed a brownish spot on his forehead about fourteen years ago. This spot increased slowly in size until it became as large as a twenty-five cent piece. It never ulcerated, and was never painful or itchy. About the same time he had a severe pulmonary affection which was attended by much cough, and later he had several slight hemorrhages, presumably from the lungs. About two years after the first appearance of the patch upon the forehead, a similar spot appeared upon the left cheek, which gradually extended until it reached downward below the jaw, forward to a line nearly perpendicular to the angle of the mouth, and upward and backward, invading the auricle, and extending for some distance (about two inches) into the hairy scalp. Under the left eye, and just within the malar prominence, a third spot appeared, which also eventually reached the size of a silver quarter.

"About the time the patch was first noticed on the left cheek the disease also invaded the right cheek, but did not become quite as extensive on this side of the face.

"The patient first consulted me in the spring of 1881. The disease presented the characteristic features of lupus vulgaris. The patient was shown at one of the medical societies in this city, and my diagnosis was concurred in by my friend Prof. I. E. Atkinson, who saw him on that occasion.

"No disease of the lungs could be detected when he first presented himself to me.

"The infiltrated patches on both cheeks, and the integument of the auricle became superficially ulcerated or eroded at times, but a simple dressing would rapidly promote cicatrization. There were never any deep ulcers.

"I scraped out the infiltrated patches on the cheeks with the curette on several occasions, and followed the scraping with nitric and chromic acids. The patch under the left eye was excised, and the edges united by fine silk sutures. This wound healed by first intention. The patient left the city about three years ago, and remained away for two years. Last year he returned and again presented himself. The lupus infiltration had generally returned, and the ear

remained in an ulcerating condition most of the time. Last summer he was prostrated by an attack of croupous pneumonia, since which time he has been more or less of an invalid. No active interference with the lupus was undertaken until January 16, 1887, when the ear, which annoyed him very much on account of the constant suppuration, was amputated with the thermo cautery. The wound healed kindly, and is now entirely cicatrized. For a time, last summer, electrolysis was tried on some parts of the infiltration, but with no very marked success. To-day, previous to writing these notes, I visited Mr. N., and on making a physical examination of his chest, found a cavity in the left apex, and disseminated mucous râles throughout the right lung. He is at present suffering from sciatica, for which complaint he is being treated by his family physician."

ELECTRICITY IN GYNECOLOGICAL PRACTICE.

BY ANDREW GRAYDON, M.D.,

CLINICAL ASSISTANT AT THE JEFFERSON MEDICAL COLLEGE HOSPITAL, AND CHIEF OF GYNECOLOGICAL CLINIC AT ST. MARY'S HOSPITAL, PHILADELPHIA.

CASE I.—*January 22, 1884.* R. S., colored, aged thirty-nine; married seventeen years, one child fifteen years ago. Menses regular, scanty, and painful. Bowels constipated. Uterus found mobile, sharply retroflexed, pressing upon the rectum, and obstructing it. The treatment consisted of the faradic current twice or thrice weekly, of five minutes' duration each.

July 23. Uterus is normal in position and curvature. All painful menstruation has disappeared. Bowels regular. Patient discharged cured. The record of this case is abridged. It belongs to a series started at that time which was interrupted. I make a note of it because the result was a marked one. The negative electrode was placed in the uterus, the positive in the bladder. The strength of the current was determined by the patient's endurance—not strong enough to be painful.

CASE II.—*June 9, 1886.* L. B., saleswoman; single, aged twenty-one. Three years ago she fell astride of a fence, at which time she was seized with an acute pain in the right ovarian region. This compelled her to remain some days in bed. Since that time she has had a constant pain, aggravated by standing, walking, or exercise of any kind, and worse at her menstrual periods. The pain is of a sharp, lancinating character, starting from the right ovarian region as a centre. Complains also of dragging, pelvic soreness, and backache, with general nervous irritability.

Examination shows the right ovary prolapsed and very painful to the touch; also some cellulitic deposits. The patient has been treated since her fall in the routine manner, iodine and glycerine tampons, hot water injections, counter-irritation, knee-chest position, etc., with no alleviation of symptoms.

An application of the galvanic current was now made in the following manner: the negative electrode was placed in the vagina, in contact with the sensitive ovary and the deposits; the positive was held in the right hand. The strength of the current was four milliampères. Length of treatment fifteen minutes.

17th. Treatment repeated.

21st. Treatment continued; five milliampères. Patient not so sore.

Same treatment repeated on June 24th, July 8th, 12th, 19th, and 21st.

August 4. Treatment ten minutes, ten to eighteen milliampères. Up to this date the improvement has been steady and unbroken. The ovary remains prolapsed, resisting any attempts at reposition, is entirely devoid of any sensitiveness, and the evidences of preëxisting cellulitis are diminished. With the local improvement the systemic disturbances also showed the good effect of the current. With the exception of a laxative at one time and a diuretic mixture at another, galvanism was the only treatment she received. She was discharged to-day, with the direction to report to us on the first evidence of any trouble.

March 1, 1887. Saw the patient to-day. She states that she has been free from all pain in the pelvis since she last saw us; that her menstrual periods are regular and painless, and that she has been able to attend to her work in the store.

CASE III.—*June 15, 1886.* L. L., aged twenty-four; married five years, sterile; suffers with severe dysmenorrhœa. She applied, August, 1884, to the hospital for relief; received no permanent benefit, and was transferred on this date to me for electrical treatment. The uterus is sharply anteflexed. She was treated with the faradic current, taking patient's feelings as the guide to the strength, each application averaging fifteen minutes, twice and thrice weekly, beginning four days after each menstrual epoch. The negative electrode was placed in the uterus, and the positive in the rectum.

July 10. The first menstrual period since beginning treatment has just passed with less pain.

August 17. This menstrual flow was increased in quantity. Slight pain. This increase in discharge was noticed in all our cases in which we used faradism.

September 18. Menstrual period similar to last one.

October 20. Menses from 10th to 17th. No pain. The curve of the canal was taken again to-day, and was markedly diminished.

November 20. Menses on from 12th to 14th. No pain whatever.

December 10. Patient discharged cured. Directed to report in a month.

February 2, 1887. Examination shows uterus in normal position and with normal curvature. Menses continued regular and painless.

CASE IV.—*October 2, 1886.* A. A., aged twenty-six, married three years, sterile. Puberty at fifteen; menstruation irregular for past two years. Bowels constipated. Uterus strongly retroflexed. Treatment same as Case I., twice and thrice weekly.

March 30, 1887. Condition greatly improved. Menses regular and painless, being before treatment very painful. The retroflexion, though not so sharp, remains.

Case V.—*June 12, 1886.* A. W., single, aged twenty-five. Complains of persistent backache, with dragging pelvic pains. Has also a great sensitiveness of the external genitalia and vaginal walls. A condition of chronic pelvic cellulitis was found upon examination, the uterus being bound down.

The galvanic current was given the patient twice a week, changing the position of the electrodes so that the current thoroughly penetrated all the cicatricial bands, and came in contact with the sensitive parts. She was treated from June 12th to July 24th, seven applications in all, with positive relief to all her symptoms, and was then transferred to another department.

Case VI.—*June 23, 1886.* M. A., colored, aged twenty-six. Married seven years. Sterile. Puberty at seventeen; menstruation normal up to marriage as to time and duration, but always very painful before and during the flow. Has also severe pain in the sacral and inguinal regions. Bowels regular. General health fair. Uterus sharply anteflexed.

The curvature admitted the sound on the finger with difficulty, a condition of stenosis existing also. Treatment of this case was by the faradic current after manner of Case III.

October 27. In the beginning we could scarcely introduce a flexible electrode, and that only after straightening the uterus with a tenaculum. The improvement kept step with the treatment. At this date the curve is greatly diminished.

The dysmenorrhœa has disappeared, and with it all backache and pelvic pain.

December 27. She complains of the reappearance of the pelvic soreness. Galvanic current was applied, ten milliampères, fifteen minutes.

March 30, 1887. Galvanic current continued to the present time. Pain disappeared. Uterus normal in curvature and position. Menses regular and painless.

Case VII.—*June 30, 1886.* L. F., aged forty. Married twenty-two years. One child twenty-one years ago. Never pregnant since. Puberty at fourteen, regular as to time and duration, but has severe pain with each period. Gives a history of acute pelvic cellulitis four years ago. Has had metrorrhagia at different times since. Has been treated for the past four years by the routine treatment, iodine, glycerine tampons, boracic acid, etc., with the varying results obtainable in this class of ailments. She suffers with the constant aches and dragging pelvic pains that make life to a woman, thus afflicted, almost unbearable.

Examination gives a condition of chronic cellulitis. Uterus immovable. Nodules are distinctly felt behind and on the right side of the cervix, very sensitive to the touch. Treatment, galvanic current; negative electrode in the vagina, resting against these tender lumps, and the positive on the sacrum. Strength of current fifteen milliampères, thrice weekly.

July 15. Pelvic pains have disappeared. Less tenderness upon examination.

December 11. Attention was to-day called to some hemorrhage the patient had eighteen days after her last menstrual period. A sore spot on the posterior vaginal wall was found, caused evidently by the current having been applied stronger than fifteen milliampères. This healed readily under the use of an iodoform ointment. The uterus shows more mobility, and the cellulitic deposits considerable diminution.

March 31, 1887. The treatment has continued to the present time, one to three times a week. The uterus is freely movable, the evidences of pelvic cellulitis have entirely disappeared. There is no sensitiveness to the touch. She says she has "no backaches or any pain." Menses are regular, lasting three days, without pain. Discharged cured.

Case VIII.—*October 26, 1886.* A. W., aged forty-five. Married, had one child and three miscarriages; last miscarriage was twelve years ago, from which time she dates her trouble. Complains of constant diffuse pelvic pain, sacral and crural neuralgia of the right side. Uterus was found immovably fixed, with hard, tender nodules to the right side of the cervix. She was treated with the galvanic current.

November 2. The patient was treated twice, and to day she expressed herself as feeling "a great deal better." She did not visit us again.

Case IX.—*November 4, 1886.* Mrs. B., aged forty-seven. Married twenty-six years; five children and two miscarriages. Was operated upon for lacerated perineum, December, 1885, which was followed by an attack of pelvic inflammation. Puberty at thirteen, and after three years her menses became regular as to intervals, but each period lasted a week, was profuse in flow, and preceded by severe pain. She was always compelled to remain in bed one week at these times. This condition has been growing worse since the operation.

The uterus is retroflexed, prolapsed, and adherent, measures three and a half inches; vaginal vault rigid and tense; retro-uterine ligaments are contracted. The sensitiveness of the patient is so great as to make the examination almost more than she can endure. She says the pain in her back and limbs prevent her from standing any length of time. Cannot do her own work; is a burden to herself. She was put upon the galvanic treatment in the usual manner and strength. After the third treatment (November 15, 1886) she reports improvement; less pain, feels stronger.

March 31, 1887. Her visits averaged five monthly, fifteen minutes each, fifteen milliampères. The improvement has been steady, and at this date she "feels better than she ever did in her life." Menses are normal in character. Is able to be about on her feet for a longer time with comfort. Is gaining in weight. Tenderness in the vagina less marked. Uterus more mobile, can be moved about with less pain to the patient. Treatment continues.

Case X.—*December 14, 1886.* E. J. J., aged twenty-eight, colored. Married seven years; one child six years ago; instrumental delivery, dead child. This patient presented herself with a large subperitoneal fibroid filling the posterior *cul de sac*, and extending to the right. The examination was attended with very great pain, the nodules being

very sensitive. She scarcely tolerated the introduction of the finger. Electrolysis was proposed, but the patient objected, and it was concluded to put her upon the usual galvanic treatment, with the view of reducing the pain, and possibly the size of the tumor.

March 31, 1887. She was given two treatments a week at first, fifteen milliampères, fifteen minutes. After the sixth application the soreness had entirely disappeared. For the past month she has received three treatments weekly. The improvement as to the pain and discomfort continued permanent, but the size of the tumor has undergone no appreciable decrease.

CASE XI.—*December 22, 1886.* M. O., aged twenty-eight. Married six years. One child and one miscarriage. Miscarriage in second month of marriage. Never been well since birth of child three years ago. Is not able to be about her house work. Has "constant pain and weakness in her left side," with feeling of heaviness, which condition is aggravated by standing, walking, or exercise of any kind.

Puberty at eleven. Menses are irregular in time, and the duration of each period is six days, with pain in first two days. Has lost forty pounds since marriage.

Uterus is retroflexed, prolapsed, measures three and a half inches. Os and canal patulous. Some cellulitic deposits are found in the posterior cul-de-sac.

March 31, 1887. She was, at first, treated with the faradic current, with the hope of rectifying the displacement. After seven treatments, averaging twice a week, with relief to the painful menstruation as a result, but no effect upon the flexion, galvanism was substituted, on account of the cellulitic features of the case.

At this date she says she has gained twelve pounds since beginning the treatment. Is better in every respect. Menses are regular and painless. The deposits have diminished in size and sensitiveness. This patient comes a distance of seventy miles three times a week.

I have submitted these cases, thinking they might be of interest to the profession, as I am confident that the treatment will prove beneficial if tried. They have been collected hastily from my case-book, with no attempt at elaboration.

The method of treatment is detailed under the individual cases. In sharp flexions we begin with a flexible electrode insulated to within two inches of the tip, and as soon as the curve of the uterus will allow, this is replaced by a stiff one, similar to a uterine sound, with the same insulation as the flexible one. This we are in the habit of connecting with the negative pole of the faradic machine. Although the choice of poles is *here* a matter of little importance, in galvanism it is. In the case of a retroflexion, the positive electrode is introduced into the bladder. If it be an anteflexion, a flexible twisted wire electrode is placed in the rectum. This electrode is insulated up to the point, which is a movable olive, allowing graded sizes to be used. This form of electrode is also found of service in treating constipation, etc., as it will follow the convolution of the bowels with ease and little pain.

The electrodes should always be placed in position before turning on the current. In the beginning a painless current should be used, slowly increasing to the point of the patient's comfortable endurance. I have found a hydro-rheostat necessary to the proper gradation of the current, since the weakest current I could get from an ordinary one cell machine always caused pain when applied through these organs. And if the patient is subjected to an ordeal of suffering at each treatment, her confidence and presence are both lost. Length of treatment is with us fifteen minutes, double that time three times a week will give better results.

In the use of the galvanic current there are some points of importance.

1. A milliampèremeter should be always used. Patients cannot be treated scientifically without it. With it we can always give them the same quantity at each treatment. This is impossible if we depend on the number of cells as a guide, since the internal and external resistance vary. I have frequently found that it required twice as many cells to give one day the current I had received from half the number the day before, this fact depending upon both battery and patient.

2. The current should never cause pain, nothing is gained by increasing it to that degree. In Case II. I used four milliampères, as a rule, once five, and at another time eighteen to twenty milliampères. In all the others I averaged fifteen milliampères. In three instances I cauterized the vaginal surface when I exceeded that strength. A rheostat will be valuable in enabling the current to be gradually increased at the beginning and diminished at the end of each treatment.

3. Position of the electrodes. As the result of cauterization by the negative pole is that of an alkaline caustic, soft and more readily absorbed, while the positive is that of an acid, more dense and firm, the negative should be placed in the vagina in contact with the part to be acted upon. We thus obtain the sedative and electrolytic effect, at these points, upon the cellulitic products.

4. Electrodes. For external position I use a plate of copper, five by six inches, covered with Canton flannel and backed with pure rubber. Internally, a straight stiff rod, terminating in a movable olive, of which we have different sizes. This is insulated with rubber to the olive, with walnut handles on the other end. Covering the olive with absorbent cotton, or a disk of Canton flannel, and wetting it in warm water, it is ready for use. The placing of these does not require any exposure of the patient.

5. The electrodes should always be placed in position before connecting them with the battery, then the current turned off gradually by means of the rheostat before removing them. Neglect of this will cause pain to the patient as the electrode passes over the perineum. A bifurcated conducting cord should be used, so that when the current is increased it will not be necessary to break the current, and thus we avoid giving any shock to the patient.

The conclusion that I draw from my work is, that in electricity we have a valuable agent. In uterine displacements, ill developed ovaries and uterus with amenorrhœa, and in subinvolution the faradic current may be used with advantage. But it is the galvanic that I have found the more valuable. All who have had anything to do with gynecological work know how stubborn many conditions are, and how slow to respond to remedial measures. Many of these cause the patient constant pain, "misery" as they term it. Chronic ovaritis, pachysalpingitis, chronic peritonitis, cellulitis, and lymphadenitis, also pelvic neuralgia, try the skill and patience of the physician. After all the routine treatment is exhausted the condition remains very much unchanged.

Now in electricity we have an agent that promotes absorption of the adventitious tissue, allays pain and irritation, and sets up reparative action. It is within the reach of all physicians, requires no very extended knowledge to be able to use it with safety and advantage; and, although it requires time in its application, the benefits it confers upon a class of patients, in which other treatment is either useless or harmful, amply repay for any outlay of time and the little expense attending it.

I am indebted to my friend, Dr. William E. Ashton, for his kind assistance in this work.

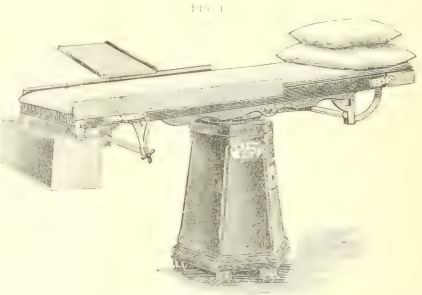
THE PENNSYLVANIA HOSPITAL OPERATING-TABLE AND WARD DRESSING-CARRIAGE.

BY THOMAS S. K. MORTON, M.D.,

PHILADELPHIA

IN the evolution of such a principle as that known as the Listerian, many more or less new means must be devised for the practical, or perhaps luxurious, carrying out of its various modes of application. Two such I wish to describe, namely, an operating bed or table, with suitable draining apparatus; and a ward dressing-carriage modified to an antiseptic end. Both have been in constant and satisfactory use in the Pennsylvania Hospital since my introduction of them there; also, they are now in service elsewhere.

The operating-table is constructed of suitable hard wood, and revolves upon a heavy pedestal, as is usual with such tables, but differs from them in being placed upon the support at a considerable angle (Fig. 1). The measurements are as follows: length, 6½ feet; breadth, 25 inches; head 38 inches, centre 36 inches, and foot 33 inches from the floor. Beginning at the foot, and running 40 inches toward the head is a wooden rail 2 inches high, while at the end of the table is swung a zinc tank of from 5 to 10 gallons capacity. The great secret of the table's proper working is the mattress. This is made of felt one inch thick, such as steam-pipes are wrapped with, and is exceedingly cheap. While presenting a soft, comfortable surface, pressure will not make hollows in it.



This mattress is sewn into a rubber bag, and after being placed upon the table, a large rubber sheet covers both it and the table. The ends of this rubber cover are tucked into the pan, where the side rails must direct all fluids falling upon it.

If the part to be operated upon is below the chest, the patient's head occupies the highest portion of the table; but if the operation be above that point, his head is placed at the foot of the table, and upon a small pillow, so that the fluids will run around it, and into the pan. In operations upon the arm or axilla, a special attachment is put on by means of an angled iron and slot in the table to receive it (see Fig. 1). This attachment consists of a board, also upon a decided incline and with side rails, so that when a smaller rubber cover is thrown over it fluids will be conveyed upon the main sheet, alongside the patient's head (which is at the foot of the table), and so into the pan.

I have also had constructed, upon practically the same model, an iron bed for use in the receiving wards of the hospital, which is found of great use.

With these beds the most perfect drainage is secured, and the usual great inconveniences of free irrigation, to both surgeon and patient, are entirely overcome.

The ward dressing-carriage is made upon the general model of the original ward carriage introduced first by my father, many years ago, in the Pennsylvania Hospital. The modifications are two or more superimposed tanks instead of one; a basin and spigot at one end; a dressing preparing-tray, and suitable receptacles for the modern dressing as used in this hospital.

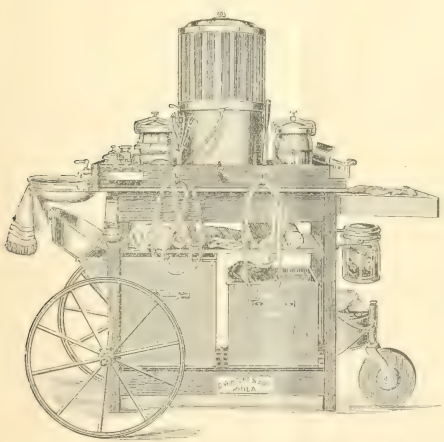
As now used (Fig. 2), the carriage has two tanks —a copper one beneath for either distilled or carbolized water, and an upper stone jar or tank for $HgCl_2$ solution. The upper tank is enclosed with wood, and has a copper lid.

Both tanks have hose attachments for wound washing, while the lower one has also an attachment to a spigot which overhangs a pivoted basin at one end of the carriage for hand washing. This basin is pivoted a little in advance of its centre, in an iron ring, and empties by tipping its contents into the common waste-bucket or tank below.

In front of the carriage a long, zinc-covered tray pulls out, on which dressings are prepared. Upon the carriage are kept, in jars, dressings, cotton, sponges, towels, gauze bandages, protective, and drain tubes; also minor operating instruments in a zinc or glass tray, constantly immersed in a three per cent. carbolized glycerine solution, and are, in addition, boiled in water every night. Bandage and plaster scissors, a palette-knife, common cotton bandages, towels, and lint, a large sugar-duster for iodoform, bottles for iodine, turpentine, alcohol, fluid soap, soap liniment, and a jar of boracic acid ointment, together with basins, rubber cloth, wax paper, soap dish, nail brush, adhesive plaster, and lamp, about complete the dressing-carriage outfit. All portions of the carriage are simple of construction, and are daily taken apart and rigorously cleansed.

The table and carriage are both manufactured by D. W. Kolbe & Son, of this city.

FIG. 2.



All instruments kept in the receiving wards, or upon the ward carriages, of this institution I have had put into carbolized glycerine, and kept as indicated above; and now, thanks to the suggestion of my former colleague, Dr. E. G. Rhoads, even the hypodermatic needles of the entire house are thus kept.

A final word in regard to the irrigation arrangements which I have introduced in our main operating-room may not be out of place. Until arrangements can be made to secure an unlimited supply of distilled water, we are using—when it is clear—simple running water. The irrigators are suspended in a rack close to a hot water faucet, from which they can be rapidly filled; they then receive their quota of antiseptic. These irrigators are common one-gallon percolator jars, to one end of which are attached four feet of rubber tubing and a hard-rubber stopcock, while to the other, or open, end an attachment is secured by which they may be hung conveniently upon an iron bar or tube which runs across the centre of the operating-room, seven and a half feet from the floor, and has hooks a foot apart upon its under surface.

MEDICAL PROGRESS.

MANIPULATION OF THE KIDNEY.—DR. W. H. BENNETT, of London, reports in the *Lancet* of May 21, 1887, his treatment of a case of probably impacted calculus. He says, "Seeing the ease with which the kidney could be felt, partly by reason of the thinness of the patient, I determined, as drugs afforded no relief, to insure complete relaxation of the abdominal parietes by the administration of an anæsthetic, and then manipulate the kidney as freely as possible, without previously exposing it by incision, with a view, if the case were one of calculus, to disturbing the stone, and, if it were not too large, perhaps bringing about its passage down the ureter, or, in the event of the symptoms being 'hysterical,' with the hope of producing a mental effect upon the patient sufficient to relieve her distress. She, however, declined the anæsthetic, and I was compelled to attempt the manipulation without its aid. The patient having been laid on her back upon a couch, the fingers of my left hand were dipped deeply into the abdominal wall over the kidney, the right hand being pressed forward into the loin. By a little management, the muscles being quite flaccid from the patient having become faint, the kidney could be felt quite easily between the two hands, and was kneaded as thoroughly as the circumstances allowed. The patient, although much discontented with the aching and tenderness which the operation seemed to have caused, was well enough to walk away almost directly afterward.

"Two days later she reappeared at the hospital in a more grateful mood, saying that, having suffered much discomfort for the rest of the day after the manipulation, she was seized as she was going to bed with a most acute pain in the affected loin and side of the abdomen. The pain lasted for about half an hour, during which she vomited twice. All at once an uncontrollable de-

sire to micturate occurred, and the pain immediately ceased. No further pain followed, and there can be little doubt that a small calculus had made its way down the ureter into the bladder, although no evidence of its having passed 'per urethram' was forthcoming. Moreover, it is quite possible that the manipulation had moved the stone from its resting-place in the kidney, and thus brought about its expulsion."

He ventures to suggest that manipulation without incision is a proceeding worthy of trial as a treatment which may possibly prove of utility in certain cases of renal calculus, not too far advanced, as a means of changing the position of the stone, and perhaps effecting its expulsion—a possibility, to his mind, sufficiently strong to commend the process to the attention of physicians as an adjunct to the medical treatment of renal calculus.

Bergeon's Treatment of Phthisis.—Dr. Heron, of London, reports his experience as follows in the *British Medical Journal* of May 21, 1887: My study of Bergeon's treatment was commenced in October of last year, and was chiefly conducted in my wards in the City of London Hospital for Chest Diseases. The cases I selected were certainly tubercular, as was shown by the physical signs of lung-disease, and the presence in the sputum of each patient of the tubercle bacillus. As regards the kind of case selected, it was of the type in which fever was not high, the urine free from albumen, and expectoration was moderately copious.

In not one single instance in which this treatment was carried out under my supervision was there the slightest evidence of any permanent good result having been achieved. Beyond a diminution of the amount of expectoration, an occasional lessening of the cough, and an unimportant lowering of the temperature, there was no evidence of any benefit having been derived from Bergeon's treatment in these cases of mine. As those results can be secured by means less unpleasant to the patient than Bergeon's method, I have ceased to employ it in the treatment of tubercular disease of the lungs.

The Treatment of Pulmonary Consumption by Hypodermatic Injections of Substances Dissolved in Vaseline.—Our readers will remember that in The Medical News of February 26, 1887, p. 240, and April 23, 1887, p. 466, we gave a series of formulæ for the hypodermatic use of substances dissolved in vaseline, as proposed by Meunier, of Lyons. We add the following formulæ, which Meunier considers especially adapted to the treatment of pulmonary phthisis, and which he publishes in an article in the *Revue Générale de Clinique et de Thérapeutique* for May 15, 1887:

1.—Eucalyptol	1 part.
Liquid pure vaseline	4 parts.

This solution affects the bacilli but little, but lessens fever and secretion, especially in bronchorrhœa; in small doses it is a tonic.

Dosage forty minims twice daily.

2.—Phenol (carbolic acid) pure	1 part.
Eucalyptol	1 "
Liquid pure vaseline	18 parts.

Eucalyptol is employed to aid in dissolving the carbolic acid, which is sparingly soluble in vaseline.

This solution diminishes the number of bacilli, and replaces with advantage the preparations of creasote which disturb the stomach; it lessens fever.

Dosage, one injection daily of eighty minims, or two of forty minims.

3.—Iodine	1 part.
Liquid pure vaseline	100 parts.

Beneficial in scrofula, tuberculosis, asthma, and tertiary syphilis.

Dosage, forty minims night and morning, daily.

4.—Eucalyptol	20 parts.
Iodoform	1 part.
Liquid pure vaseline	80 parts.

In infectious diseases, phthisis pulmonalis, and chronic bronchitis.

Dosage, forty minims twice daily.

These solutions may be used in phthisis in rotation in periods of five days each. The reason of rotation is to avoid the cumulative effect of eucalyptol, which is manifested by depression and loss of appetite of the patient. These solutions influence, to some extent, the life of the bacilli.

Coffee and Iodoform.—Dr. Neale writes as follows of his experience with this combination in the *British Medical Journal* of May 21, 1887: Valuable as coffee, when freshly ground, has proved in disguising the odor of iodoform, it has the following disadvantages: 1. It is only for a limited period that its effects last; and, 2, it is very difficult to grind the coffee so fine as to prevent the grains irritating a sore part; and especially is this felt if the iodoform be used in the form of an ointment. I have found that by macerating the coffee in hot lard or vaseline, all the deodorizing powers are absorbed by and retained in the vehicle employed, and a perfectly smooth, inodorous, and unirritating ointment can be prepared.

The Treatment of Diarrhœa in Infants.—Conby, of Paris, describes the symptomatology and etiology of this affection, stating that, in Paris, the mortality from this disease during the summer is 600 per month. He advises the use of dietetic measures; the subnitrate of bismuth, and laudanum. In the severer cases the writer recommends the following prescriptions:

1.—Aquæ destillat.	ʒ 12½.
Syrup of quince	ʒ 3.
Acid hydrochloric. dil.	♏ 8.—M.

Sig. Teaspoonful every two hours.

2.—Sacch. pulver.	ʒ 2½.
Naphthalin	gr. 15.
Iodoform.	gr. 3.
Ol. bergamot.	gtt. 2.—M.

Ft. in chart. 20 in num.

Sig. One powder every hour, in milk.

3.—Naphthalin	gr. 8.
Spirt. vini Gallici	ʒ 2½.
Syrup. althææ	ʒ 12½.—M.

Sig. To be taken during twenty-four hours, in teaspoonful or coffee spoonful doses.—*L'Abeille Médicale*, May 16, 1887.

INTRALARYNGEAL PAPILLOMA AND EPITHELIOMA.

DISCRIMINATION between intralaryngeal epithelioma and sessile papilloma is not difficult in the majority of instances; the clinical history of the case, the age of the patient, the location and physical appearances of the neoplasm being sufficiently characteristic to establish the diagnosis. During a limited period in the growth and progress of some instances of epithelioma in the larynx, however, considerable difficulty may be experienced in its differentiation from sessile papilloma; the uncertainty being resolvable neither by laryngoscopic inspection of the undisturbed neoplasm, nor by microscopic inspection of exsected fragments.

Papilloma is often presumptively an outgrowth from fibrous hyperplasia in repair of erosions or deeper losses of substance in chronic inflammatory processes in the mucous membrane, or in long-continued inflammation without losses of substance. It remains an outgrowth, and does not infiltrate the submucous connective tissue. It increases at its periphery by the division of the papillæ, and at the base by general enlargement only, so that the circumference at the base is smaller than in some parts of the free portion, sometimes smaller than in any other portion of the growth. In many instances several growths are developed singly, in close proximity, and, contracting adhesions, subsequently augment in bulk as a single mass. These are the growths that resemble some examples of epithelioma at a certain stage of its progress. Hence, with a clinical history of hoarseness and dyspnœa following a laryngitis, a mass of sessile warty excrescence in the larynx, bulkier in some portion of its body than at its base, with or without congestion or inflammatory tumefaction of the surrounding mucous membrane, may well be regarded as papilloma in the absence of histological evidence to the contrary.

Epithelioma is not, as a rule, directly referable to general laryngitis as a cause of attendant hoarseness and dyspnœa. It does not undergo demarcation at its base. It does not remain an outgrowth of the mucous membrane, even though it originate therein, but it infiltrates the submucous connective tissue, so that any surrounding congested or inflamed mucous membrane presents a deformed semiglobose, ovoidal, or bossellated outline in marked contrast to the more diffuse inflammatory tumefaction adjoining the benign growth. In the earlier stages of epithelioma this deformity of structure precedes the distinctive appearance of a tumor; but, as a rule, laryngoscopic inspection is not made until after this period has passed, and so an important discriminating feature escapes recognition. Epithelioma of the larynx, too, and especially when it occupies a vocal band, sometimes becomes overlaid with papillomatous outgrowths; perhaps due here, likewise, to inflammation of the mucous membrane from functional irritation in talking and in coughing. In this stage of its progress it is indeed difficult to differentiate from pure papilloma, especially when seen laryngoscopically for the first time in an apparently healthy subject. It is in this stage, too, that absolute reliance cannot be placed upon the negative results of microscopic examination of fragments removed for the purpose; for the papillomatous outgrowths alone may be detachable by access of instruments through the mouth; a circumstance under which absence of evidence of histologic malignity is no criterion as to the real nature of the main portion of the neoplasm. Furthermore, in a most instructive instance in Semon's practice, recently announced in the *Brit. Med. Journ.* of June 4, 1887, p. 1240, a warty growth removed from a vocal band showed typical epithelioma in close juxtaposition to inflammatory tissue in one and the same section, as prepared for microscopy. Thus an apparently benign growth may have an actual malign integrant that would escape detection, not only under ordinary inspection, but even under ordinary microscopic interrogation. This fact raises the question whether the benign growths hitherto supposed to have undergone transformation into malign ones without extraneous influence, may not have been histologically malignant from the start. It likewise tends to confirm the opinion of most laryngologists, that an underlying tendency to malignancy exists, if not absolute malignancy, even in those occasional instances in which, after subjection to repeated or long-continued irritation, epithelioma has been eventually demonstrated in growths to all appearance originally benign. Such irritation has been attributed in some

instances to functional disturbance in coughing and in talking; and in others to operative interference, whether in repeated cauterizations with a view to destruction, or in instrumental procedures for purposes of evulsion. The more skilled the laryngoscopic operator, the less likely is subjection of a neoplasm, or its surrounding tissue, to useless or pernicious irritation; and the better his judgment, the more likely will be early cessation of the inefficacious irritative procedure and resort to a more radical one.

The treatment of these doubtful cases will cast the utmost responsibility upon the medical attendant; a responsibility in which his judgment is at stake equally with his skill. Time is valuable; extremely so in malignant cases; and, for the time being, hardly less so in cases clinically malign by their location, although benign histologically. To subject a doubtful case to extreme measures may unnecessarily deprive the patient of an important organ, or even imperil his life. To delay such measures too long may sacrifice his only chance for recovery.

We would say that due intralaryngeal interference under the most promising conditions having proved inadequate to the eradication of a suspicious morbid growth, whether from position, from bulk, or from recurrence, the proper plan would be to divide the anterior wall of the larynx so that, if at all practicable, the morbid mass may be thoroughly eradicated by direct access; the decision having been previously made, whether, in case the proposed eradication should be found impracticable, radical laryngectomic procedures, partial, complete, or complex, should immediately follow, or whether subsequent treatment should remain confined to measures merely palliative and symptomatic. In coming to this decision due prominence must be given to the risk of death from laryngectomy or its immediate consequences; and to the likelihood of recurrence after a successful operation; for the instances of epithelioma of the larynx in which life has been prolonged by laryngectomy beyond its probable continuance under the undisturbed progress of the disease, are still far less numerous than those in which the remnant of life has been shortened.

Intralaryngeal epithelioma remains confined to the inner portion of the tube for a long while before extending beyond its borders or through its walls; and consequently, if the general health of the patient does not suffer in the interval, a serious operation like that of excision of the larynx, unilateral or bilateral as may be, may well await positive demonstration that the deeper seated portions of a doubtful growth are more malignant in character than any inflammatory growths or outgrowths which may have been removed. Even then, too, it may be possible to cut away merely the respiratory walls infiltrated with the neoplasm and thus save the wings of the thyroid cartilage with their important attachments of the muscles of deglutition; an operation involving far less immediate risk to life than excision of the whole of the laryngeal skeleton; and which, theoretically at least, should be equally efficacious in ridding a patient of disease limited to the interior of his larynx.

In cases of undoubted papilloma so extensive or so located as to preclude eradication through the mouth, or exhibiting uncontrollable recurrence, it is far better to divide the larynx externally and to operate efficiently in the direct manner, than to continue to tear away little fragments at a time, indefinitely to little purpose.

THE TREATMENT OF TUBERCULOSIS OF THE JOINTS BY ACID CALCIUM PHOSPHATE.

At a recent meeting of the Society of Physicians of Vienna, Kolischer, of Vienna, exhibited four cases of tubercular joints, three of which had recovered, while the fourth was in process of recovery, under a method of treatment which he had recently introduced, which aimed at the destruction of tubercle bacilli and the induction of calcification in tuberculous matter, in imitation of the process often observed in healed lung cavities. It is supposed to act by producing a mild grade of inflammation and cicatrization which destroys tuberculous matter. The method consisted in the injection into the diseased joints of a solution of acid calcium phosphate, whose strength and dosage are not reported.

In one class of cases a prompt inflammatory reaction followed the injection, lasting from four to seven days, and was succeeded by a period of calcification which continued from two to four weeks, ending in absorption; the final result was a restoration of the contour of the joint. In the other class of cases—those in which cheesy degeneration was rapidly progressing—injections into the joints were followed in about a week by the breaking down of tubercle and the rupture and discharge of the abscess; and healing by granulation resulted promptly. Cicatrization of tuberculous ulcers and separation of necrosed bone were readily caused by the solution. Tuberculous fistulæ and cavities were tamponed by gauze saturated with the solution.

The cures exhibited were two cases of acute tuberculosis of the elbow-joint in children; the results were normal contour, good motion, absence of all general symptoms. Also a case of knee-joint tuberculosis, under treatment six weeks, whose gait and symptoms were greatly improved. The fourth case was a man, whose carpal joint had been acutely tuberculous; result normal contour, the joint capsule filled with calcified material; slight movements of the fingers possible.

ALBERT, MAYDL, and others of the surgical staff of the Vienna Krankenhaus, fully endorsed the favorable statements of Kolischer.

While these cases are too few to base a final judgment upon, they are highly suggestive. The results of this method, so far as contour and mobility are concerned, are greatly superior to ankylosis, or excision. The danger to life is apparently less than even under antiseptic resections; the time consumed by the treatment is no longer than by excision. It remains to be proved, however, whether the nidus of the tubercular infection is as thoroughly destroyed by this method as by excision, and the use of iodoform.

DEATH IN THE TEA-BUN.

LAST JANUARY THE MEDICAL NEWS called attention to the fact that bakers were using a preparation known to the trade as "egg-yolk," which contains chromate of lead, to impart to their cakes the rich yellow color which is given by egg—and the risk of lead poisoning thereby was pointed out. In our issue of last Saturday, we presented a report by DR. DAVID D. STEWART of eight cases of illness in one family which came under his observation, and which he had by patient and intelligent investigation clearly traced to poisoning from eating tea-buns containing chromate of lead. Of these cases four died. He also ascertained that the baker who made these buns had had within two years nine cases of similar illness in his own household, of which seven had been fatal.

Our report of these eleven fatal cases has attracted the attention of the District Attorney, who has brought the matter to the official notice of the Coroner for investigation, and the Board of Health has also referred the subject to its Sanitary Committee, so that we may hope that the publication of these cases will lead to effective measures for the immediate suppression of this insidious source of poisonous adulteration, which is probably more widely practised than is generally supposed.

THE Board of Overseers of Harvard University have just confirmed the following appointments in the Medical Faculty: Dr. C. B. Porter, Professor of Clinical Surgery, and Dr. J. Collins Warren, Associate Professor of Surgery.

THE American Orthopædic Association was organized and the first meeting held at New York last week, under the temporary chairmanship of Dr. Virgil P. Gibney, of New York. A number of excellent papers were read, and the following officers were elected for the ensuing year: *President*, Newton M. Shaffer, M.D., of New York; *Vice-Presidents*, Drs. A. Sydney Roberts, of Philadelphia, and E. H. Bradford, of Boston; *Secretary and Treasurer*, Dr. L. Hall Sayre, of New York.

THE Alumni Association of the College of Physicians and Surgeons of New York offer a prize of five hundred dollars, open for competition to the Alumni of the school, for the best essay upon any medical subject which may be submitted to the committee.

THE medical profession of Philadelphia gave a reception at the Hotel Bellevue last Tuesday evening to Dr. R. J. Levis, on the occasion of his retirement from active professional work.

DR. T. G. RICHARDSON, of New Orleans, sailed for Europe last Saturday, having been hastily summoned to Naples by the severe illness of a near relative.

THE Pennsylvania State Medical Society meets at Bedford on Wednesday, June 29th.

SOCIETY PROCEEDINGS.

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting, Washington, D. C., May 11, 12, and 13, 1887.

(Specially reported for THE MEDICAL NEWS.)

Concluded from page 692.

FRIDAY, MAY 13TH—THIRD DAY,

AFTERNOON SESSION.

DR. THOMAS J. DUNOTT offered

SOME REMARKS ON HYPERTROPHY OF THE TONGUE (LINGUA VITULI, LINGUA PROPENDULA, MACROGLOSSIA).

He stated that this affection, although rare, is mentioned by almost all surgeons of large experience. The case reported was the only one which had come under his observation.

Hypertrophy of the tongue, according to S. D. Gross, may be limited to its muscular substance, to its papillæ, or to its mucous investment, or there may be a simultaneous affection of all these structures, constituting general hypertrophy of the organ. This hypertrophy must not be confounded with tumors or fibro-cellular growths, nor with cysts which are met in the tongue. This form of hypertrophy is nothing but an overdevelopment of normal tissue, which is, of necessity, associated with prolapse, when it is in any degree; and, therefore, the name "propendula linguæ" is not inappropriate.

Most authors who have met with it consider it congenital; but he is inclined to think that, except where it is associated with other congenital imperfections, as especially with idiocy, it is rather the result of inflammatory conditions affecting the various tissues of the tongue.

The case he reported was a girl twelve years old, admitted to the Harrisburg Hospital on January 6, 1886,

with an enormously large tongue. The organ protruded between the lips for three inches. It was kept enclosed in a muslin bag. Its surface was covered with patches of exfoliated mucous membrane, from underneath which there constantly dribbled a seropurulent discharge. The mucous membrane was cracked and fissured. The circumference of the tongue was 9¾ inches, and its greatest width 4¾ inches. The organ was firm to the touch, almost cartilaginous in consistence. The patient could partake only of liquids. The prolapse of the tongue was of only two months' duration, and it was stated that it began without any apparent cause, there having never been previously noticed any enlargement of the member. On January 15th, measurement demonstrated that a very decided increase in size had occurred, and the patient had to be nourished to a great degree by rectal alimentation. An operation having been determined upon, the patient was anæsthetized with chloroform, to which she responded readily. A needle was then passed under the ranine artery on either side, about 1¼ inches from the lips. The thread was withdrawn and tied in a loop which was permitted to hang out of the angles of the mouth, the intention being to command the arteries and the stump after section. He then fully described the further steps of the operation, consisting in the drawing forward of the tongue, and its removal by the scissors and scalpel, the knife being so directed as to secure a conical stump. The operation was successful, and the patient made a good recovery. The stump protruded as far as the frenum. Articulation was tolerable.

The great danger in this operation, according to most authors, is from hemorrhage. This could be easily controlled by a rubber coil passed about the base of the tongue, with the ligature around the ranine arteries. The patient in the operation should be placed in the recumbent posture, in order to prevent the flow of blood into the trachea.

Four methods of ablation of the tongue are practised: 1, the oral of Paget; 2, the symphyseal of Syme and Sedilott; 3, the submental introduced by Regnoli, in 1838, and its subsequent modification by Nunnely, of Leeds, in 1861. These operations are, for the most part, intended for the removal of malignant disease of the tongue.

In the case reported, microscopic examination showed that the enlargement was made up for the most part of dilated lymph vessels, with increase of the connective tissue, and some striated muscular fibres.

Dr. L. McLane Tiffany submitted photographic illustrations of cases of the same character as that reported by Dr. Dunott. The case was that of a negro five years old, the affection being congenital. The same deformity of the lower jaw was present as is usually found in these malformations, the incisor teeth projecting forward, instead of resting perpendicularly upon the bone. The operation was done simply by putting the child to sleep, drawing the tongue forward and cutting it off with Paquelin's cautery. The incision was made vertically to the long diameter of the tongue. No attempt was made to form flaps. The tissue as cut through was found to present the appearance of being composed very largely of the tissues of an unaffected normal tongue, the lymph spaces being probably filled. There was no hemorrhage at all until the ranine artery was reached. One of these, after a single spurt, did not bleed at all; the other was closed by pinch forceps, and afterward by ligature. The patient within a week was eating solid food, and left the hospital on the twelfth day after the operation.

Dr. J. Ford Thompson reported two cases of

VAGINAL HYSTERECTOMY.

He had determined to report these two cases, he said, in the hope that the discussion they elicit will settle the vexed question whether the operation is to be encouraged or condemned.

Case 1.—A. E., white, æt. forty-five, married seven years, had given birth to one child three years previous to the record of the case, the labor being very difficult. Malignant disease of the cervix was diagnosticated by her attendant. Examination revealed great destruction of the cervix, the loss extending beyond the internal os. She had been losing a great deal of blood at each menstrual period, which was prolonged, but not attended with much pain. She had a cachectic appearance. The uterus was movable, and there did not appear to be any infiltration. She was admitted to the Garfield Hospital April 15, 1885. On the 23d, after consultation, it was decided to avoid hysterectomy, if possible, and to limit the operation to that for amputation of the cervix.

April 24th, the patient having been prepared for operation, was anæsthetized, and placed in the lithotomy position. The cervix was seized and brought forward as far as practicable. The spoon was used to scrape away the softened tissue, and the scissors to sever the vaginal attachments. After cutting away the cervix with the scissors, it was attempted to use the spoon, but it was discovered that Douglas's cul-de-sac had been opened, and it was thought advisable to extirpate the entire organ. The uterus was then, without much difficulty, freed from the bladder, a silk ligature was placed about the organ, and the uterus was split into halves. Each part was then brought down, a ligature applied above it, and the stump cut away. There was no loss of blood from the ligaments, but a constant oozing from the parts severed in the first steps of the operation; this, however, was stopped with hot water. A knuckle of the intestine protruded, but was readily returned. Sutures of the peritoneum were not used. The patient at the close of the operation was very weak, and complained of pain.

April 25th, 11 A.M., pulse 140, and feeble; temperature 103°. The vaginal tampon was removed, and the vagina irrigated. She died twenty-four hours after the operation.

Case 2.—Mrs. M. H., white, æt. fifty-five, admitted to the Garfield Hospital February 26, 1887, married at nineteen, had three children. The menopause passed at fifty-one. Hemorrhage had been noticed for some time. First saw her in consultation shortly before admission to the hospital. Her general condition was good, but she was very much reduced in flesh and cachectic in appearance. Advanced laceration of the cervix was recognized upon examination, especially of the posterior lip. The malignant disease had extended backward, and had encroached upon the posterior cul-de-sac. The uterus was next drawn down, when the disease was found to extend along the cervical canal to the internal os, and probably beyond, but no evidence was present of its having extended beyond the uterine

walls. Bleeding during the examination was free. A month later he again saw her, in consultation, and it was decided that she should go to the Garfield Hospital.

February 28th, at 11 A.M., she was etherized. Antiseptic precautions were employed; she was placed in the lithotomy position, and no speculum was used. The vaginal wall was separated from the uterus all around; the attachments to the bladder in front were divided, the uterus drawn down through the opening, and dissected from its other attachments. She made a fair recovery.

He then compared the operation thus made with laparo-hysterectomy, which, he said, has been almost entirely abandoned because of its great mortality. The first operation of hysterectomy was performed by Langenbeck in 1813. It was occasionally resorted to by operators afterward; in 1830 a number of successes were recorded, but fatal cases again occurred, and it was abandoned. From the history, however, he did not think its fatality was sufficient to deter the surgeon from resorting to it. Certain accidents are, of course, liable to occur, as injury to the bladder, peritonitis, etc. There are at least six methods which are used at the present time, the relative advantages and disadvantages of which he briefly discussed. With reference to the use of peritoneal sutures, he was, on general principles, in favor of them, and was aware of no reasonable objection to their use. He would certainly favor the partial closing of the vaginal vault by bringing the edges together.

Are the dangers of the operation so great as to cause us to reject it, or to cause us to hesitate to perform it in carcinomatous disease? Although its history dates far back, it is still a modern operation, and it is too soon to decide its merits or demerits as a therapeutical method. The statistics of the immediate results are becoming more and more favorable, and, in the hands of skilled operators, it will soon lose its terrors, and be considered as rather easy of execution. Until recently, the mortality of the operation was about thirty per cent., but lately some authors have reduced it to a little more than twenty per cent. There is no doubt a disease of the cervix called cancroid, or papilloma of the cervix, which may be cured by a partial operation, and this may lead to error in some instance. There is no reason that we should except from total extirpation the uterus, when we are insisting upon its adoption in all other organs where it is possible for malignant disease.

DR. T. R. VARICK thought the time had not yet arrived to make positive statements with reference to the operation, and cautioned against placing too implicit reliance upon the statistics which have been published.

DR. T. F. PREWITT thought the conclusions of Dr. Thompson in the main correct. He very readily agreed with him that extirpation is the better operation for malignant disease; but went further, and said that upon the earliest appearance of epithelioma of the cervix there should be total extirpation of the organ, for he thought this would be the better cure, the safer course. We all know how prone these carcinomatous diseases are to return, and that all operations that have been made heretofore by the supra-vaginal operation, the curette, the cautery, etc., have failed. It has been claimed by some that they have operated fifteen years ago, and that there has been no return, but he suspected that the cases were not carcinomatous. We know that we derive great encouragement by doing a thorough operation for the disease in other localities. Epithelioma of the lip frequently shows no disposition to return; but, if it goes on for years, there is a period after which it will return in spite of any cutting we can do. He had a case some months ago that is a good illustration of the advantages of a thorough operation. A woman of fifty had evidences of malignant disease for some time, offensive and bloody discharge, etc., while she was becoming emaciated and her health impaired. An epitheliomatous growth was found which extended laterally. The uterus was movable, and the surrounding tissues were apparently not involved. The only course that apparently would give her any possible chance for prolonged life was hysterectomy. This was done and the patient recovered. He also narrated a case in which, in attempting to make this operation, he caused a rupture of the bladder, the tissues being so friable that any attempt at traction on them resulted in a tearing, and the operation had to be abandoned, and the opening in the bladder closed. The patient did well afterward, living for several months at least.

DR. E. H. GREGORY had always been taught that the grandeur of surgery was to save every part possible, and he would no more think of removing the entire uterus for an epithelioma of the cervix than he would think of removing the entire lip for an epithelioma of that region. We know that epithelioma and carcinoma are entirely different in their behavior; we know that epithelioma is, of all malignant growths, the least malignant. He would not think of removing the entire lower jaw for a malignant growth of one side of the jaw. He did not believe that the fact that a part of an organ is diseased is a warrant for the extirpation of the whole. He could narrate as many successes after the removal of part of an organ where the patients had lived for years afterward, and are alive to-day, as could be related after total extirpation. He called attention to the fact that in the case of Dr. Prewitt, where the operation could not be completed, the patient may be living yet, and still the disease was left there which it was proposed to remove; and the fact that the patient from whom Dr. Prewitt removed the entire organ is still alive is counterbalanced by the fact that the patient from whom he failed to remove the disease is also alive.

DR. A. R. KINLOCH said that the only way to decide with regard to an operation is from the statistics of successes. If the last speaker can prove that he can cut far and wide of an epithelioma of the cervix, without extirpating the uterus, then he was with him. If he can prove that in cases where he extirpated the uterus he did not save the life of the patient or prolong it, then he is right in sticking to his old rules, as he calls them, and not try new ones; but if the modern surgeon can show that life has been prolonged by it, then he would ask him not to condemn the teachings of what he calls modern surgery.

DR. GREGORY stated that when he assumed what he had in regard to the uterus, he did so in all sincerity, for he was absolutely certain as to his conclusions. We cannot assume with as much certainty that the infiltration of the uterus is limited, as we can of any other organ of the body. Again, we know that in attempting

to remove thoroughly all traces of cancer of the mamma, we remove not only the entire breast, but go up into the axilla and dissect it out. Now, if we were to apply to the uterus the rules that we apply elsewhere, we would remove the entire contents of the pelvic cavity. The man who would cut "far and wide" of this organ would have no limit but that of the wall of the pelvis.

DR. C. B. NANCREDE thought the question of the anatomy of the uterus and of the lymphatics and blood-vessels of the vagina could not be entered into here, but that it had an immense bearing upon the question which had been raised. We do not cut into the axilla unless it is involved. Quite a number of patients can be shown in Philadelphia in whom malignant disease extended to the axilla, and where the patients have lived from ten to fifteen years after its removal. He held firmly to the belief that carcinoma is curable if operation is performed early enough and freely enough. There is a pathological law which applies to this, namely, that if the whole of an organ that is afflicted with carcinoma is not removed, there is no evidence that the disease will not return, but there is the almost certainty that it will return. If the lymphatics are not involved, there is the almost certainty that the disease will not return after removal.

DR. T. G. RICHARDSON then read a paper on

THE TREATMENT OF ANEURISMS,

based upon two cases which had come under his observation, one an aneurism of the left subclavian, the other affecting the femoral artery.

In regard to the aneurism of the left subclavian he expressed regret at his not being able to alter the uniformly fatal termination of the disease. His patient, an Irishman, forty-five years of age, had for two years suffered from pain in the left shoulder, and loss of power in his left arm. A few months before he came under his care, he had discovered a pulsating tumor protruding above the collar-bone. The tumor was about the size of a hen's egg, but flattened posteriorly and crowded down behind the clavicle. The patient's sufferings had been such that he had been kept under the influence of chloral and opium. When he first came under observation, medical treatment was tried; the patient was confined to bed, on a spare diet, and the heart's action reduced by veratrum viride, together with doses of the iodide of potassium. No diminution in the size of the tumor having taken place at the end of a week, direct compression was attempted by a compress and an ordinary rubber band; but this became almost intolerable, and was substituted by a rubber band passing around the chest, with a belt over the shoulder. The apparatus was all that could be desired, and the patient carried out his part of the treatment fully, but at the end of a month all that could be said was that it had slightly retarded the progress of the growth. Nineteen pins, measuring one and a quarter inches in length, were passed through the anterior wall of the tumor, care being taken not to injure the adjacent nerves and bloodvessels. Several pins disappeared from view into the skin, in consequence of the swelling that ensued. The tumor appeared to be getting harder, but it became apparent that it was due to to inflammation of the skin and subcutaneous tissues, while the tumor was growing rapidly. He decided upon the ligation of the axillary artery, and the injection of the perchloride of iron. The ligation was carefully done, and a solution of the perchloride of iron (1 : 20, in water) was injected into the centre of the tumor. No coagulation occurred, and a solution of double the strength was used. Secondary hemorrhage occurred, and death quickly followed. Upon necropsy, the tumor was found to be about the size of a fist, and involving about three-fourths of the axillary artery, having caused almost complete occlusion of the left subclavian vein. A fairly thick layer of fibrin lined the interior, corresponding to where the pins had been. The walls of the rest of the tumor were very thin. The walls of the artery on the proximal side were very soft. Another aneurism of the right subclavian, involving the innominate, was also found.

The second patient was a shoemaker, fifty-five years of age, who was admitted into the hospital for a painful swelling of the left thigh. The tumor, an aneurism of the femoral artery, was about the size of a goose's egg, irregularly flattened. None of the characteristic signs of aneurism were wanting. It was supposed to possess thin walls. The man looked anæmic and delicate. He had had syphilis about nine years before. The cause of the disease was supposed to be the irritation caused by hammering leather on an iron placed on his thigh. The tumor appeared to be inflamed by the manipulation. To overcome this, Dr. Richardson suspended the limb flexed at right angles at the hip and knee. He found on the first day an improvement in the condition of the tumor, and a few days later, that coagulation had occurred. A week later he was discharged, cured, and a few months after only a small nodule could be felt at the site of the tumor.

As this is probably the first case of femoral aneurism cured by this method, he desired to call attention to the fact that no pressure was exerted on the tumor, but that the only treatment was flexion, and suspension of the limb, especially the latter. He thought that gravity had a great deal to do with effecting the cure.

DR. DAVID PRINCE read a paper on

WOUNDS: THEIR ASEPTIC AND ANTISEPTIC MANAGEMENT.

The aseptic treatment, he said, consisted in (1) diminishing the amount of floating material in the air by means of filtration through cotton, for wounds in the process of formation. (2) By the subsequent seclusion of the same floating material by investments that are proof against penetration by the dust floating in the atmosphere. The antiseptic consisted in the employment of agents which are unfriendly or destructive to minute organisms, in such dilution as not to be injurious to the wound itself. Under this head are the dry, the wet antiseptic dressing, and drainage. He then demonstrated his favorite plan for filtering the atmosphere.

DR. JAMES MCCANN, of Pittsburg, then reported a successful case of

SPLENECTOMY,

which will appear in full in an early number of THE MEDICAL NEWS.

Votes of thanks were extended to the President for his efficient manner of conducting the meetings of the Association; to the Surgeon-General, for the use of the

Library of the Museum Building as a place of meeting; and to the Cosmos Club, of Washington, for their proffered hospitalities.

The Association then adjourned, subject to the call of the President.

THE AMERICAN LARYNGOLOGICAL ASSOCIATION.

Ninth Annual Congress,
held in New York, May 26, 27, and 28, 1887.

(Concluded from page 635.)

SATURDAY, MAY 28TH—MORNING SESSION.

DR. S. W. LANGMAID read a paper on the

CONSTITUTIONAL CAUSES OF THROAT AFFECTIONS.

He suggested that the most interesting lesson to be drawn from the observation of the lesions in the throat trouble, is that there is some underlying cause which may be external or intrinsic. Our attention has been directed too much to the local condition, and to atmospheric influences. Why atmospheric conditions are active at one time and not at another, is a matter worthy of consideration. One of the most intractable diseases which we have to treat is chronic recurring coryza. Sometimes destruction of the mucous membrane of the nose is sufficient, but, as a rule, the treatment must take in all the circumstances of the life of the sufferer. A sense of a lump in the throat, so often complained of, is often an indication of an overloaded colon, and more good is done by a dose of castor oil than by local treatment.

The so-called clergyman's sore throat, or follicular laryngitis, has its origin, not in the necessary use of the throat, but in the sedentary life which, with errors in diet and other conditions, plays an important part. Throat trouble is sometimes a rheumatic or gouty manifestation, and treatment has to be directed to this condition. Local treatment in many throat troubles is of the nature of repair; constitutional and hygienic treatment must be in the direction of a renewal of the normal processes. Swelling and congestion of the mucous membrane, hypertrophy of the tonsil, elongation of the uvula, etc., must be regarded as symptoms, and the symptoms will not be banished unless the underlying constitutional abnormality is removed.

DR. GLASGOW agreed with the author that many of these local conditions are symptomatic. Many of them are due to some derangement of the digestive apparatus.

DR. SOLIS COHEN said, with reference to rheumatic sore throat, that he had doubts as to the correctness of this term. He had found symptoms closely like those of this affection follow the application of the galvano-cautery to the pharynx and tonsils. Patients often suffer pain in the trapezius muscle from an application of the cautery to the tonsil. He had found the use of guaiac as serviceable here as where the trouble was due to exposure to cold. Whether this is nervous or not, he could not say. He treats his patients constitutionally, using purgatives two or three times a week. There is one form of pharyngitis in adolescents which he had considered to be due to over-feeding.

DR. DELAVAN thought that in this country we pay too little attention to the hygienic surroundings which are employed at the various spas abroad. This method of treatment is very beneficial in cases of interference with the portal circulation and in the gouty diathesis. He had found the salicylates of great service in some of these cases of throat trouble. Habital constipation usually accompanies chronic disease of the pharynx. He had used in these cases the officinal pill of iron and aloes, directing that one be taken at night.

DR. MORRIS J. ASCH then reported

A CASE OF STENOSIS OF THE LARYNX TREATED BY DIVULSION AND SYSTEMATIC DILATATION.

Miss K. up to the age of twenty-seven years enjoyed good health. She then had some pulmonary trouble, the exact nature of which could not be ascertained. In 1884 she had some wheezing in breathing with slight cough. These symptoms increased in intensity gradually, and in May, 1885, the patient came under the observation of the author. There was at this time great dyspnœa which was increased by lying down. Examination of the throat showed no abnormality in the larynx or above the cords. Below the cords there were two white swellings united by a membrane posteriorly.

The opening of the larynx was diminished to one-third of the normal size. The membrane was cut and divulsion performed. This caused great improvement. Later, metallic sounds were used daily and the forceps once a week. She grew much better and ceased attending. In September she again returned, with the difficulty of the breathing as great as before. This was the result of acute inflammation of the larynx. Under the use of steam and cold compresses the swelling subsided. O'Dwyer's tubes were tried, but they at once produced spasm and were coughed out. Schröder's hard-rubber tubes were then used and within three months the cure was perfect. All the symptoms have now disappeared. There was no history of syphilis and no history of previous inflammation. The trouble was evidently the result of subcardial hypertrophic laryngitis.

DR. SOLIS COHEN said that his experience in stenosis of the larynx had been limited. In one case, reported twenty years ago, he removed a morbid growth by thyrotomy after it had been destroyed by the internal use of the galvano-cautery, which was probably the first use of the galvano-cautery for this purpose in the United States. Preliminary tracheotomy had been performed ten days previously. The operation was followed by adhesion of the vocal cord to the tissue of the opposite side. He then devised an instrument to cut this adhesion. He thought better to perform tracheotomy so as to have nothing to interfere with the breathing and then pursue the most active measures for the relief of the stenosis. When the operation is performed with antiseptic precautions, the tracheotomy wound heals up in a very short time. He thought that the danger from the operation is less than the risk of injury from the other methods of treatment.

DR. E. C. MORGAN had recently under treatment a case of laryngeal stenosis. During a period of eight or ten months he was enabled to control this by the administration of iodide of potassium and by the local applications of iodo-glycerine to the larynx. Finally, the disease advanced so far that on several occasions

he advised tracheotomy to be followed by dilatation. The patient postponed the operation a number of times, although warned of his danger. He had at times suffocative spells at night and finally succumbed to one of these spasmodic attacks. The speaker thought that if tracheotomy had been allowed and dilatation performed the man would have been alive to-day.

Dr. Delavan thought that the various forms of dilators used in these cases are likely to be replaced by O'Dwyer's tubes. This method has a most promising future before it. The tube can be left in for a length of time and respiration not interfered with.

Dr. Langmaid reported a case of

FOREIGN BODY IN THE LARYNX.

The patient came under observation three months after swallowing a pin about two inches in length. The pin had lodged in the throat, and immediately after the accident an unsuccessful effort had been made to remove it with the bristle probang. At the time that she came under his notice, there were ulcerations of the larynx which were relieved by treatment. Two years later the patient again presented herself, and an examination showed the pin, which had emerged from the ventricular band with the head down. It was with some difficulty removed.

Dr. Solis Cohen stated that in several instances he had seen on examining the pharynx, what appeared to be the belly of a muscle above the mouth of the Eustachian tube, and that from this there extended to the fornix of the pharynx what looked like a tendon. This he had seen on both sides. He asked whether or not any of the other members had observed the same appearance.

Dr. Rufus P. Lincoln, of New York, reported a case of

RECURRENT NASO-PHARYNGEAL TUMOR CURED BY ELECTROLYSIS.

The patient presented himself in April, 1886. A growth had been removed from the posterior nares by another physician one year previously. It returned, and the operation was repeated six months later. When the patient came under observation he was unable to breathe through the left nostril. On examination, a large growth was found occupying the left half of the posterior nares, and it was decided to treat this by electrolysis. On June 3d, two needles connected with the negative pole of the battery were introduced through the anterior nares into the growth, while the positive pole terminated in two large sponge electrodes, which were applied to the front and back of the chest. In all, sixteen applications were made at intervals of three or four days. This caused an entire disappearance of the growth. The immediate effect of the electrolysis was to cause distention and a change in the color of the growth, but these passed off in the course of twenty-four hours. There is, up to the present time, no evidence of the return of the growth.

Dr. Hooper said that in October, 1881, a youth presented himself with a tumor extending from the tip of the right nostril into the naso-pharyngeal cavity. There had been a great deal of hemorrhage and the patient was in a bad condition. He was sent into the hospital and operated on by Dr. J. C. Warren, with the galvano-cautery snare, and the whole mass removed in one piece. From that time to this the patient has been constantly under treatment. The tumor had been growing and from time to time he had snared it off. The tumor has been pronounced to be a most malignant form of myxo-sarcoma, but the general health is excellent. He proposed next to try the effect of electrolysis.

Dr. Delavan said that during the past fifteen years he had seen a number of these patients operated upon, and recalled many cases in which the result was disastrous. Although there had been successful cases, none had come under his observation. The great point is in the early diagnosis. If taken in time, even if it cannot be cured, it can, as a rule, be kept in check. After the age of twenty-five years, it has been stated that these tumors have a tendency to stop growing, so that if kept in check until this age, they may entirely disappear. It seemed to him that the galvano-cautery exercises a modifying influence on the tissues which remain, which cannot be caused by the knife.

Dr. W. C. Jarvis, of New York, reported

TWO UNIQUE CASES OF CONGENITAL OCCLUSION OF THE ANTERIOR NARES.

Complete congenital occlusion of the anterior nares is rare, and the author had been unable to discover any cases in searching the literature of the subject. The first case was a man eighteen years of age, with complete closure of both nostrils. Inspection showed on each side within the anterior nares, a cup-shaped depression of white glistening membrane. On the left side a small hole was discovered. The operation was performed in April, 1886. The burrs devised by the speaker, connected with an engine, were used to cut through the cartilaginous occlusion. This was accomplished in a few minutes; the air passed freely through the nostril. At a subsequent operation the right nostril was opened. In April, 1887, the opening in the right nostril had become contracted and had to be reopened. In a second case in which the anterior nostrils were occluded by a osseous formation, the operation was performed in the same manner as in the previous case, with successful result.

Afternoon Session.

Dr. Alexander W. Mac Coy, of Philadelphia, related

A COMPARATIVE STUDY OF SOME OF THE METHODS OF TREATMENT BEST ADAPTED TO THE RELIEF OF THE POSTERIOR NARES.

He confined his remarks to occlusion due to enlargement of the soft parts. He had never seen occlusion of the posterior nares due to osseous growth. He referred to the methods used in the treatment of occlusion of the posterior nares, and highly recommended the use of chromic acid fused on the end of a probe, the end of which is covered with a tube, which is withdrawn when the probe has reached the desired position. This is followed by the use of an antagonistic solution. He had found this better than the use of the galvano-cautery. Since using cocaine, he had not been able to use the cold wire snare in these cases on account of the contraction caused by the drug. He had also found difficulty in using the needles recommended by Dr.

Jarvis. The chief object of the paper was to call attention to the superiority of chromic acid, used in this way, over the other methods of treatment which had been recommended. He did not recommend the use of the acid either in crystal or in solution, for then it was not easy to limit the application to the desired point.

DR. JARVIS stated that he never used cocaine as a preliminary measure where he intended to remove posterior hypertrophies. He first includes the hypertrophies in the loop and draws the wire home and then applies the cocaine spray. The tissue included in the loop can not be affected by the contraction produced by the drug. We thus have the advantages of the anæsthetic without its disadvantages. It has been pretty generally recognized that chromic acid has many disadvantages. It may produce serious symptoms. The snare will accomplish in a few minutes what chromic acid requires considerable time to do.

DR. RICE agreed in the main with what the author of the paper had said. The turbinate bodies are difficult to penetrate with the needles, and there are many cases in which it is difficult to apply the loop posteriorly. He had not found any special disadvantages in the use of chromic acid.

DR. DELAVAN, of New York, formerly used chromic acid, but then gave it up. Lately he had again tested it, selecting for this purpose five patients, three of whom were physicians. He added enough water to the crystals to make them deliquesce, and then applied it with a cotton wrapped probe, the excess of acid having been removed. He had also used it by fusing it on a probe. In all these cases there was more reaction than followed the use of the cautery or the snare, and all the patients preferred the cautery to the chromic acid.

DR. DEBLOIS exhibited a plaster splint which he had employed with advantage in a case of

FRACTURE OF THE NOSE.

The splint consisted simply of a plaster cast, into which a piece of roller bandage had been incorporated. This was applied over the nose and held in position by the strips of bandage.

EXECUTIVE SESSION.

The report of the Committee on the Congress of American Physicians and Surgeons presented its report, embracing the conclusions of the Conference Committee, which were adopted.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. R. P. Lincoln, of New York.

Vice-Presidents.—Drs. J. N. Mackenzie, of Baltimore, and S. W. Langmaid, of Boston.

Secretary and Treasurer.—Dr. D. Bryson Delavan, of New York.

Librarian.—Dr. T. R. French, of Brooklyn.

Council.—Drs. Frank Donaldson, of Baltimore; J. Solis Cohen, of Philadelphia; F. H. Hooper, of Boston; and E. C. Morgan, of Washington.

The following were elected *Corresponding Fellows:* Dr. A. Gougenheim, of Paris; and S. Moure, of Bordeaux.

Dr. A. Jacobi, of New York, was elected *Honorary Fellow.*

The Association then adjourned.

NEWS ITEMS.

ANÆSTHESIA IN HEART DISEASE.—A special meeting of the Philadelphia County Medical Society was held on June 15th to receive the report of a Committee appointed, at the request of Dr. H. F. Formad, to inquire into certain testimony given by him at a coroner's inquest; which testimony, he stated, had been imperfectly reported, giving rise to a false impression in the public mind. The opinion attributed to Dr. Formad was "that ether should not be administered to persons suffering with heart disease." It is true that he did so state, but the important omission of the words additionally used by him, "without due precaution and proper care both during the administration of the drug and after its withdrawal," materially altered the import of his testimony as reported.

That Dr. Formad qualified his testimony by the use of the language quoted, was substantiated by the statement of the Coroner and the evidence of the records of the Coroner's office.

In view of these facts the Committee reported the following resolutions, which were unanimously adopted:

Resolved, That in the opinion of the Philadelphia County Medical Society, the testimony of the Coroner's physician, Dr. H. F. Formad, "that ether should not be administered to patients with heart disease, without due precaution and proper care both during the administration of the drug and after its withdrawal" is correct and proper; and the same caution should be observed in any other case.

And whereas, A false impression may have been given to the public by the imperfect reports of Dr. Formad's testimony published in the daily papers, and the medical profession placed in a false and dangerous position, therefore be it further

Resolved, That, in the opinion of this Society, the administration of ether is not only necessary and proper when pain is to be inflicted upon patients with cardiac lesions, but lessens the dangers incident to operation; provided that due care be taken during the administration of the anæsthetic, and proper regard be paid to its after-effects.

PHARMACY AT CORNELL UNIVERSITY.—A School of Pharmacy is to be opened in connection with Cornell University during the coming Fall. Women and men are to be admitted.

THE TWELFTH MEETING OF THE SOCIETY OF NEUROLOGISTS AND ALIENISTS OF SOUTHWESTERN GERMANY was held on June 11th and 12th at Strassburg. Among the papers of interest read was one on the Use of Hyoscin in Nervous Diseases, by Erb, of Heidelberg, and Demonstrations of Nervous Diseases, by Kussmaul, of Strassburg.

ILLNESS OF PROFESSOR BILLROTH.—As the name of the great Vienna surgeon is almost as much a household word among his English-speaking brethren as it is

in Germany, a few details respecting the indisposition which recently threatened to cut short his brilliant career cannot fail to be interesting to our readers. He had been confined to bed for some time by a sharp attack of bronchitis, when acute pneumonia supervened. These conditions, combined with fatty degeneration of the heart, brought about a state of alarming prostration, from which it was for some time thought impossible that he could rally. His celebrated colleagues, Von Bamberger and Nothnagel, were in constant attendance, and it is needless to say that everything was done for his relief that the most advanced science could suggest. Billroth appears to have derived most benefit from inhalations of pure oxygen, which were prepared for him every day by Professor Ludwig. Under this treatment the dyspnœa diminished, the pulse became stronger, and consciousness gradually returned. The illustrious patient is now fully convalescent, and will in a week or two be able to go to the fine country house at St. Gilgenfer belonging to his wife. It is seldom that the illness of a member of our fraternity has excited such universal interest and sympathy in all ranks of society. The varying phases of the disease were chronicled in the daily press, as if he had been a crowned head or a statesman of the first rank; and telegraphic messages of inquiry as to his condition were continually being received from royal and other exalted personages by those in charge of the case. It is particularly pleasant to record that the Imperial-Royal Society of Physicians, of Vienna, has sent Billroth a formal congratulation on his recovery.—*British Medical Journal*, June 11, 1887.

THE ACCIDENT TO THE KING OF THE COWBOYS.—The case of the celebrated cowboy, Buck Taylor, who met with an accident at Buffalo Bill's "Wild West" last week, is not without surgical interest. The peculiar character of the injury is explained by the circumstances under which it was inflicted. He was engaged in the quadrille on horseback, and was passing between two horses, when one of them, ridden by a "Western girl," swerved, and left little space for his horse to pass on. He attempted, however, to go forward, when the swerving horse swung itself with great force against his right thigh, and he felt the bone snap as he received the blow. Buck Taylor then tried to rest the injured limb along the back of the horse, but found at once that he had lost all control over the muscles of the thigh; so he threw his arm round the horse's neck, and looked out for the right moment to slip as comfortably as possible on the tan. Unfortunately, he could not control himself as he slid off, but fell on his back and sprained the muscles of his neck. Mr. Maitland Coffin was present, and improvised a splint for the injured thigh without disturbing the patient's clothes. Buck Taylor was removed in an ambulance to the West London Hospital, and admitted into Mr. Keetley's accident-ward. A simple and perfectly transverse fracture of the right thigh-bone was discovered, at the junction of the upper with the middle third of the shaft. The shortening hardly amounted to half an inch, owing, probably, to the direct violence which had broken the bone, without the aid of muscular action, and also to the transverse character of the fracture. This trifling amount of shortening is observed after an artificial transverse fracture as produced in Macewen's operation. The chief point of interest, however, in this case is the production of the fracture by direct force applied to the outer aspect of the thigh, not apparently high in degree, and without injury to the soft parts. A few similar cases have been recorded. The limb was placed in a long splint, with extension by a weight and pulley, and a kettle-holder splint was fitted to the anterior aspect of the thigh. Buck Taylor is quite the hero of the hour, and receives daily a large number of visitors, including many persons of high social position and culture, who take an interest in an unsophisticated child of nature. —*British Medical Journal*, June 11, 1887.

A SANITARIUM FOR THE PHTHISICAL.—FRIEDMANN has established at Berka, 800 feet above sea level, a small sanitarium accommodating ten patients, where the general treatment of phthisis, as recommended by Dettweiler at the recent German Congress, will be carried out.

PROFESSOR SENATOR has succeeded Professor Henoch in the charge of the clinic for children's diseases at Berlin; Professor Henoch being obliged to retire on account of ill health.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM JUNE 14 TO JUNE 20, 1887.

HALL, JOHN D., *Captain and Assistant Surgeon.*—Leave of absence extended one month.—*S. O. 136, A. G. O.*, June 14, 1887.

FORBES, W. C., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for one month.—*S. O. 138, A. G. O.*, June 16, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JUNE 18, 1887.

WALTON, THOMAS C., *Surgeon.*—Ordered, June 15, for examination [illegible] Medical Inspector.

PRICE, A. F., *Surgeon.*—Detached from special duty, Annapolis, Maryland, proceed home and wait orders.

FLINT, JAMES M., *Surgeon.*—Detached from the "Albatross," and ordered to the Smithsonian Institution.

WILLSON, W. G. G., *Passed Assistant Surgeon.*—Ordered to the Receiving Ship "Independence," Mare Island, Cal.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING JUNE 18, 1887.

BRATTON, W. D., *Assistant Surgeon.*—To proceed to Seattle, W. T., on special duty, June 8, 1887. When relieved, to rejoin station at San Francisco, Cal., June 11, 1887.

WATKINS, R. B., *Assistant Surgeon.*—Granted leave of absence for thirty days, June 8, 1887.

HEATH, F. C., *Assistant Surgeon.*—To proceed to Marine Hospital, Detroit, Mich., for temporary duty, June 17, 1887.

THE MEDICAL NEWS *will be pleased to receive early intelligence of [illegible] of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*
